The most common cause of hepatomegaly in patients with heart disease is hepatic engorgement from elevated right-sided pressures associated with right ventricular failure of any cause. Hepatojugular reflux is elicited by pressing on the liver and showing an increase in the jugular venous pressure; it indicates advanced right ventricular failure or obstruction to right ventricular filling. Evaluation of the abdomen also may reveal an enlarged liver caused by a systemic disease, such as hemochromatosis (Chapter 219) or sarcoidosis (Chapter 95), which also may affect the heart. In more severe cases, splenomegaly and ascites also may be noted. Large, palpable, polycystic kidneys (Chapter 129) commonly are associated with hypertension. A systolic bruit suggestive of renal artery stenosis (Chapter 127) or an enlarged abdominal aorta (Chapter 78) is a clue of atherosclerosis.

Extremities

Extremities should be evaluated for peripheral pulses, edema, cyanosis, and clubbing. Diminished peripheral pulses suggest peripheral arterial disease (Chapters 79 and 80). Delayed pulses in the legs are consistent with coarctation of the aorta and are seen after aortic dissection.

TABLE 50-7 SOME COMMON CAUSES OF HEART MURMURS*

	USUAL LOCATION	COMMON ASSOCIATED FINDINGS
SYSTOLIC		
Holosystolic		
Mitral regurgitation	Apex → axilla	↑ with handgrip; S_3 if marked mitral regurgitation; left ventricular dilation common
Tricuspid regurgitation	LLSB	↑ with inspiration; right ventricular dilation common
Ventricular septal defect	LLSB → RLSB	Often with thrill
Early–mid systolic		
Aortic valvular stenosis	RUSB	
Fixed supravalvular or subvalvular	RUSB	Ejection click if mobile valve; soft or absent A_2 if valve immobile; later peak associated with more severe stenosis
Dynamic infravalvular	LLSB → apex + axilla	Hypertrophic obstructive cardiomyopathy; murmur louder if left ventricular volume lower or contractility increased, softer if left ventricular volume increased†; can be later in systole if obstruction delayed
Pulmonic valvular stenosis	LUSB	↑ with inspiration
Infravalvular (infundibular)	LUSB	↑ with inspiration
Supravalvular	LUSB	↑ with inspiration
"Flow murmurs"	LUSB	Anemia, fever, increased flow of any cause‡
Mid–late systolic		
Mitral valve prolapse	LLSB or apex → axilla	Preceded by click; murmur lengthens with maneuvers that decrease left ventricular volume†
Papillary muscle dysfunction	Apex → axilla	Ischemic heart disease
DIASTOLIC		
Early diastolic		
Aortic regurgitation	RUSB, LUSB	High-pitched, blowing quality; endocarditis, diseases of the aorta, associated aortic valvular stenosis; signs of low peripheral vascular resistance
Pulmonic valve regurgitation	LUSB	Pulmonary hypertension as a causative factor
Mid–late diastolic		
Mitral stenosis, tricuspid stenosis	Apex, LLSB	Low pitched; in rheumatic heart disease, opening snap commonly precedes murmur; can be due to increased flow across normal valve‡
Atrial myxomas	Apex (L), LLSB (R)	"Tumor plop"
Continuous		
Venous hum	Over jugular or hepatic vein or breast	Disappears with compression of vein or pressure of stethoscope
Patent ductus arteriosus	LUSB	
Arteriovenous fistula		
Coronary	LUSB	
Pulmonary, bronchial, chest wall	Over fistula	
Ruptured sinus of Valsalva aneurysm	RUSB	Sudden onset

*See also Chapters 69 and 75.
†Left ventricular volume is decreased by standing or during prolonged, forced expiration against a closed glottis (Valsalva maneuver); it is increased by squatting or by elevation of the legs; contractility is increased by adrenergic stimulation or in the beat after an extrasystolic beat.
‡Including a left-to-right shunt through an atrial septal defect for tricuspid or pulmonic flow murmurs, and a ventricular septal defect for pulmonic or mitral flow murmurs.
LLSB = left lower sternal border (4th intercostal space); LUSB = left upper sternal border (2nd-3rd intercostal spaces); RLSB = right lower sternal border (4th intercostal space); RUSB = right upper sternal border (2nd-3rd intercostal spaces).

Edema (Fig. 50-7) is a cardinal manifestation of right-sided heart failure. When it is caused by heart failure, pericardial disease, or pulmonary hypertension, the edema is usually symmetrical and progresses upward from the ankles; each of these causes of cardiac edema commonly is associated with jugular venous distention and often with hepatic congestion. Unilateral edema suggests thrombophlebitis or proximal venous or lymphatic obstruction (Fig. 50-8). Edema in the absence of evidence of right-sided or left-sided heart failure suggests renal disease, hypoalbuminemia, myxedema, or other noncardiac causes. Among unselected patients with bilateral edema, about 40% have an underlying cardiac disease, about 40% have an elevated pulmonary blood pressure, about 20% have bilateral venous disease, about 20% have renal disease, and about 25% have idiopathic edema.

Cyanosis (Fig. 50-9) is a bluish discoloration caused by reduced hemoglobin exceeding about 5 g/dL in the capillary bed. Central cyanosis is seen in patients with poor oxygen saturation resulting from a reduced inspired oxygen concentration or inability to oxygenate the blood in the lungs (e.g., as a result of advanced pulmonary disease, pulmonary edema, pulmonary arteriovenous fistula, or right-to-left shunting); it also may be seen in patients with marked erythrocytosis. Methemoglobinemia (Chapter 161) also can present with cyanosis. Peripheral cyanosis may be caused by reduced blood flow to the extremities secondary to vasoconstriction, heart failure, or shock.

Clubbing (Fig. 50-10), which is loss of the normal concave configuration of the nail as it emerges from the distal phalanx, is seen in patients with pulmonary abnormalities such as lung cancer (Chapter 197) and in patients with cyanotic congenital heart disease (Chapter 69).

Examination of the Skin

Examination of the skin may reveal bronze pigmentation typical of hemochromatosis (Chapter 219); jaundice (see Fig. 149-2 in Chapter 149) characteristic of severe right-sided heart failure or hemochromatosis; or capillary hemangiomas typical of Osler-Weber-Rendu disease (see Fig. 176-1 in Chapter 176), which also is associated with pulmonary arteriovenous fistulas and cyanosis. Infectious endocarditis may be associated with Osler's nodes (see Fig. 76-2 in Chapter 76), Janeway's lesions, or splinter hemorrhages (Fig. 50-11) (Chapter 76). Xanthomas (Fig. 50-12) are subcutaneous deposits of cholesterol seen on the extensor surfaces of the extremities or on the palms and digital creases; they are found in patients with severe hypercholesterolemia.

Laboratory Studies

All patients with known or suspected cardiac disease should have an ECG and chest radiograph. The ECG (Chapter 54) helps identify rate, rhythm,

TABLE 50-8 SENSITIVITY AND SPECIFICITY OF BEDSIDE MANEUVERS IN THE IDENTIFICATION OF SYSTOLIC MURMURS

MANEUVER	RESPONSE	MURMUR	SENSITIVITY (%)	SPECIFICITY (%)
Inspiration	↑	RS	100	88
Expiration	↓	RS	100	88
Valsalva maneuver	↑	HC	65	96
Squat to stand	↑	HC	95	84
Stand to squat	↓	HC	95	85
Leg elevation	↓	HC	85	91
Handgrip	↓	HC	85	75
Handgrip	↑	MR and VSD	68	92
Transient arterial occlusion	↑	MR and VSD	78	100

HC = hypertrophic cardiomyopathy; MR = mitral regurgitation; RS = right sided; VSD = ventricular septal defect.

conduction abnormalities, and possible myocardial ischemia. The chest radiograph (Chapter 53) yields important information on chamber enlargement, pulmonary vasculature, and the great vessels.

Blood testing in patients with known or suspected cardiac disease should be targeted to the conditions in question. In general, a complete blood cell count, thyroid indices, and lipid levels are part of the standard evaluation. Point-of-care biomarker measurements in the emergency department can decrease unnecessary admissions and reduce median length-of-stay.

Echocardiography (Chapter 55) is the most useful test to analyze valvular and ventricular function. By use of Doppler flow methods, stenotic and regurgitant lesions can be quantified. Hand-held ultrasonography performed by generalists can improve the assessment of left ventricular function, cardiomegaly, and pericardial effusion. Transesophageal echocardiography is the preferred method to evaluate possible aortic dissection and to identify clot in the cardiac chambers. Radionuclide studies (Chapter 56) can measure left ventricular function, assess myocardial ischemia, and determine whether ischemic myocardium is viable. CT can detect coronary calcium, which is a risk factor for symptomatic coronary disease (Chapter 56). In the setting of acute chest pain, multislice CT is effective in diagnosing coronary disease, but it currently cannot adequately determine the physiologic significance.■

Stress testing by exercise or pharmacologic stress is useful to precipitate myocardial ischemia that may be detected by ECG abnormalities, perfusion abnormalities on radionuclide studies, or transient wall motion abnormalities on echocardiography. These tests are often crucial in diagnosis of possible myocardial ischemia (Chapter 71) and in establishment of prognosis in patients with known ischemic heart disease.

Cardiac catheterization (Chapter 57) can measure precise gradients across stenotic cardiac valves, judge the severity of intracardiac shunts, and determine intracardiac pressures. Coronary angiography provides a definitive diagnosis of coronary disease and is a necessary prelude to coronary revascularization with a percutaneous coronary intervention (Chapter 74) or coronary artery bypass graft surgery (Chapter 74).

Continuous ambulatory ECG monitoring can help diagnose arrhythmias. A variety of newer technologies allow longer-term monitoring in patients with important but infrequently occurring symptoms (Chapter 62). Formal invasive electrophysiologic testing can be useful in the diagnosis of ventricular or supraventricular wide-complex tachycardia, and it is crucial for guiding a wide array of new invasive electrophysiologic therapies (Chapter 66).

SUMMARY

The history, physical examination, and laboratory evaluation should help the physician establish the cause of any cardiovascular problem; identify and quantify any anatomic abnormalities; determine the physiologic status of the valves, myocardium, and conduction system; determine functional capacity; estimate prognosis; and provide primary or secondary prevention. Key preventive strategies, including diet modification, recognition and treatment of hyperlipidemia, cessation of cigarette smoking, and adequate physical exercise, should be part of the approach to every patient, with or without heart disease.

EPIDEMIOLOGY OF CARDIOVASCULAR DISEASE

MICHAEL J. KLAG

DEFINITION OF CARDIOVASCULAR DISEASES

Cardiovascular diseases, which encompass congenital malformations (Chapter 69) and acquired diseases of the circulatory system, include coronary heart disease (Chapters 70 to 74), arrhythmias (Chapters 62 to 65), valvular heart disease (Chapter 75), cardiomyopathy (Chapter 60), pericardial disease (Chapter 77), heart failure (Chapter 59), stroke (Chapter 413), peripheral arterial disease (Chapter 79), aortic diseases (Chapter 78), venous diseases (Chapter 81), and pulmonary vascular diseases (Chapter 68). However, because of their incidence and prevalence, their impact on survival and quality of life, and their shared pathogenesis (Chapter 70), this chapter mainly focuses on the epidemiology of coronary heart disease, stroke, and heart failure.

BURDEN OF CARDIOVASCULAR DISEASE

Impact in the United States

The age-adjusted mortality rate for cardiovascular disease has decreased substantially in the past few decades, with a 69% decline for coronary heart disease and a 76% decline for stroke in 2006 compared with 1950 (Fig. 51-1). This decline is considered to be about equally attributable to reductions in major risk factors and to evidence-based medical therapies.

Despite this decline in the cardiovascular disease mortality rate, heart disease (about 620,000 out of about 2.4 million deaths total) and stroke (about 135,000 deaths) are still the first and third leading causes of deaths in the United States. Because of a growing and aging population, the total number of cardiovascular disease deaths has decreased only modestly, by about 16% since 1979. Cardiovascular disease, including congenital defects, still accounts for more than one of every three deaths in the United States.

An estimated 17.6 million American adults currently have coronary heart disease, about 6.4 million have had a stroke, and 5.8 million have heart failure. The prevalence of peripheral arterial disease is estimated to be 8 million, and about 2.2 million people are estimated to have atrial fibrillation.

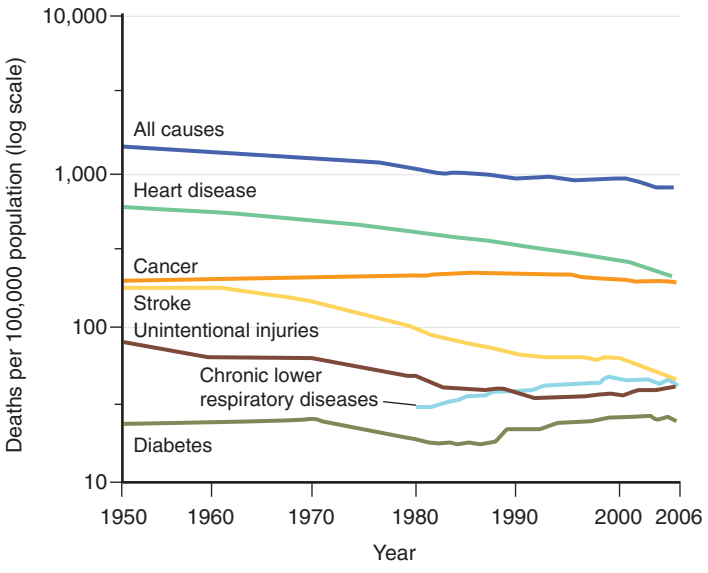

FIGURE 51-1. Age-adjusted death rates for selected leading causes of death: United States, 1958-2006. (From CDC/NCHS, Health United States, 2009. Figure 18. Data from the National Vital Statistics System.)

The annual estimated incidence in the United States is 785,000 for coronary heart disease, 610,000 for stroke, and 670,000 for heart failure. Importantly, heart disease and stroke are the 3rd and 12th leading chronic conditions that limit activity, and stroke is the leading cause of serious long-term disability.

Hospitalization rates for myocardial infarction and stroke have been relatively steady in the United States over the past few decades. However, diagnostic measures have improved substantially during this time period, likely leading to hospitalization of milder cases. Improved survival of patients with severe disease, who are at greater risk for recurrence, may also have contributed to this constant hospitalization rate. In contrast, hospitalization rates for heart failure and atrial fibrillation have substantially increased (two- to three-fold) in the past few decades.

In 2010, cardiovascular diseases are projected to cost $324 billion in health care expenditures (direct costs) and $189 billion in lost productivity (indirect costs). Direct and indirect costs are estimated to be $96 billion and $81 billion for coronary heart disease, $48 billion and $26 billion for stroke, and $35 billion and $4 billion for heart failure, respectively.

Worldwide Impact

Coronary heart disease and stroke are the leading causes of death in both economically developed and developing countries. Each year, more than 17 million people die from cardiovascular disease worldwide. Currently, 80% of deaths due to coronary heart disease or stroke take place in developing countries. Cardiovascular disease occurs at a younger age in developing countries than in developed countries, thereby resulting in serious loss of productivity. For example, 50% of cardiovascular disease deaths in India occur before 70 years of age, whereas only about 25% of cardiovascular disease deaths in developed countries occur before age 70 years. Traditional risk factors play an important role in the excess risk for cardiovascular disease in developing countries, thereby emphasizing the urgent need to develop cost-effective programs to control these risk factors in settings with limited resources.

PRIMARY AND SECONDARY PREVENTION

Primary prevention is defined as preventing cardiovascular disease among persons without clinically apparent cardiovascular disease. *Secondary prevention* denotes preventing the recurrence of cardiovascular disease among those who already have it. Preventive interventions are largely the same for primary and secondary intervention, except that the targeted levels of low-density lipoprotein cholesterol (LDL-C) are lower when cardiovascular disease is present (Chapter 213), and some medications, such as aspirin, are recommended for every patient with coronary heart disease. Cardiovascular disease is also an indication for influenza vaccination.

The absolute risk of a future cardiovascular disease event is substantially higher in persons who already have cardiovascular disease. Because the reduction in absolute risk is greater for secondary than primary prevention, secondary prevention is more cost-effective than primary prevention. Nevertheless, the control of blood pressure (Chapter 67) and the use of statins (Chapter 213) can markedly lower the risk of cardiovascular disease in apparently healthy individuals, with low rates of adverse effects.

RISK FACTORS FOR CARDIOVASCULAR DISEASE

Atherosclerotic disease in the arteries of the heart and brain is the most common cause of clinically apparent coronary heart disease and stroke. Heart failure most commonly occurs as a result of coronary heart disease or hypertension, although valvular heart disease (Chapter 75) and cardiomyopathy (Chapter 60) also can lead to heart failure.

Risk factors for cardiovascular disease can be categorized as traditional (i.e., those identified in the Framingham Heart Study) or novel (Table 51-1). Risk factors can also be grouped as modifiable or nonmodifiable.

Individual Risk Factors

Age

Older age is one of the strongest risk factors for coronary heart disease, stroke, and heart failure. An age over 45 years in men and 55 years in women is considered a risk factor for coronary heart disease, and every 10 years of older age imparts a risk of coronary heart disease equivalent to the presence of hypertension or diabetes. In general, traditional risk factors are more strongly associated with the risk of cardiovascular disease at younger compared with older ages.

TABLE 51-1 RISK FACTORS FOR CORONARY HEART DISEASE AND/OR STROKE

	TRADITIONAL (OR ESTABLISHED)*	NOVEL (OR LESS ESTABLISHED)
Modifiable	Hypertension Diabetes Dyslipidemia† Smoking Obesity Physical inactivity Kidney dysfunction/damage Left ventricular hypertrophy Alcohol Atrial fibrillation‡	Socioeconomic status Psychological factors Inflammatory markers Infection Homocysteine Thrombotic factors Natriuretic peptide Troponin†
Nonmodifiable	Age Gender Ethnicity Family history	Genetic polymorphism Coronary artery calcification†

*Factors incorporated in multiple risk scoring systems or dealt with in clinical guidelines and potentially affecting clinical decisions for cardiovascular disease prevention.
†Risk factor mainly for coronary heart disease.
‡Risk factor mainly for stroke.

Gender

Before age 60, men have a 1.5- to 2-fold higher risk of coronary heart disease and stroke than do women. After 60 years of age, however, the risk of coronary heart disease and stroke in women increases at a faster rate than men, and the risk becomes equivalent in both sexes at 80 years of age. This gender difference at younger ages is thought to be primarily due to differences in levels of estrogen and other endogenous sex hormones. Clinical trials of hormone replacement therapy in postmenopausal women, however, have not reduced the risk of cardiovascular disease.[1]

Race and Ethnicity

The incidence and prevalence of cardiovascular disease vary substantially across ethnic groups. For example, the incidence of stroke and heart failure in the United States is 1.5- to 2-fold higher in blacks compared with whites, whereas the incidence of coronary heart disease is relatively comparable between these groups. Asians are less prone to developing coronary heart disease than whites or blacks. These differences in the incidence of cardiovascular disease among ethnic groups are largely attributable to differences in risk factor profiles. Numerous studies demonstrate that migrants assume the cardiovascular disease risk of their new environment within two generations. Thus, lifestyle and other environmental factors appear to be more important than ethnicity in influencing the risk of cardiovascular disease. There are also ethnic differences in awareness of traditional modifiable risk factors. Individual ancestry, as estimated by genetic markers, may provide better information for differentiating the genetic and environmental contributions to ethnic differences.

Hypertension

Hypertension (Chapter 67), defined as systolic/diastolic blood pressure of 140/90 mm Hg or higher, is the most prevalent modifiable risk factor for coronary heart disease, stroke, and heart failure. Hypertension affects one third of U.S. adults. Systolic pressure is a stronger risk predictor than diastolic blood pressure, and each 20-mm Hg increase in systolic blood pressure is associated with two-fold increased risk of coronary heart disease in middle-aged populations. Numerous studies have demonstrated that blood pressure control by antihypertensive drug therapy decreases cardiovascular disease risk when used in either primary or secondary prevention.[2] Adoption of a diet that is rich in potassium, magnesium, calcium, protein, and fiber can reduce blood pressure to a degree equivalent to using one antihypertensive medication, and substituting additional protein or unsaturated fats leads to additional improvement in blood pressure and the lipid profile.[3]

Diabetes Mellitus

Diabetes mellitus (Chapters 236 and 237), which is defined as fasting plasma glucose of 126 mg/dL or higher, a nonfasting plasma glucose or a plasma glucose 2 hours after an oral glucose tolerance test of 200 mg/dL or higher, or a hemoglobin A_{1c} level of 6.5% or higher, is associated with a two-fold increased risk for cardiovascular disease. Diabetes is often considered as equivalent to a history of coronary heart disease in terms of predicting the risk for coronary heart disease events. Intensive glucose control among diabetic patients has been associated with a reduction in the incidence or progression of microvascular disease, such as retinopathy or nephropathy, but not necessarily with that of macrovascular disease.[4] By comparison, aggressive blood pressure reduction in persons with diabetes prevents both microvascular and macrovascular disease.[5]

Dyslipidemia

Elevated LDL-C is a strong risk factor, particularly for coronary heart disease (Chapter 213). Each 1-mg/dL increase in the LDL-C level is associated with approximately a 1% higher risk of coronary heart disease. Decreased HDL-C levels and elevated triglyceride levels are also associated with the risk of coronary heart disease. Current clinical guidelines for treatment of hyperlipidemia (Chapter 213) are based mainly on LDL-C levels, but the nonfasting non-HDL cholesterol level (total cholesterol minus HDL-C) and the HDL cholesterol level are sufficient to estimate the risk of coronary heart disease.

The effectiveness of statins to reduce coronary heart disease risk is established in both primary and secondary prevention.[6] In contrast, drugs that specifically increase HDL-C and reduce triglycerides have not demonstrated consistent benefits for reducing cardiovascular events.[9,10]

Serum total cholesterol and triglyceride levels are inversely associated with the risk of hemorrhagic stroke in many, but not all, studies. Persons with the highest blood pressures and lowest serum cholesterol levels are at the greatest risk. Several studies have reported neutral or weak associations of dyslipidemia with ischemic stroke. Nevertheless, statin treatment reduces the incidence of stroke.[6]

Smoking

Current smokers have an approximately two-fold higher risk of cardiovascular disease compared with former and never smokers. Second-hand smoke is also associated with a 30% or greater increase in the risk of coronary heart disease. Bans on smoking in public places have been associated with a 20% reduction in incident coronary heart disease.

In patients with coronary heart disease, the risk for recurrent coronary heart disease events is substantially reduced by smoking cessation, and the risk in former smokers returns to the level of nonsmokers within 3 years. Smoking cessation is associated with increased risk of incident diabetes, in part due to weight gain. Thus, body weight and glucose metabolism should be carefully monitored among persons who attempt to quit smoking.

Obesity

Obesity (Chapter 227) is closely associated with hypertension, dyslipidemia, and diabetes. Even accounting for these traditional cardiovascular risk factors, obesity may be an independent predictor of coronary heart disease, stroke, and heart failure. Each 5-kg/m^2 higher body mass index (BMI) is associated with 40% increased risk for cardiovascular mortality in middle-aged populations. Among individuals with morbid obesity (BMI $\geq$ 35 kg/m^2), weight reduction through bariatric surgery may reduce the risk of coronary heart disease by more than 50%.

Among patients with established coronary heart disease or heart failure, higher adiposity is paradoxically associated with better prognosis, probably because of weight loss in persons with severe illness, especially heart failure, who also experience high mortality. In addition, persons with severe heart disease who are very obese probably die earlier than persons who weigh less. Thus, prevalent patients with heart disease and obesity likely have less severe disease, thereby imparting a survival advantage.

Physical Inactivity

Physical inactivity and sedentary lifestyle (Chapter 15) are associated with increased risk for cardiovascular disease. Exercise is an important adjunct to

diet for achieving and maintaining weight loss, and exercise improves lipid and glucose metabolism and decreases blood pressure. In patients who have survived an acute myocardial infarction, exercise-based cardiac rehabilitation is associated with reduction of mortality but not of recurrent myocardial infarction.[11]

Kidney Dysfunction or Damage

Chronic kidney disease (Chapter 132), defined as a persistently reduced glomerular filtration rate of less than 60 mL/minute/1.73 m^2 or kidney damage, usually detected by albuminuria, raises the risk of incident cardiovascular disease. Cardiovascular mortality increases exponentially with lower glomerular filtration rate and increases linearly on a log-log scale at higher levels of albuminuria. Cardiovascular mortality is two-fold higher at a glomerular filtration rate of 30 to 45 mL/minute/1.73 m^2 or albuminuria of more than 100 mg/day, compared with normal levels of about 90 mL/minute/1.73 m^2 and about 5 mg/day, respectively, independently of each other and of traditional risk factors.

Left Ventricular Hypertrophy

Left ventricular hypertrophy usually represents target-organ damage from hypertension, although multiple factors play a role in its development. The regression of left ventricular hypertrophy by antihypertensive treatment may be associated with more favorable outcomes.

Socioeconomic Status

Most of the evidence for the link between socioeconomic status, an individual's social position relative to other members of a society, and cardiovascular disease comes from economically developed countries. In general, low socioeconomic status is associated with increased risk of cardiovascular disease. The mechanism for this association is multifactorial, perhaps mediated through in utero and childhood exposures and lack of educational opportunities that result in deleterious health behaviors and risk factor patterns (Chapter 4). In addition, a reduced accessibility to health care (Chapter 5) and greater exposure to residential and occupational harmful exposures almost certainly play a role. For example, neighborhood characteristics, such as accessibility to healthy food and walkability, are associated with higher prevalence of obesity, and air pollution predicts incident coronary heart disease.

Psychological Factors

Acute and chronic stress, in daily life or due to a natural disaster, is associated with an increased risk for cardiovascular disease. Acute or chronic stress may raise blood pressure, alter glucose or lipid metabolism, and increased blood viscosity.

Inflammation

Higher levels of inflammatory markers are associated with a higher risk of cardiovascular disease, consistent with the concept that atherosclerosis is an inflammatory process (Chapter 70). C-reactive protein, which is the most studied inflammatory marker, is undoubtedly associated with the future risk for cardiovascular disease, although this association is considerably attenuated by the adjustment for conventional risk factors. Genotypes associated with elevated levels of C-reactive protein are not associated with the risk of coronary heart disease, suggesting that C-reactive protein itself is not a cause of cardiovascular disease. Nevertheless, the C-reactive protein can be used for risk stratification beyond traditional risk factors.

Infection

Infection with microorganisms such as *Chlamydophila pneumoniae* (Chapter 326), *Helicobacter pylori* (Chapter 141), cytomegalovirus (Chapter 384), hepatitis A virus (Chapter 150), and influenza virus (Chapter 372) has been reported to be associated with the risk of coronary heart disease. However, antibiotic treatment of these pathogens has not reduced risk.[12] In contrast, vaccination for influenza virus may help prevent recurrent coronary heart disease and is currently recommended for secondary prevention.

Homocysteine

Blood homocysteine levels are associated with the risk of cardiovascular disease, but reducing blood homocysteine levels using folic acid alone or in combination with other B vitamins is not effective for either primary or secondary prevention.[13]

Alcohol

A J-shaped association between alcohol consumption (Chapter 32) and the risk of incident coronary heart disease has been noted in both primary and secondary prevention settings, with the lowest risk at light (<3 drinks per week) to moderate (3 to 7 [for female] or 14 [for male] per week) alcohol consumption. Alcohol use, however, is also associated with injuries and other harmful outcomes, including hypertension and atrial fibrillation. Thus, persons who do not drink should not be encouraged to initiate regular alcohol consumption.

Family History

Premature coronary heart disease in a first-degree relative (male relative <55 years and female <65 years or <60 years in both genders) is associated with increased risk of coronary heart disease. Family history of premature coronary heart disease likely integrates genetic predisposition to cardiovascular disease or cardiovascular risk factors, lifestyle preferences, and environmental factors.

Genetic Factors

Numerous single nucleotide polymorphisms have been associated with cardiovascular disease risk factors or the incidence of cardiovascular disease. Nevertheless, current genetic risk scoring using 101 single nucleotide polymorphisms has not yet improved the prediction of incident cardiovascular disease after accounting for traditional risk factors. However, single nucleotide polymorphisms have been associated with differing response to specific antihypertensive and antiplatelet drugs.

Thrombotic and Fibrinolytic Factors

Various thrombotic and fibrinolytic factors, such as fibrinogen and plasminogen activator inhibitor, have been associated with incident cardiovascular disease. Whether such information improves the prediction of prognosis over prediction based on traditional risk factors alone and, if so, whether such factors provide targets for prevention, are not yet clear.

Risk Prediction

Although clinical interventions to prevent cardiovascular disease usually target individual risk factors, methods to predict the risk of cardiovascular disease use information on multiple risk factors, including age, gender, smoking, hypertension, diabetes, and lipids. Of these, the Framingham Risk Score is most commonly used in the United States. Some clinical guidelines use an individual's probability of coronary heart disease within 10 years to make clinical decisions about treatment with statins and aspirin. Although the original Framingham Risk Score estimated coronary heart disease risk, a new score predicting global cardiovascular disease risk (coronary heart disease, stroke, heart failure, and peripheral artery disease) has recently been published (Tables 51-2 and 51-3).

New Aspects of Traditional Risk Factors

Global risk prediction and the management of traditional risk factors in clinical practice are generally based on the most recent assessments of risk factors or the average of multiple measurements over a short period of time. However, change over time or the duration of an abnormal risk factor level may be associated with future risk independent of baseline values. The association of traditional risk factors with cardiovascular disease risk is generally graded and continuous, such that higher levels of the risk factors impart greater risk; as a result, cutoffs to define elevated levels of risk factors are somewhat arbitrary. In general, the definition of normal is becoming stricter with increasing recognition that "borderline" levels of risk factors are associated with cardiovascular risk, that the greatest population burden may be in persons with lower elevations of risk because they are much more numerous than persons with very high levels of risk, and because interventions are becoming safer and more effective. For example, diabetes is now defined as a fasting glucose level of 126 mg/dL rather than 140 mg/dL.

NEW BIOMARKERS OF SUBCLINICAL DAMAGE OR DISEASE

New biomarkers of subclinical cardiovascular disease include the coronary artery calcium score (Chapter 56), troponin level, and natriuretic peptide levels. Because these biomarkers are related to ongoing pathophysiologic processes, it is not surprising that they may be better predictors of future events than are traditional risk factors.

TABLE 51-2 POINTS OF FRAMINGHAM RISK SCORE FOR CARDIOVASCULAR DISEASE PREDICTION ACCORDING TO TRADITIONAL RISK FACTORS

POINTS	AGE (YR)	HDL-C (MG/DL)	TOTAL CHOLESTEROL (MG/DL)	SBP NOT TREATED	SBP TREATED	SMOKER	DIABETES
WOMEN							
–3				<120			
–2		60+

CARDIAC FUNCTION AND CIRCULATORY CONTROL

ANDREW R. MARKS

The heart has the daunting task of pumping sufficient amounts of blood to meet both its own metabolic demands and those of the other organs. Uniquely among all the organs, the heart's failure to perform its task for even a few minutes causes death. The heart continuously fulfills this physiologic role with a variety of electrical, contractile, and structural functions that control the flow of blood to the organs.

STRUCTURE OF THE HEART

Cardiac Development

In humans, the formation of a linear heart tube from the primary cardiac crescent occurs between days 21 and 23 of gestation. Looping of the heart tube and trabecular formation of the ventricle occurs at 26 days of gestation (E-Fig. 52-1). At 6 weeks, the embryonic interventricular communication closes, followed by thickening and remodeling of the ventricular walls in the first trimester. By the end of week 7, heart development is essentially finished, although the heart continues to enlarge throughout gestation.

Electrical Cells

The heart is a muscular pump controlled by regular electrical discharges from specialized muscle cells in the conduction system (Chapter 61). The molecular basis for the electrical activity of the heart is the activation of specific ion-conducting channels (Fig. 52-1). Coordinated activation and inactivation of cardiac ion channels regulate the membrane potential of the cardiac cells, thereby resulting in a rapid sequence of depolarization followed by repolarization. This electrical activity, which is manifested on the body surface as the electrocardiogram (ECG), is known as the action potential, and it is responsible for activating the contraction of the cardiac muscle. At a typical heart rate of 70 beats per minute, the heart beats about 100,000 times per day, or 37 million beats a year, corresponding to 3 billion beats over a lifespan of 80 years. Failure to propagate the signal throughout the heart (e.g., heart block), or abnormal rhythms (arrhythmias) that are either too slow (bradycardia) or too fast (tachycardia), can result in death (Chapter 62).

Ion Channels

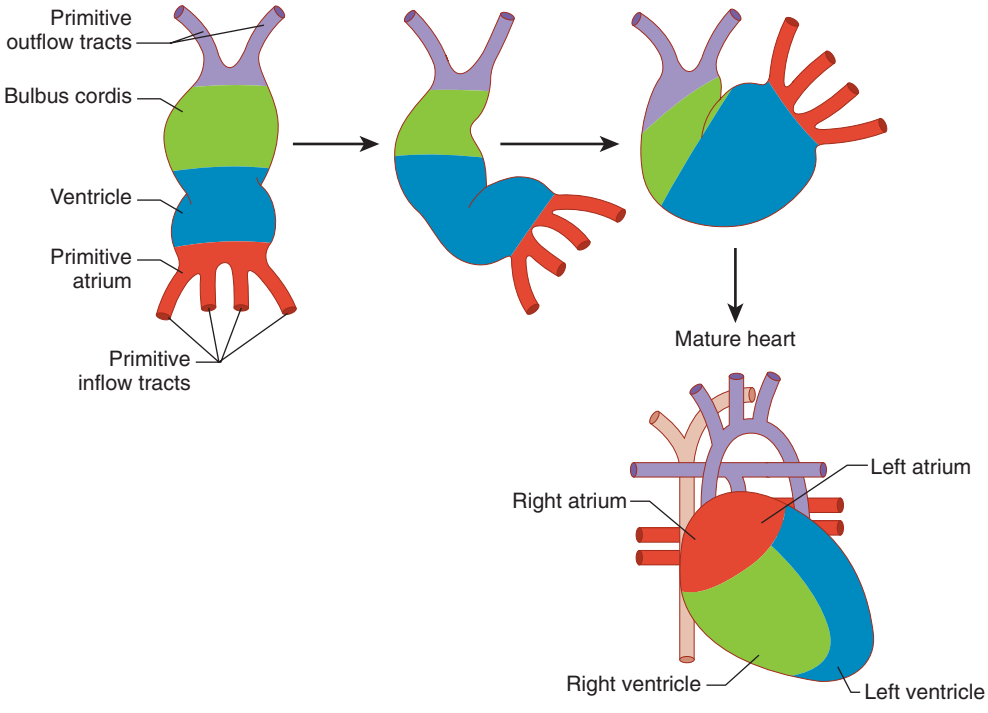
Sodium, potassium, and calcium channels determine the electrical activity of the heart by opening and closing in a highly choreographed pattern that determines the action potential of the heart. The electrical regulation of the heart, which is reflected in the relative concentrations of ions inside and outside the heart muscle cells, determines the five phases of the action potential. The action potential is initiated when the opening of sodium channels results in a rapid influx of sodium (phase 0) down its concentration gradient (~145 mmol outside the heart muscle cell, ~10 mmol inside). After a brief early repolarization owing to activation of potassium channels (phase 1), the rapid sodium influx depolarizes the cell, thereby activating calcium channels that allow calcium influx (phase 2) down its concentration gradient (~3 mmol outside, ~100 nmol inside). This calcium influx triggers excitation-contraction coupling that results in pumping by the heart. Potassium channels then open and cause repolarization (phase 3) as potassium fluxes out of the cell down its concentration gradient (~4 mmol outside, ~135 mmol inside). The membrane potential returns to the resting level of about −90 mV (phase 4).

Conduction System

Specialized pacemaker cells in the sinoatrial (SA) node (Fig. 52-2) have slightly higher (less negative) resting potentials and gradually depolarize during phase 5 owing to the activity of the potassium and calcium channels and the hyperpolarization-activated cyclic nucleotide gated (HCN) channels that are responsible for a small inward (depolarizing) current. In the normal heart, pacemaker cells are the first cells to depolarize, and they trigger the subsequent depolarization of the cells in specialized conducting fibers that propagate the electrical signal throughout the heart muscle in a highly regular and integrated fashion. Electrical activation (depolarization) spreading through the atria to the atrioventricular (AV) node is reflected as the P wave on the ECG (Chapter 54). The slowing of conduction in the AV node accounts for the PR interval on the ECG. After passing through the AV node, the depolarizing signal enters the bundle of His, where conduction is rapid. The bundle of His divides into the right and left bundle branches, which conduct the depolarizing signals into the ventricles and account for the QRS complex on the ECG. Repolarization is represented by the ST segment and the T and U waves of the ECG.

Contractile Cells

Heart muscle is composed of millions of individual cells, which are known as *cardiomyocytes* and which contain an elaborate machinery required for coordinated contraction that pumps blood. Each cardiomyocyte is connected to its neighbors through specialized junctions that enable them to work as a single contractile unit. The cardiomyocytes are filled



E-FIGURE 52-1. Folding of the heart tube during development. The primitive outflow tracts develop into the pulmonary artery and aorta. The left and right atria, along with the pulmonary veins and the superior and inferior vena cava, arise from the primitive inflow tracts. The area covered by the bulbus cordis and ventricle contributes to the development of the left and right ventricles.

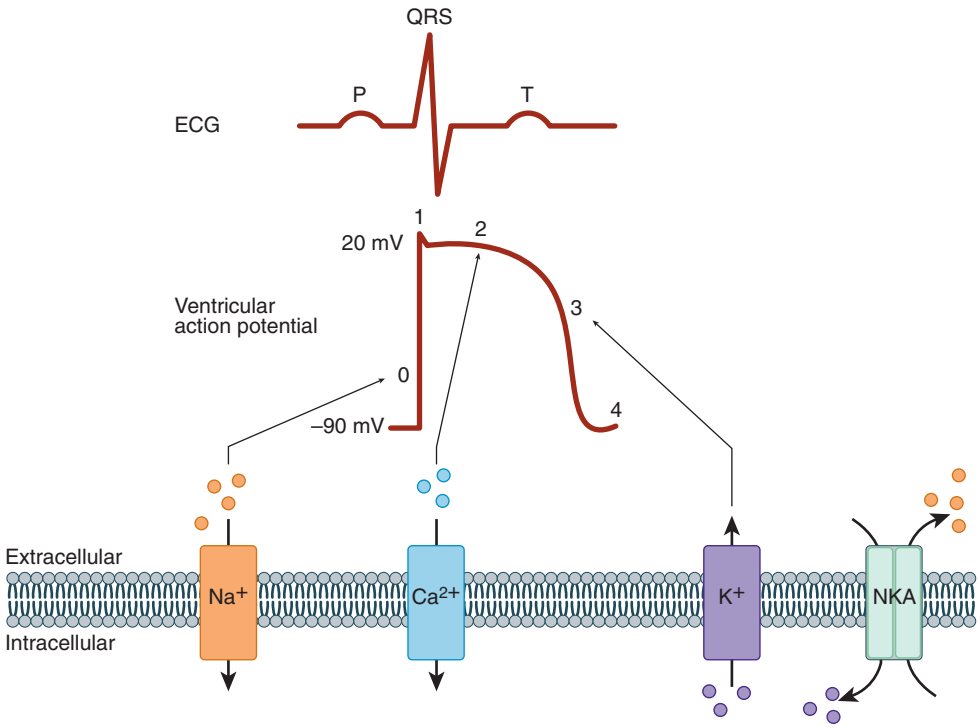


FIGURE 52-1. Cardiac action potential and ion channels. Myocardial contraction begins when sodium channels open and positively charged sodium ions flow into the cell and cause membrane depolarization (phase 0). During phases 1, 2, and 3, calcium ions flow into the cell through L-type calcium channels, while potassium flows out of the cell through voltage-gated potassium channels. These three phases correspond to the myocardial contraction, which corresponds to the QRS complex on the surface electrocardiogram (ECG). The sodium-potassium adenosine triphosphatase (NKA) helps return the system to its resting state.

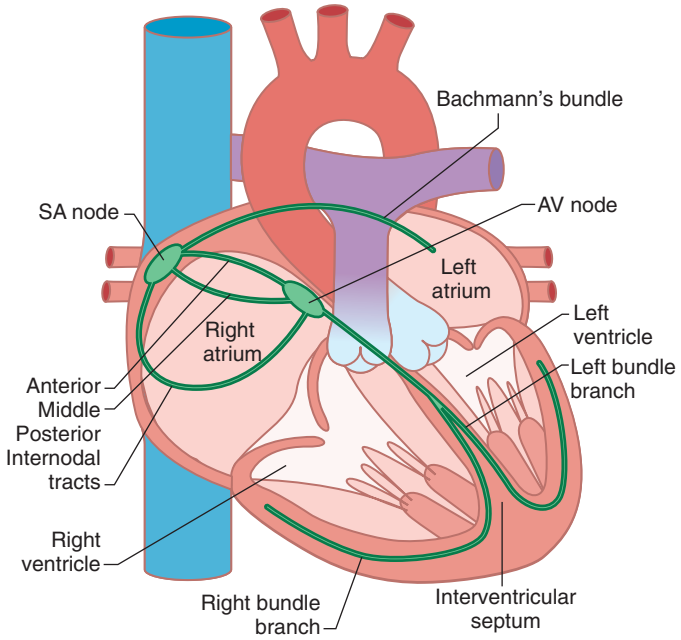

FIGURE 52-2. Cardiac anatomy. Cardiac anatomy comprises electrical and structural components. The electrical impulse that directs cardiac contraction originates in the sinoatrial (SA) node and is rapidly conducted through the atria by specialized conduction tracts. The impulses merge at the atrioventricular (AV) node where, after a brief pause, they are rapidly conducted into the ventricles through the bundle of His, which is composed of specialized Purkinje cells. Blood moves from the atria into the ventricles through the tricuspid and mitral valves during diastole. During systole, blood from the ventricles is pumped into the pulmonary artery and aorta through the pulmonic and aortic valves.

with specialized contractile proteins arranged in highly regulated units, called sarcomeres, that give the muscles characteristic patterns known as striations (E-Fig. 52-2). Hence, like skeletal muscle, cardiac muscle is termed *striated*, as opposed to smooth muscles that form the vasculature and other organs such as the bladder, uterus, and stomach. Cardiomyocytes are also loaded with mitochondria that provide the energy (ATP) required to fuel the heart's lifelong contractions (systole) and relaxations (diastole).

Ultrastructure

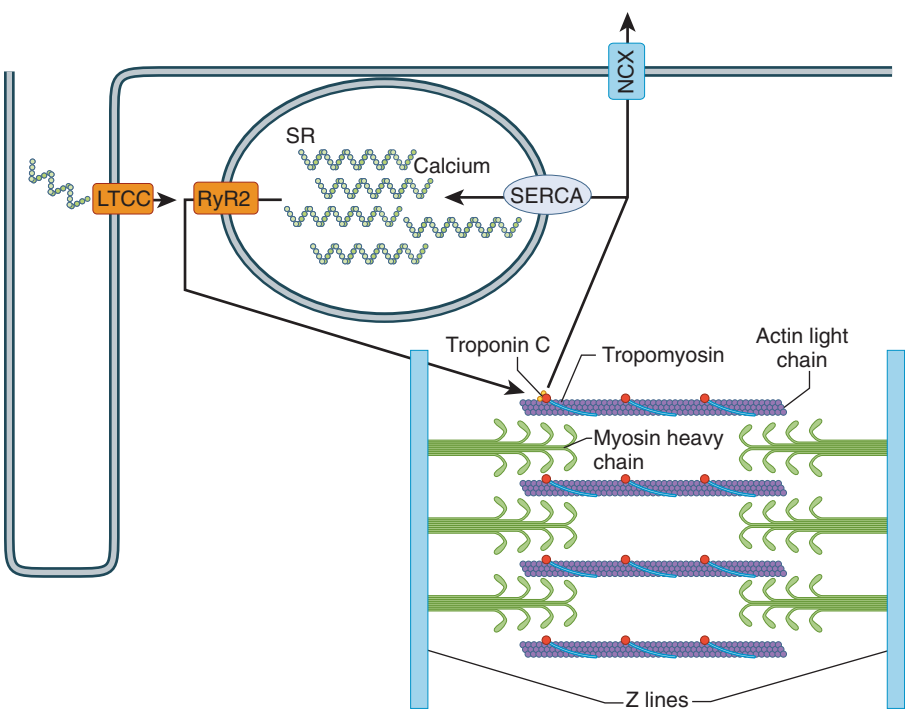
The basic unit of the contractile system is the sarcomere, which is defined anatomically as the distance between two Z lines that anchor thin filaments composed of actin, tropomyosin, and troponin. Thin filaments slide past thick filaments (composed of myosin and titin) in a calcium-dependent manner to shorten the sarcomere length. The contractile proteins are surrounded by a calcium-filled membrane called the *sarcoplasmic reticulum*. The sarcoplasmic reticulum forms specialized associations with the transverse tubules, which are invaginations of the plasma membrane and contain voltage-gated calcium channels. When the muscle is activated by depolarization of its membrane, this electrical signal travels deep into the muscle through the transverse tubules. Inside the muscle, the electrical depolarizing signal activates the voltage-gated channels, which open to allow a small amount of calcium to enter the muscle cells. This influx of calcium in turn activates the type 2 ryanodine receptor (RyR2)–calcium-release channels on the sarcoplasmic reticulum. The RyR channels open and release enough calcium from the sarcoplasmic reticulum to raise the calcium concentration in the myoplasm about ten-fold. As a result, calcium binds to troponin C in the thin filaments and causes a conformational change that enables cross-bridging between actin and myosin, thereby leading to sliding of the filaments, shortening of the sarcomere, and muscle contraction. Hydrolysis of ATP provides the energy required for the generation of force by the actin-myosin interaction. The conversion of electrical energy (depolarization of the cell membrane) to mechanical energy is known as excitation-contraction coupling. Relaxation of the heart muscle occurs when calcium is pumped back into the sarcoplasmic reticulum through the sarcoendoplasmic reticulum ATPase.

Signals That Regulate Contraction

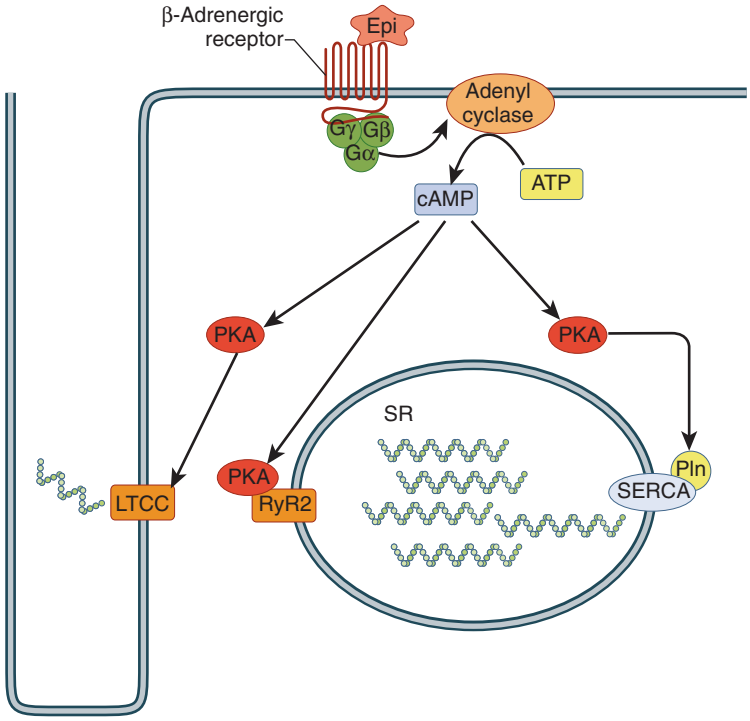
Contractile force can be enhanced during stress by activation of the β-adrenergic pathway, which increases both the amount of calcium released and the rate of calcium uptake in the sarcoplasmic reticulum (E-Fig. 52-3). β-Agonists (e.g., epinephrine or norepinephrine) bind to β-adrenergic receptors to activate adenylyl cyclase, which generates cyclic adenosine monophosphate (cAMP) and activates protein kinase A. Protein kinase A phosphorylates phospholamban, the voltage-gated calcium channel, the ryanodine receptor, and sarcomeric regulatory proteins, thereby resulting in increased release of calcium from the sarcoplasmic reticulum and enhanced contractility of the heart.

Nonmuscle Cells

Although the heart is a muscular pump, 60 to 70% of its cells are cardiac fibroblasts, not muscle cells. These fibroblasts provide critical components of the extracellular matrix that determine the structure of the heart. Collagen, which is produced by the cardiac fibroblasts, is a major component of the extracellular matrix, where it forms a network that surrounds the cardiomyocytes and creates tissue that is able to withstand the stress of constant pumping. In certain pathologic conditions, including hypertension,



E-FIGURE 52-2. Sarcomere and excitation-contraction coupling. Depolarization of the cell membrane leads to calcium influx through L-type calcium channels (LTCC), which activate ryanodine receptors (RyR2) to release the large calcium stores from the sarcoplasmic reticulum (SR). Calcium binds to troponin C and induces a conformational change in tropomyosin, which enables myosin heads to interact with actin filaments and cause contraction. During relaxation, calcium is pumped back into the sarcoplasmic reticulum through the sarcoendoplasmic reticulum calcium ATPase (SERCA) and out of the cell through the sodium-calcium exchanger (NCX).



E-FIGURE 52-3. Cardiomyocyte signaling. Binding of catecholamines (epinephrine, norepinephrine) to β-adrenergic receptor, a G-coupled protein receptor, leads to activation of adenyl cyclase, which converts adenosine triphosphate (ATP) to cyclic adenosine monophosphate (cAMP). cAMP activates protein kinase A (PKA), which phosphorylates multiple calcium-handling proteins, including L-type calcium channels (LTCC), ryanodine receptors (RyR2), and phospholamban (Pln), leading to a general increase in their activity and greater contractility. Epi = epinephrine; SERCA = sarcoendoplasmic reticulum calcium ATPase; SR = sarcoplasmic reticulum.

myocardial infarction, and heart failure, the cardiac fibroblasts respond to stress by generating excess extracellular matrix, resulting in fibrosis, which can impair cardiac function. Indeed, a number of commonly used therapies for heart disease, including lipid lowering with statins or fibrates, and antihypertensive treatments with angiotensin-converting enzyme inhibitors, β-blockers, and angiotensin receptor blockers, exert part of their beneficial effects on cardiac fibroblasts by reducing fibrosis, thereby resulting in favorable "reverse" remodeling of the heart.

ANATOMY OF THE HEART

The primary pumping chamber of the heart is the thick-walled left ventricle, which is composed of billions of cardiomyocytes connected end to end through gap junctions. The right ventricle is a thinner-walled chamber, divided from the left ventricle by the *interventricular septum*. Above the ventricles are the right and left atria, which are thin-walled chambers that receive low-pressure venous blood; they are separated from the ventricles by the *tricuspid valve* on the right side and the *mitral valve* on the left side. These valves are attached to *papillary muscles* that emerge from the ventricular walls through *chordae tendineae*. The pressure gradient between the ventricles and the atria opens the AV valves. The papillary muscles help establish the positions of the valve leaflets and prevent regurgitant flow during contraction. The *aortic and pulmonary valves* separate the left and right ventricles from their arterial connections and enable blood flow out of the ventricles.

Coronary Blood Flow

The coronary arteries receive blood from the aorta, directly above the aortic valve, and travel through the epicardium that surrounds the heart to supply blood to the heart muscle (see Fig. 57-3 in Chapter 57). The diastolic blood pressure in the ascending aorta just above the aortic valve determines most of the flow of blood into the normal (nonstenosed) coronary arteries while the heart is relaxed. During systole, coronary flow is determined by the left ventricular intracavitary pressure, which equals the pressure within the inner myocardial wall, where coronary arteries are compressed during systole. Coronary blood flows to the epicardium during both systole and diastole but flows to the endocardium predominantly during diastole.

Metabolic Regulation of the Cardiovascular System

Cardiac muscle requires constant coronary perfusion to supply oxygen and other metabolites. Increased energy consumption owing to enhanced contractility necessitated by increased pressures or higher heart rates (e.g., during exercise) can be met only by increased coronary blood flow. Signals that augment coronary blood flow (by up to six-fold) include nitric oxide, adenosine, bradykinins, prostaglandins, and carbon dioxide. The breakdown of ATP is the source of adenosine, whereas nitric oxide is produced by the action of nitric oxide synthases that metabolize the amino acid L-arginine. Autoregulatory mechanisms, including constriction in response to increased luminal pressures and dilation in response to reduced pressure, also play a role in determining coronary artery blood flow. Other metabolic factors that cause vasoconstriction include endothelin peptides, serotonin, 5-hydroxytryptamine, thromboxane, angiotensin II, and β_1-adrenergic stimulation.

Sympathetic and parasympathetic pathways of the autonomic nervous system and the renin-angiotensin system exert potent regulatory effects on cardiovascular function. The sympathetic nervous system plays the key role

in the response to stress (e.g., the fight-or-flight response) by increasing heart rate and myocardial contractility and decreasing vascular tone. Regulation of cardiovascular function by the sympathetic nervous system is mediated by norepinephrine that is released at the nerve endings and by epinephrine from the adrenal gland. β-Adrenergic signaling is mediated by epinephrine, which increases the heart rate and vasodilates the central arterial bed, thereby resulting in reduced afterload, which in turn helps augment cardiac output.

The SA and AV nodes are regulated by parasympathetic innervation that slows the pacemaker's rate of firing and conduction through the AV node by the release of acetylcholine. Vasoconstriction of the venous system is mediated by the sympathetic nervous system, which limits fluid and blood loss after trauma.

The renin-angiotensin system also regulates blood pressure, peripheral vasoconstriction, and contractility in coordination with the sympathetic nervous system. Both the sympathetic nervous system and the renin-angiotensin system are chronically activated in heart failure (Chapter 58), where the resulting maladaptive remodeling of the cardiovascular system promotes the progression of heart failure. Decreased perfusion to the kidney, decreased delivery of sodium to the macula densa, or increased sympathetic activity result in the release of the hormone renin from the macula densa cells within the juxtaglomerular apparatus of the kidney. Renin results in the production of angiotensin II, a potent constrictor of peripheral and coronary arteries. In turn, angiotensin II causes the release of the sodium-retaining hormone aldosterone from the adrenal gland (Chapter 234). Together, these signals result in sodium retention and increased arterial blood pressure.

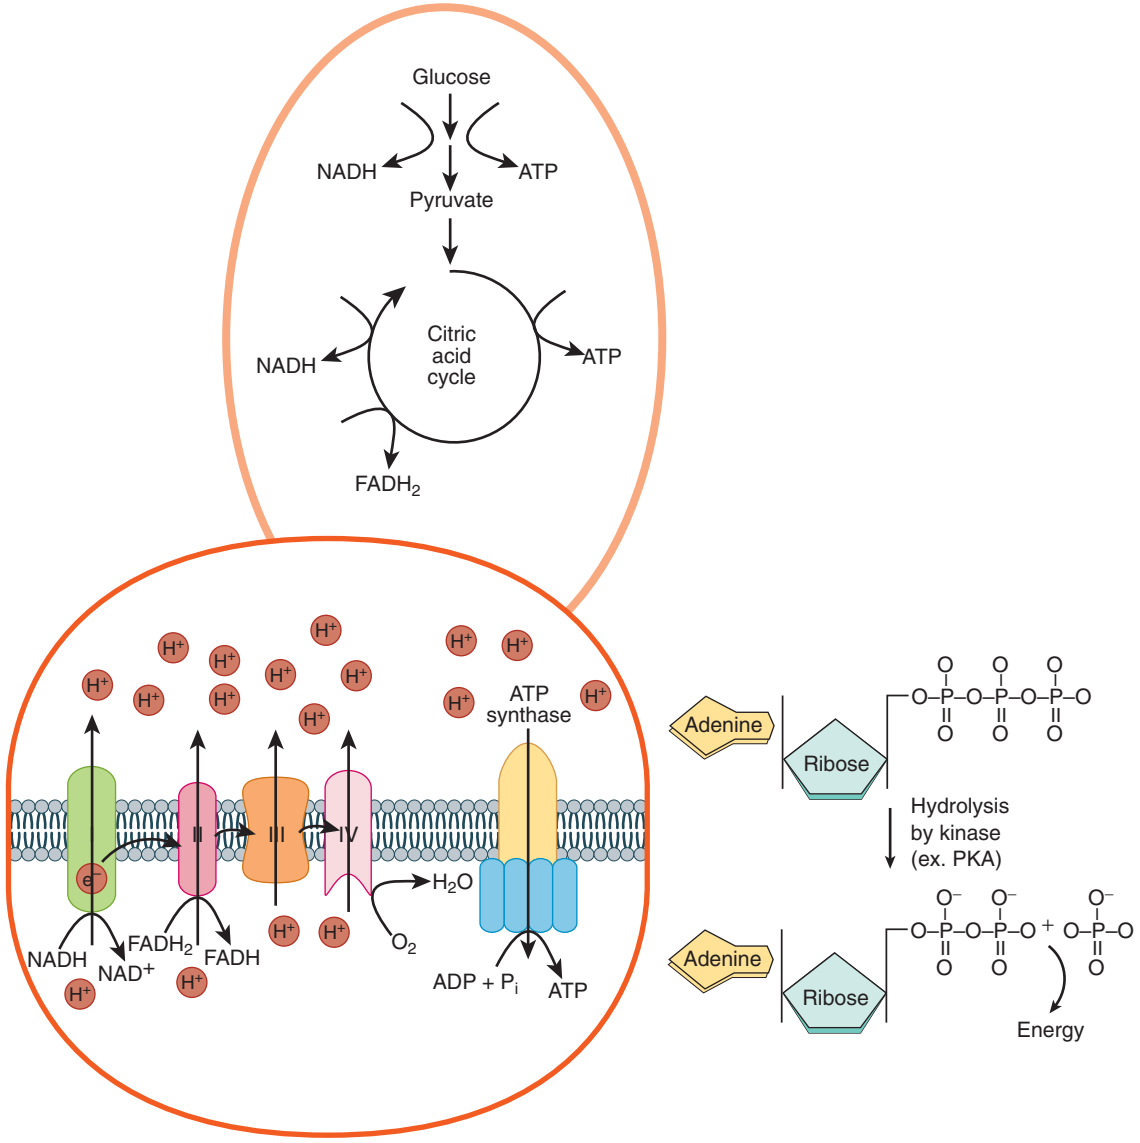
PHYSIOLOGY OF THE HEART AND CIRCULATORY CONTROL

Cardiac Energetics

The major immediate source of energy in the heart is the oxidation of fatty acids and glucose. When oxygen supply is limited, glucose metabolism is favored because it generates more ATP per oxygen consumed. The heart has virtually no ability to conduct anaerobic metabolism (i.e., glycolysis) and therefore is dependent on oxygen for its function. For example, heart function deteriorates immediately under conditions of hypoxia, ischemia, and carbon monoxide poisoning.

Basal metabolism, total mechanical work performed by the heart, contractility, and heart rate determine the oxygen and energy consumption of the heart. During excitation-contraction coupling, two key steps require energy consumption (ATP hydrolysis): release of the myosin head–actin interaction, and reuptake of calcium into the sarcoplasmic reticulum.

The mechanical work of the heart is determined by the total *pressure-volume area* (E-Fig. 52-4), which is related to the number of actin-myosin cross-bridges formed during the contraction. It is the sum of the external work performed by the heart in pumping blood from the ventricle to the aorta



E-FIGURE 52-4. Adenosine triphosphate (ATP) production. Cells produce maximal adenosine triphosphate by catabolizing glucose through aerobic respiration. During glycolysis, glucose is converted into two molecules of pyruvate, thereby producing a net of two ATP as well as NADH. Both pyruvate molecules then enter the citric acid cycle, where they result in the formation of six more molecules of NADH, two molecules of $FADH_2$, and two of ATP. NADH and $FADH_2$ are energy-rich electron donors, which pass electrons down the electron transport chain, where they ultimately are used to reduce oxygen and form water. During electron transport, specialized proteins, called cytochromes, pump protons into the intermembrane space of mitochondria, where they build up a concentration gradient, ultimately powering the conversion of adenosine diphosphate (ADP) + inorganic phosphate (P_i) into ATP through ATP synthase. ATP can be hydrolyzed to produce energy and a phosphate group that can be covalently attached to other proteins.

(represented by the area inside the pressure-volume loop) plus energy stored in the myocardium at the end of contraction. Enhanced contractility requires increased oxygen consumption because an increased amount of calcium released from the sarcoplasmic reticulum requires increased ATP and oxygen consumption to pump the released calcium back into the sarcoplasmic reticulum through the sarcoplasmic reticular ATPase. Based on these principles, increasing the heart rate requires increased oxygen consumption. If the heart rate increases from 70 to 140 beats per minute during exercise or stress, oxygen consumption increases almost two-fold over the basal value.

Contractility and Relaxation

The Cardiac Cycle

In resting humans, the heart beats approximately once per second. With each beat, the heart cycles through a series of four hemodynamic events represented by changes in pressures and volumes (Fig. 52-3) as well as electrical activity as represented by the ECG. When the heart muscle is relaxed at end diastole, the ventricular pressure is at its resting level *(end-diastolic pressure)* and the ventricular volumes are at their maximal value *(end-diastolic volume)*. Aortic pressure declines as the blood ejected into the aorta during the previous ventricular contraction flows to the peripheral circulation. Atrial contraction provides a final boost to ventricular volume immediately before ventricular systole. Ventricular contraction increases the pressure in the ventricle; when this pressure exceeds the pressure in the atrium, the mitral valve closes. However, because ventricular pressure remains less than aortic pressure, the aortic valve remains closed, and no blood enters or leaves the ventricle during this first phase of the cardiac cycle, the *isovolumic contraction* phase. During systole, ventricular pressure eventually exceeds aortic pressure, at which time the aortic valve opens, blood is ejected into the aorta, and ventricular volume decreases during the *ejection* phase of the cycle. At the end of systole when contraction is maximum, ejection ends, and the ventricular volumes are at their lowest *(end-systolic volume)*. The volume of the ejected blood, which is termed the *stroke volume* (SV), is defined as the difference between the end-diastolic and end-systolic volumes. The ejection fraction (EF), defined as the percentage of end-diastolic volume (EDV) ejected during a contraction (EF = 100 × SV/EDV), is an index of heart function. The next phase in the cycle occurs when the heart muscle relaxes, ventricular pressures are less than the aorta pressure, and the aortic valve closes. During this *isovolumic relaxation* phase, ventricular volumes remain constant because, once again, both the mitral and aortic valves are closed. When ventricular pressures fall below atrial pressures, the mitral and tricuspid valves open, and blood flows from the atria into the ventricles during the *filling* phase.

These four phases of the cardiac cycle can be represented by a *pressure-volume diagram* (Fig. 52-4), which plots the instantaneous ventricular pressure versus volume to calculate the *pressure-volume loop*. Similar effects occur on the left and right sides of the heart, but with higher pressures on the left side (Table 52-1).

Pressure-Volume Relationships

The volume of a ventricular chamber correlates with length of its muscles and sarcomeres. In the left ventricle, with its circular cross section, Laplace's law defines the relationship among pressure in the chamber (P), muscle tension (T, force/unit cross-sectional area of the muscle), chamber wall thickness (h), and the internal radius of the chamber (R): $P \approx 2 \cdot T \cdot h/R$. Both calcium and the length of the heart muscle determine force (Fig. 52-5). Each muscle is

TABLE 52-1 RANGE OF NORMAL RESTING HEMODYNAMIC VALUES

PRESSURE
Central venous (mean): 0-5 mm Hg
Right atrial (mean): 0-5 mm Hg
Right ventricular (systolic/diastolic): 20-30/0-5 mm Hg
Pulmonary artery (systolic/diastolic): 20-30/8-12 mm Hg
Left atrial (mean): 8-12 mm Hg
Left ventricular (systolic/diastolic): 100-150/8-12 mm Hg
Aortic (systolic/diastolic): 100-150/70-90 mm Hg
VOLUME-RELATED MEASURES
Right ventricular end-diastolic volume: 70-100 mL
Left ventricular end-diastolic volume: 70-100 mL
Stroke volume: 40-70 mL
Cardiac index: 2.5-4 L/min/m^2
Ejection fraction: 55-70%
ARTERIAL RESISTANCE
Systemic vascular resistance: 10-20 mm Hg · min/L
Pulmonary vascular resistance: 0.5-1.5 mm Hg · min/L

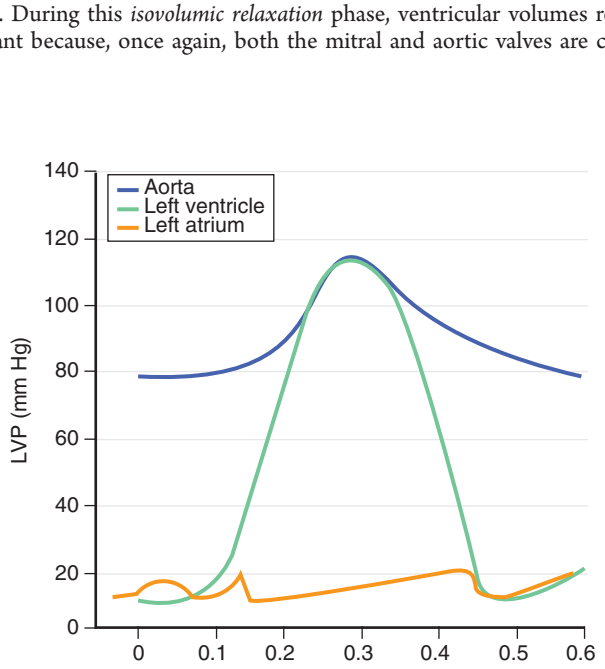


FIGURE 52-3. Wigger's diagram. Changes in aortic, left ventricular, and left atrial pressures represented graphically as a function of time, with the corresponding electrocardiogram signal for each. LVP = left ventricular pressure.

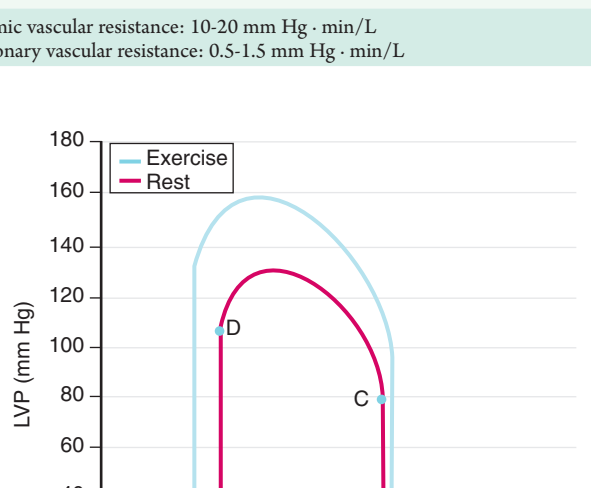

FIGURE 52-4. Pressure-volume loop. The left ventricle (LV) begins to fill when pressure in the chamber falls below that of the left atrium, and the mitral valve opens (point A). Pressure in the ventricle slowly rises as the muscle fibers are stretched by the increasing volume. When the myocardium contracts (point B), pressure in the left ventricle rises, causing the mitral valve to close and trapping the blood inside the chamber (isovolumic contraction). When the pressure in the left ventricle is higher than in the aorta, the aortic valve opens (point C), and blood is ejected out of the left ventricle. As the left ventricle stops contracting, pressure in the aorta becomes higher than that in the left ventricle, and the aortic valve closes (point D). During this period of isovolumic relaxation, the ventricle rapidly relaxes until it starts filling again. During exercise, the release of norepinephrine from sympathetic nerve terminals leads to enhanced myocardial contractility. As a result, the left ventricle generates higher pressures and ejects a greater volume of blood during each beat. LVP = left ventricular pressure.

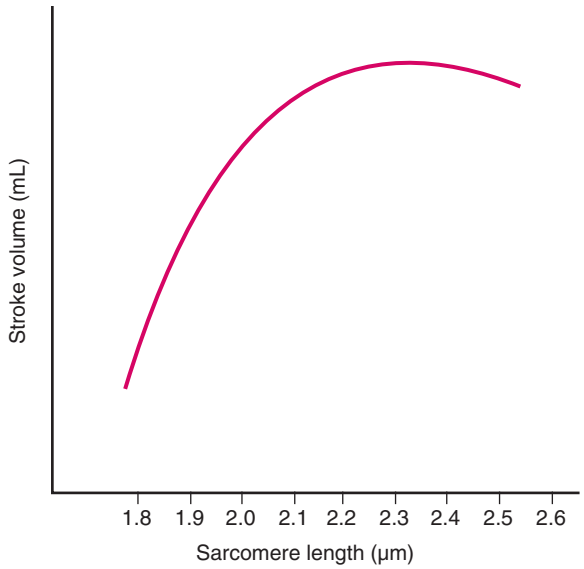

FIGURE 52-5. Starling's law. Cardiac output, represented as stroke volume (end-systolic volume minus end-diastolic volume), as a function of initial sarcomere stretch. The greater the initial stretch on the fibers during diastole, referred to as *preload*, the more force is generated during systole.

composed of a linear array of sarcomere bundles. Maximal force is achieved at a sarcomere length of about 2.2 to 2.3 mm, which results in the optimal overlap of thick and thin filaments. When the sarcomere length is less than 2.0 mm, the ends of the thin filaments contact each other, thereby resulting in a reduction in force. Conversely, when sarcomeres are stretched beyond 2.3 mm, force decreases owing to reduced overlap between myosin heads and actin.

Force-length relationships, which are determined by measuring the force developed at different muscle lengths while preventing the muscle from shortening (isometric contractions), characterize the systolic and diastolic contractile properties of cardiac muscle. With increasing muscle length, end-systolic force increases to a greater degree than does end-diastolic force. The difference in force at end diastole versus end systole increases as muscle length increases as a result of the greater developed force of the stretched muscle. This relationship of force to length is referred to as the Frank-Starling law of the heart.

Work of the Heart

Cardiovascular performance is reflected in the arterial blood pressure and cardiac output (mean arterial blood flow), which in turn are dependent on four factors: preload, afterload, ventricular contractility, and heart rate.

Preload, which refers to the degree to which sarcomeres are stretched just before systole, is defined as the end-diastolic pressure or volume. The Frank-Starling law of the heart dictates that ventricular pressure and output vary with preload, so a decrease in preload decreases end-diastolic volume and pressure, peak pressure, and stroke volume. Conversely, increased preload increases ventricular pressure and output, subject to the limits to which preload pressures can be increased. Left ventricular end-diastolic pressures of 20 to 25 mm Hg and greater cause exudation of fluid into the alveoli and pulmonary edema (Chapter 58).

Afterload refers to the stress that the ventricle must overcome to eject blood. Peak arterial pressure reflects the peak stress imposed on cardiomyocytes according to Laplace's law (described previously as $P \approx 2 \cdot T \cdot h/R$). As long as there is no left ventricular outflow obstruction, arterial pressure reflects myocyte afterload, as does *total peripheral resistance* (TPR), which corresponds to the tone of the resistance vessels. TPR is the ratio between the mean pressure decrease across the arterial system (mean arterial pressure [MAP] minus mean central venous pressure [CVP]) and cardiac output (CO): TPR = (MAP − CVP)/CO. When TPR is increased, the pressure-volume relationship shifts such that peak pressure is increased whereas stroke volume and ejection fraction are decreased.

Contractility of cardiac muscle *(myocardial contractility)* or a ventricle *(ventricular contractility)* is the intrinsic ability to generate force independent of preload or afterload. When contractility is increased, the pressure-volume relationship shifts so that pressure, stroke volume, and ejection fraction are increased at constant preload volume and arterial resistance.

Cardiac output is measured in liters per minute and is equal to the amount of blood ejected at each heartbeat (stroke volume in liters per beat) multiplied by the number of beats per minute. As a result, *heart rate* is a powerful determinant of cardiac performance. Cardiac output and mean arterial pressure can be related to preload, afterload, contractility, and heart rate through the Frank-Starling curves, which plot end-diastolic pressure versus cardiac output or mean arterial pressure, to yield an overall picture of left ventricular function.

CARDIOVASCULAR RESPONSES TO STRESSORS

Exercise

Exercise requires dramatic increases in cardiac function combined with remodeling of the peripheral circulation to meet the enhanced metabolic demands of critical organs and redirect blood flow to those organs. Indeed, the oxygen consumption during exercise can increase as much as 18-fold. About one third of the requirement for increased oxygen consumption is met by improved extraction of oxygen from the blood in the muscles (reducing venous saturation from about 75% to about 25%) and the remainder by increasing cardiac output as much as 6-fold. Increased cardiac function is achieved largely through sympathetic stimulation and reduction in vagal tone, which combine to increase the heart rate, contractility, ejection fraction, filling rates, and systolic blood pressure and to decrease aortic impedance. In young healthy individuals, heart rate can increase from a baseline of 60 to 70 beats per minute at rest to as much as 170 to 200 beats per minute with exercise. To increase rather than decrease cardiac output at these high heart rates, which can limit ventricular filling and stroke volume, contractility must also increase, through a phenomenon known as the positive force frequency relationship or Bowditch phenomenon. Along with increased cardiac contractility, arterial vasodilation in the aorta and other major arteries reduces the resistance to cardiac outflow. Both enhanced cardiac contractility and arterial vasodilation are triggered by the same sympathetic nervous system signals. With increased cardiac outflow, venous return also must increase, so preload can be maintained as well as possible to enhance cardiac function by the Frank-Starling mechanism.

Heart Failure

Heart failure can be defined as the inability of the heart to provide sufficient blood flow to meet the metabolic demands of the organs (Chapter 58). Heart failure can be due to systolic dysfunction with volume overload, most often as the consequence of ischemic heart disease (myocardial infarction) or as the end-stage consequence of hypertension. Systolic heart failure is characterized by increases in the size of the various cardiac chambers (rightward shift of the end-diastolic pressure-volume relationship). In another form of heart failure, known as *diastolic heart failure*, the heart is not necessarily increased in size, and systolic function is preserved.

Aging

Prolongation of contraction and relaxation times, which are common abnormalities in older individuals, may be related to cardiac hypertrophy as a consequence of the high prevalence of hypertension with advancing age (Chapter 67). A progressive "stiffening" of the large arteries with advancing age increases resistance, although the mechanism underlying this change is not understood. The heart rate and contractile responses to sympathetic signals are reduced and lead to a diminished ability to respond to conditions of acute overload, such as increased blood pressure or an acute myocardial infarction.

RADIOLOGY OF THE HEART

MURRAY G. BARON

The heart casts a homogeneous shadow on the chest film. No internal detail can be seen within its contours because the radiodensities of blood, myocardium, and other cardiac tissues are so similar that one cannot be distinguished from the others. Only two borders of the heart, where it contacts the radiolucent, air-containing lung, can be discerned in any one projection. Changes in the size or shape (or both) of the chambers of the heart and the great vessels usually alter the shape of the cardiac silhouette. However, because the heart is a three-dimensional structure, multiple views are required for complete radiographic evaluation. With the advent of echocardiography, the need for this "cardiac series" has disappeared. However, a remarkable amount of information regarding the heart is contained on standard frontal and lateral chest films, which remain a useful tool for detecting disease, evaluating the severity of known disease, documenting the progress of disease, and assessing the efficacy of treatment.

RADIOLOGIC ANATOMY

Except for the more complex cardiac anomalies, which are rare, especially in adults, the positions and spatial relationships of the cardiac chambers and the great vessels are the same from one patient to the next and are not significantly affected by disease. On a frontal chest film, the right cardiac border is composed of a straight vertical upper half formed by the superior vena cava and a gently convex lower half representing the lateral wall of the right atrium (Fig. 53-1). The break in the contour of this border of the heart indicates the

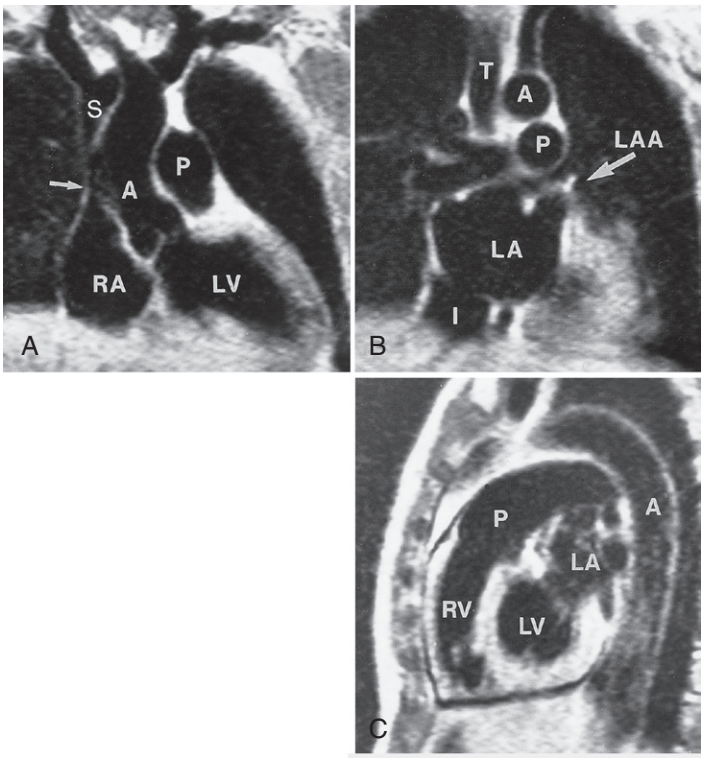

FIGURE 53-1. Normal radiographic anatomy, magnetic resonance images. A, Coronal section at the level of the aortic valve. The right border of the cardiac silhouette is formed by the superior vena cava (S) and the right atrium (RA). The *arrow* indicates the caval-atrial junction. The lower portion of the left cardiac border is formed by the left ventricle (LV). A = ascending aorta; P = main pulmonary artery. **B,** Coronal section at the level of the left atrium. The upper portion of the left cardiac border is formed by the aorta (A), main pulmonary artery (P), and left atrial appendage (LAA), see *arrow*. I = inferior vena cava; LA = left atrium; T = trachea. **C,** Sagittal section near the midline. The right ventricle (RV) forms the anterior surface of the heart, which abuts the sternum. The pulmonary artery (P) extends upward and posteriorly from the ventricle. The posterior border of the heart is formed by the left atrium (LA) and left ventricle (LV). The aorta (A) is behind the heart.

caval-atrial junction. Some patients are able to inhale deeply enough to uncover a small, straight segment of the inferior vena cava between the diaphragm and the right atrium.

Abnormalities of the caval segment are usually due to dilation of the ascending aorta. A localized bulge in its midportion usually indicates poststenotic dilation secondary to aortic valve stenosis, whereas aortic insufficiency is commonly associated with a more generalized dilation of the aorta. A bulge in the region of the caval-atrial junction may be due to an aneurysm of either the right coronary artery or the noncoronary sinus of Valsalva or to a markedly enlarged left atrium. Dilation of either atrium tends to extend the cardiac silhouette to the right, whereas dilation of either ventricle enlarges the silhouette to the left.

The left cardiac border is composed of four distinct segments. The uppermost bulge represents the aortic knob, the most distal portion of the aortic arch where it turns downward to become the descending aorta. The prominence below the knob is formed by the main pulmonary artery and the subvalvular portion of the outflow tract of the right ventricle. The lowermost third of this border represents the anterolateral wall of the left ventricle. Between this bulge and that of the pulmonary artery is a short, flat, or slightly concave segment where the left atrial appendage reaches the border of the heart.

Aneurysms of the descending thoracic aorta commonly involve its most proximal portion in the region of the ligamentum arteriosum and appear as a dilated aortic knob. Prominence of the pulmonary artery segment is common in younger individuals, but after the age of 35 to 40 years, such dilation is almost always an indicator of pulmonary arterial hypertension.

In the lateral view (see Fig. 53-1C), the anterior border of the cardiac silhouette is formed by the body and the outflow tract of the right ventricle. The heart lies in the anterior portion of the chest, and the right ventricle abuts the lower third of the sternum. Both the outflow tract and the pulmonary artery slope posteriorly. Air-containing lung interposed between this portion of the heart and the anterior chest wall forms the "retrosternal clear space." The posterior border of the heart extends from the level of the pulmonary carina to the diaphragm. Its upper half is formed by the back of the left atrium, and the lower half represents the posterior wall of the left ventricle. The shadow of the inferior vena cava is usually seen in the lateral projection extending obliquely upward and anteriorly from the diaphragm to enter the posterior aspect of the right atrium. The lowermost contour of the normal left ventricle curves anteriorly and crosses the inferior vena cava about 2 cm above the left side of the diaphragm.

Alterations in the contour of the heart usually reflect dilation or hypertrophy of the chambers, or both. Many times the pattern of these changes, together with the appearance of the pulmonary vasculature, points to a specific underlying cardiac abnormality. Chest films are most sensitive for detecting chamber dilation. Cardiac hypertrophy is more difficult to recognize because the thickened myocardium tends to encroach on the ventricular lumen more than extending outward and enlarging the cardiac silhouette. With severe hypertrophy, as in hypertrophic cardiomyopathy, the heart enlarges to the left and the apex becomes blunted, but this appearance is not pathognomonic.

HEART SIZE

A normal-sized heart does not guarantee the absence of cardiac disease. Angina, for example, no matter how severe, does not affect heart size until the left ventricle decompensates. Similarly, patients with restrictive cardiomyopathy may be in severe heart failure with a normal-appearing heart. Conversely, an enlarged heart always indicates the presence of cardiac or pericardial disease. Therefore, accurate evaluation of heart size is important.

Heart size, in the absence of disease, is directly related to the habitus of the patient. The cardiothoracic ratio, which compares the transverse diameter of the heart with the width of the chest, gives a readily obtainable, rough estimate of heart size. This ratio is measured by dropping a vertical line through the heart and summing the greatest distance to the right and left cardiac borders (Fig. 53-2) to give the transverse cardiac diameter. The transverse thoracic diameter, the greatest width of the chest, is measured from the inner surfaces of the ribs. Dividing the cardiac diameter by the chest diameter gives the cardiothoracic ratio. A value of less than 0.6 can be considered within the limits of normal. Setting this value at 0.5, as is often done, produces too many false-positive results.

In most cases, exact measurement of the cardiac silhouette is not necessary, and a reasonably experienced observer can achieve an acceptable degree of accuracy by visual estimation. With either method, several cautions must be observed. The single greatest effect on apparent cardiac size is the degree of inspiration. The volume of the heart is essentially constant throughout the cardiac cycle. As the diaphragm moves up with expiration, the vertical diameter of the heart is shortened, and its transverse diameter increases. Because heart size is estimated primarily from its width, the heart appears larger on expiratory films. The degree of inspiration can be determined from the relationship of the diaphragm to the ribs. On a properly positioned frontal chest film, a reasonable degree of inspiration is indicated if the diaphragm is lowered to at least the level of the posterior portion of the ninth rib.

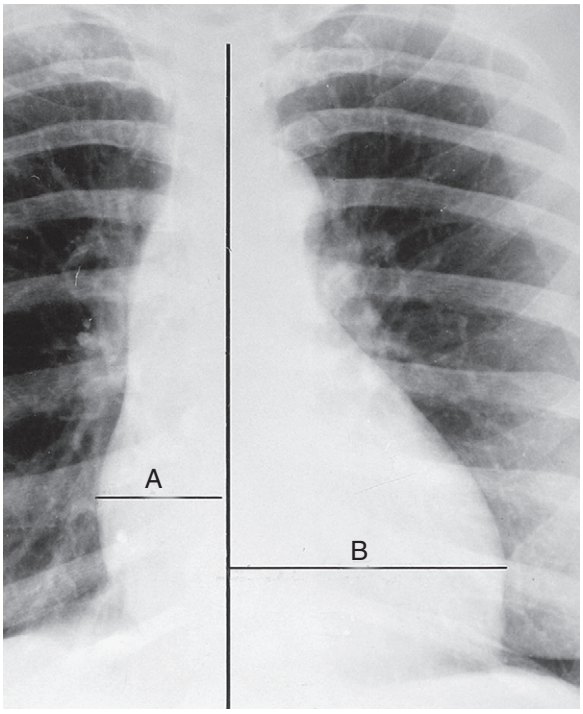

FIGURE 53-2. Measurement of the transverse cardiac diameter. Severe aortic stenosis with a 95-mm systolic gradient across the valve is present. The heart, though considerably hypertrophied, is normal in size and configuration. A *vertical line* is drawn through the heart. The greatest distances to the right cardiac border (A) and to the left cardiac border (B) are then measured. Transverse cardiac diameter = A + B.

When the anteroposterior diameter of the chest is small, the heart may be compressed between the sternum and the spine so that it splays to one or both sides. For this reason, the heart often appears enlarged in patients with the straight back syndrome or with a pectus excavatum deformity of the sternum. An epicardial fat pad (actually it is extrapleural fat outside the pericardium) can occur in one or both cardiophrenic angles and make the heart appear larger than it actually is. The fat pad can be recognized because the cardiophrenic angle appears obtuse or the cardiac apex is indistinct. In addition, the slightly greater density of the heart can usually be distinguished from the more radiolucent image of the fat.

A change in size of the cardiac silhouette can also occur between systole and diastole. This point is important because chest films are exposed at random with reference to the cardiac cycle, so a change in heart size between two examinations may be solely due to the timing of filming. In most cases, the difference in the transverse cardiac diameter between systole and diastole is small, no more than several millimeters. However, in younger patients, especially the more athletic with a slow heart rate and a large stroke volume, phasic change in the normal cardiac diameter can be as large as 2 cm.

CHAMBER ENLARGEMENT

Left Atrium

Dilation of the left atrium alone, in the absence of a left-to-right shunt, is most often due to disease of the mitral valve, although it can also result simply from atrial fibrillation. The two "popular" radiologic signs of left atrial enlargement—a double contour within the right cardiac border and elevation of the left main bronchus—are accurate when present, but they are insensitive and seen in only about half the cases of mitral valve disease. To produce a discernible margin within the cardiac silhouette in the frontal projection, the thickness of the heart must increase sharply at some point. This increase in thickness occurs in mitral disease when the left atrium enlarges and

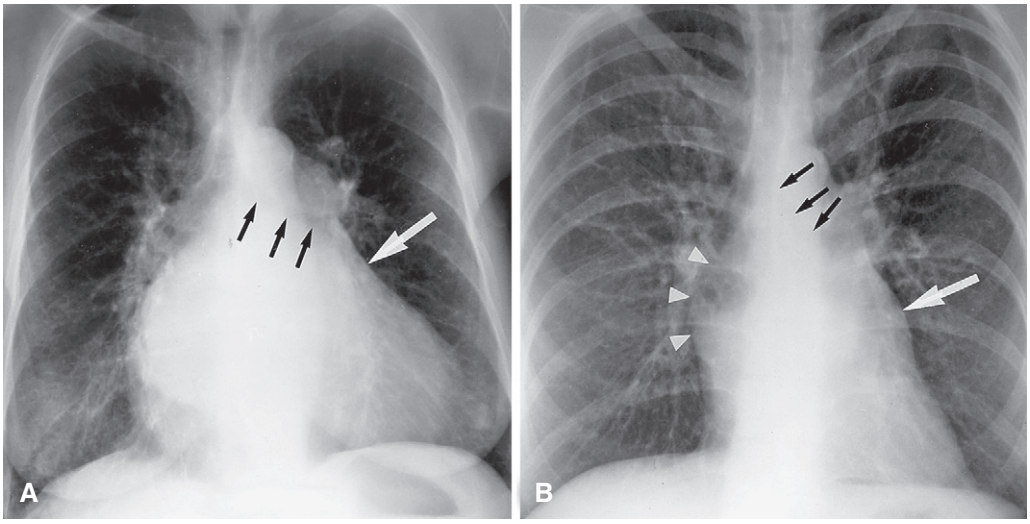

FIGURE 53-3. Left atrial enlargement in mitral valve disease. A, Patient 1: The enlarged left atrium is causing the central portion of the cardiac silhouette to be abnormally dense. The right border of the atrium is seen within the right side of the cardiac silhouette. The left main bronchus *(black arrows)* is elevated. The region of the left atrial appendage *(white arrow)* is slightly concave because this structure was resected at a previous mitral commissurotomy. **B,** Patient 2: The enlarged left atrial appendage bulges from the left side of the heart *(white arrow),* whereas the body of the atrium *(arrowheads)* extends beyond the right atrium to form a part of the right heart border. No double density is seen within the heart, and the left main bronchus *(black arrows)* is not elevated.

protrudes posteriorly from the back of the heart. The right border of the left atrium is then silhouetted where it abuts the right lung, and its contour is seen within the cardiac silhouette (Fig. 53-3A). This pattern is not apparent with lesser degrees of left atrial enlargement. Conversely, when the right atrium also enlarges, as is common in long-standing mitral valve disease, it forms a continuous curve on the posterior cardiac border with the enlarged left atrium. Thus, the double contour is not seen with mild left atrial enlargement or in severe cases of mitral valve disease. Furthermore, because the radiologic technique used for chest films is chosen to provide optimal images of the lungs, the enlarged heart is underexposed and the double contour may be hidden within its opaque silhouette. For the same reason, the position of the left main bronchus often cannot be clearly visualized through the mediastinal shadow.

A more sensitive sign of left atrial enlargement in the frontal projection is dilation of the left atrial appendage. The appendage extends anteriorly from the atrium along the left side of the heart, below the level of the pulmonary artery (see Fig. 53-1B). It forms the part of the left heart border between the pulmonary artery segment and the left ventricular segment. Normally, the border of the appendage is flat or slightly concave. Any convexity is abnormal and usually indicates left atrial enlargement.

Left Ventricle

The shape of the dilated left ventricle depends to a large extent on the underlying cause. When it is due to insufficiency of the aortic or mitral valve, the ventricle elongates and its apex is displaced downward, to the left, and posteriorly (Fig. 53-4). When the dilation is due to coronary artery disease or primary myocardial disease, the ventricle tends to assume a more globular shape. In the lateral view, the downward extension of the enlarged left ventricle covers more of the vena cava shadow than normal, and the crossing point of their posterior borders occurs nearer to the diaphragm than normal. Unfortunately, the usefulness of this sign is limited because of the distortion produced by even slight rotation of the patient from the true lateral position.

Enlargement of the left ventricle produces a smoothly curved dilation of the lower portion of the cardiac silhouette. A localized bulge in this contour most often represents a ventricular aneurysm (Fig. 53-5). Dilation of the left ventricle is usually associated with elevated left ventricular end-diastolic pressure. The latter increases resistance to left atrial emptying and can result in dilation of the atrium. Therefore, left atrial enlargement in the presence of a large left ventricle does not necessarily indicate the presence of mitral valve disease.

Right Atrium

Enlargement of only the right chambers of the heart is seen in severe pulmonary hypertension without coexisting left heart failure, in bacterial endocarditis of the tricuspid or pulmonic valve (or both), and in carcinoid syndrome. Dilation of the right atrium causes an accentuation and outward bowing of the curvature on the lower half of the right cardiac contour in the frontal view. With greater degrees of dilation, the cardiac silhouette enlarges to the right (Fig. 53-6).

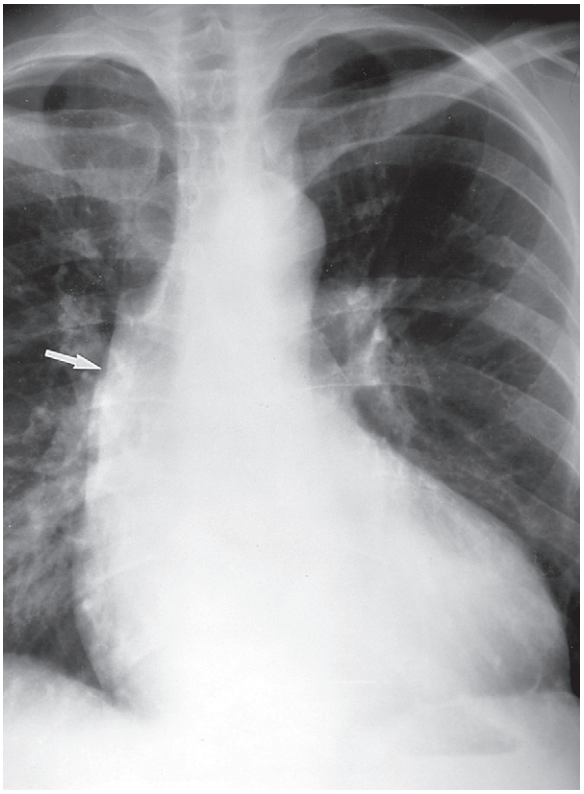

FIGURE 53-4. Left ventricular dilation, aortic insufficiency. The apex of the heart is displaced downward and to the left. The ascending aorta *(arrow)* is diffusely dilated. The pulmonary vasculature is normal.

Right Ventricle

The right ventricle is the most difficult of the four cardiac chambers to evaluate on chest films. Except for a small area in the subpulmonic region, the chamber is not border-forming in the frontal projection. Even moderate right ventricular enlargement may produce no abnormality in this view other than some prominence of the main pulmonary artery. As right ventricular size increases, the transverse diameter of the heart enlarges to the left, and the cardiac apex becomes blunted and elevated (see Fig. 53-6). Enlargement of either or both ventricles displaces the apex of the heart to the left. It is not often possible to distinguish between biventricular enlargement and dilation of one or the other ventricle.

As the right ventricle enlarges, its area of contact with the sternum increases and tends to obliterate the retrosternal clear space in the lateral view. This sign is nonspecific inasmuch as it also depends on the shape of the chest and the size of the left ventricle, as well as the size of the right ventricle.

CALCIFICATION

Most calcifications involving the heart occur in cardiac structures as a result of inflammatory or necrotic processes (or both) or degenerative disease. Because the calcific deposits have greater radiodensity than cardiac tissues, they can often be seen within the cardiac silhouette.

The aortic and mitral valves abut each other, both inserting on the central fibrous tendon of the heart. On a frontal chest film, the two valves lie next to each other in the midportion of the cardiac silhouette, to the left of the spine (Fig. 53-7A), the aortic valve being slightly higher. It is often difficult to determine which valve is calcified in this view. They can be separated by fluoroscopy because the aortic valve tends to move in a vertical direction as the heart beats, whereas the motion of the mitral valve approximates the horizontal. This distinction can also be made accurately from the lateral chest film. If a line is drawn from the left main bronchus, seen as a dark circular shadow over the lower end of the trachea, to the anterior costophrenic angle, the mitral valve lies below the line and the aortic valve above it (Fig. 53-7B).

In the United States, calcification of only the aortic valve is most likely to represent degenerative disease of the cusps (a process in older patients akin to coronary artery calcification) or deterioration of a congenitally bicuspid valve (Chapter 75). In developing countries, calcification of the aortic or mitral valves, or both, is usually a late sequela of rheumatic fever. Calcification of the mitral annulus, which is seen in patients older than 70 years and is about four times more frequent in women than in men, is only rarely of clinical significance. The pattern of calcification is characteristic and should not be confused with that of the mitral valve. Calcium is deposited mainly between the base of the posterior mitral leaflet and the posterior wall of the left ventricle. It is seen as a broad, curvilinear band of calcium in a C shape, open superiorly and to the right on the frontal film and anteriorly on the lateral. In severe cases, the calcific deposits may also extend across the base of the anterior mitral leaflet and then form an O encircling the mitral orifice.

Calcification of the myocardium almost always indicates a previous transmural infarction and, frequently, a ventricular aneurysm. The calcified scar appears as a fine, curvilinear density, most commonly on the anterolateral

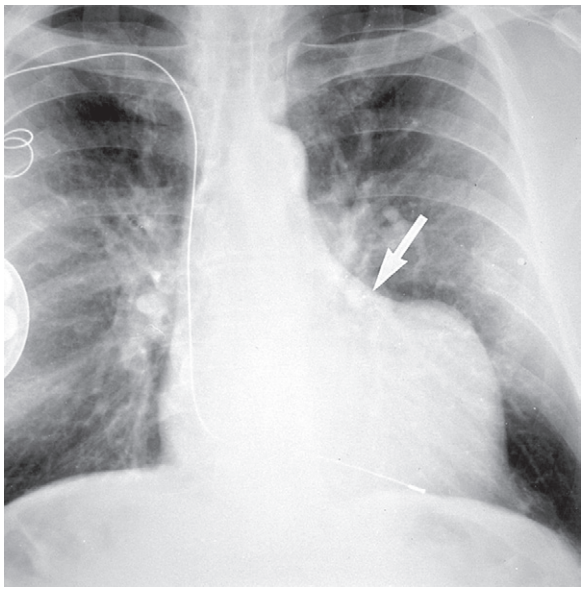

FIGURE 53-5. Left ventricular aneurysm. A bulge on the lower portion of the left cardiac border, formed by the anterolateral wall of the left ventricle, represents a ventricular aneurysm. The patient had suffered a myocardial infarction 1 year previously. The left atrial appendage segment *(arrow)* is normal. A transvenous pacemaker has been inserted through the right subclavian vein. The electrode tip is situated in the apex of the right ventricle.

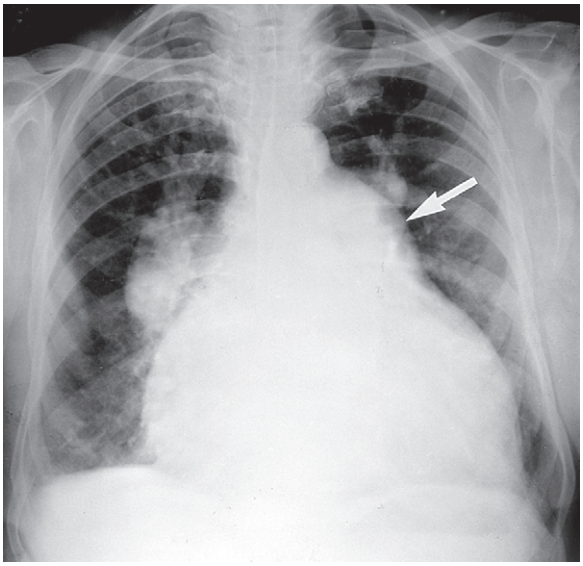

FIGURE 53-6. Right ventricular enlargement seen in a patient with resistive pulmonary hypertension secondary to an atrial septal defect. The main pulmonary artery *(arrow)* and the right pulmonary artery are markedly dilated. The left pulmonary artery was also dilated but is hidden by the heart in this view. The sudden "cutoff" of the vascular shadows just beyond the hila is characteristic of resistive pulmonary hypertension. Enlargement of the right ventricle is elevating the cardiac apex and displacing it to the left. Accentuation of the curvature of the lower right cardiac border and enlargement of the cardiac silhouette to the right are caused by dilation of the right atrium.

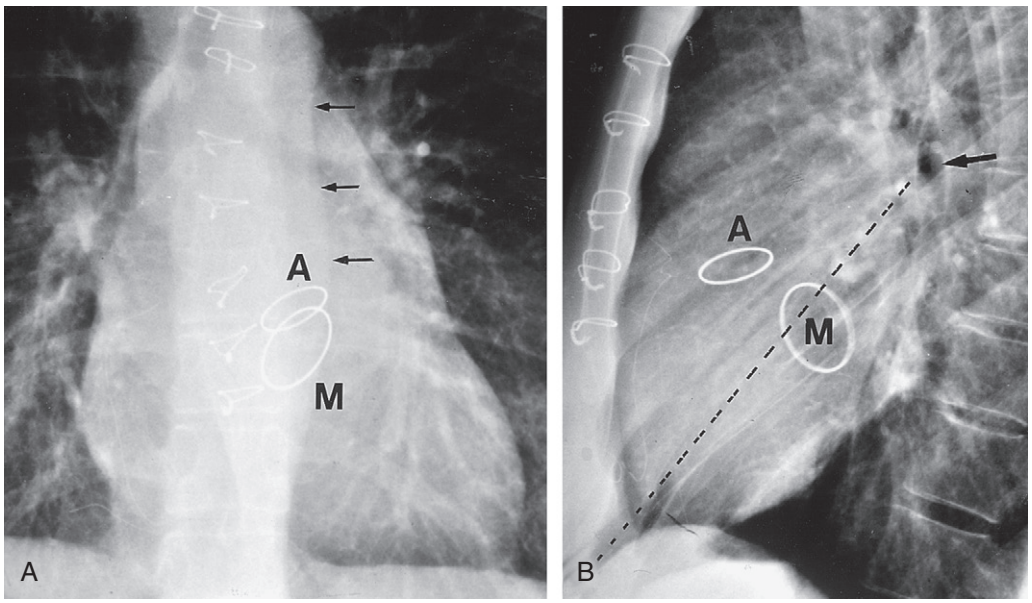

FIGURE 53-7. Location of the mitral and aortic valves. Both the mitral (M) and aortic (A) valves have been replaced by porcine heterografts. The circular stents indicate the location and tilt of each valve. **A,** Frontal projection. The two valves are normally in contact with each other, and it is difficult to separate them in the frontal projection. Furthermore, on a routinely exposed film, calcific deposits are not easily seen because of the overlapping shadows of the descending aorta *(arrows)* and the spine. **B,** Lateral projection. The valves can be differentiated on the lateral view by drawing a line from the left main bronchus *(arrow)* to the anterior costophrenic sulcus. The aortic valve lies above this line and the mitral valve below it.

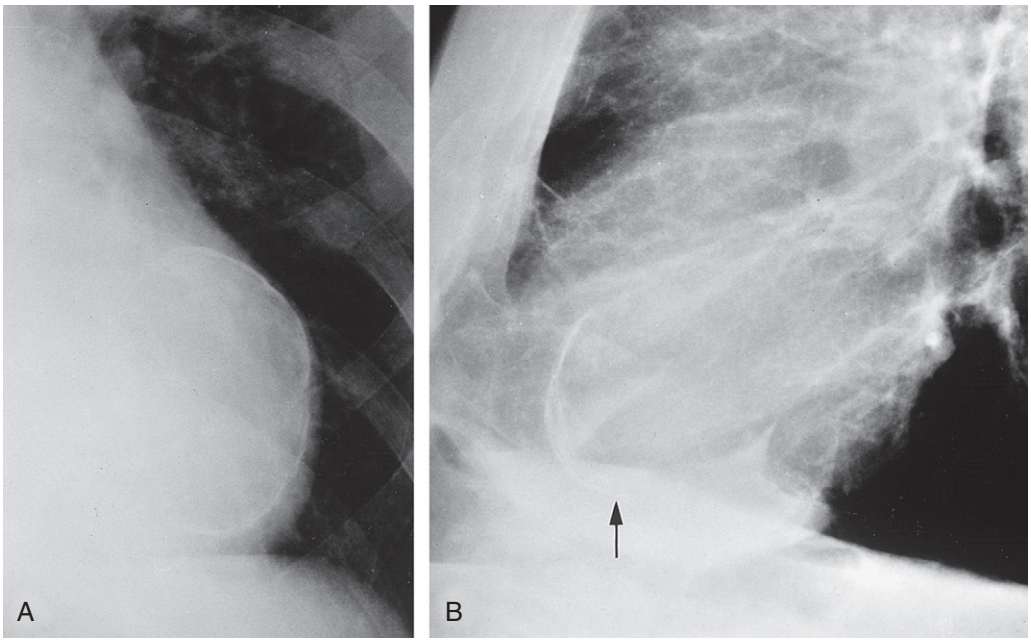

FIGURE 53-8. Calcified myocardial infarctions. **A,** Patient 1: frontal projection of an anterolateral left ventricular aneurysm. The fine calcific line outlines an anterolateral aneurysm of the left ventricle. The calcific deposit is much finer than that seen with pericardial calcification. The patient had suffered a myocardial infarction several years earlier. **B,** Patient 2: lateral projection of a septal infarction. The curvilinear calcific deposit is within the scarred lower portion of the ventricular septum. The infarction extended posteriorly along the base of the heart to involve the diaphragmatic wall of the left ventricle *(arrow)*.

aspect of the heart, best seen on the frontal view (Fig. 53-8A), or in the lower portion of the interventricular septum, best seen on the lateral projection (see Fig. 53-8B). Calcification of the pericardium is usually coarser and tends to occur in clumps. Often, pericardial calcium is distributed primarily over the interventricular sulcus and the atrioventricular grooves, but when extensive, the deposits may coalesce and completely surround the heart (Fig. 53-9).

Calcification of the coronary arteries is a specific sign of complicated atheromatous plaques in which previous hemorrhage has occurred. Not uncommonly, this type of plaque, which may not produce significant narrowing of the vessel, is the site of acute thrombosis and vascular occlusion leading to myocardial infarction. There is no correlation between the sites of calcium deposition and the sites of greatest stenosis, but a strong correlation exists between the extent of coronary artery calcification and the extent of coronary arterial sclerosis.

Calcification of the coronary arteries is difficult to visualize on chest films because the deposits are thin and their shadows are blurred by the motion of the heart. Ultrafast computed tomography (CT) scanning using either electron beam or helical CT is very sensitive and accurate for detecting and quantifying the extent of coronary arterial calcification (Chapter 56). However, the data accumulated to date have not clearly shown a correlation between the volume of coronary calcification and the clinical status of the patient. Although high calcium scores indicate extensive atherosclerosis, acute events, such as myocardial infarction or sudden death, can occur in patients with little or no calcification of their coronary arteries.

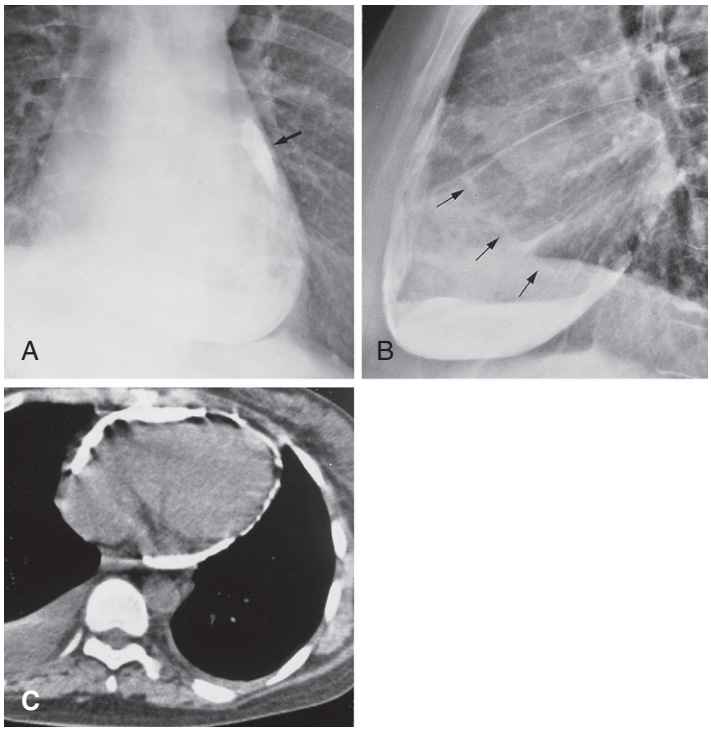

FIGURE 53-9. Calcific pericarditis. **A,** Frontal projection. A large, thick, calcific plaque *(arrow)* lies just below the level of the left upper lobe bronchus. More caudad, the calcific deposits become confluent and cover the diaphragmatic surface of the heart. **B,** The dense calcific peel around the cardiac apex and the diaphragmatic aspect of the heart is better seen. Linear calcific deposits *(arrows)* lie within the atrioventricular sulcus. **C,** Nonenhanced computed tomography shows the irregular, thick, calcific peel almost encircling the heart.

PERICARDIAL EFFUSION

The pericardium completely invests the heart, except for a small area on its posterior surface between the entrances of the pulmonary veins and the superior and inferior venae cavae. When fluid accumulates in the pericardium, the sac distends smoothly to enlarge the cardiac silhouette and give it a flask-shaped appearance. A similar shape can occur with a dilated, failing heart.

The two conditions are readily differentiated by the appearance of the pulmonary hila on a frontal chest film. The pericardial sac extends onto the great vessels and up to or slightly above the level of the bifurcation of the main pulmonary artery (Fig. 53-10). As the sac distends with fluid, it tends to overlap and obscure the hilar vessels. Conversely, when the heart fails, the vessels become congested and appear more prominent than normal (Fig. 53-11).

Posterior displacement of the epicardial fat line is a second reliable sign of pericardial effusion (Chapter 77). In adults, fat is often insinuated between the myocardium and the visceral pericardium (the epicardium) and is sometimes seen on the lateral projection as a curvilinear, radiolucent shadow paralleling the anterior aspect of the heart. The anterior surface of the parietal pericardium borders the retrosternal mediastinal fat. The soft tissue density between these two fat lines therefore represents the pericardium, the epicardium, and the fluid between them. When normal, this stripe is no more than 2 to 4 mm thick. As fluid accumulates in the pericardial sac, the epicardial fat line is displaced posteriorly and the pericardial stripe widens (Fig. 53-12).

PULMONARY VASCULATURE

Almost all of the linear shadows in the lung represent large and medium-sized pulmonary arteries and veins. The terminal branches of the vessels are too small to be visualized as individual structures. The same is true of the interstitial tissues that support the alveoli and form the primary and secondary

interlobular septa. However, summation of the minimal densities cast by these structures gives the pulmonary fields an overall grayish cast. The large vessels are seen because their soft tissue density is contrasted against the surrounding air-containing alveoli.

The caliber of the pulmonary vessels reflects the volume of blood flowing through the lungs. When this volume is diminished because of a right-to-left shunt, venous blood bypasses the pulmonary vessels, and, as a result, these vessels are smaller in caliber and the lungs appear abnormally radiolucent. Increased size and prominence of the pulmonary vessels, both central and peripheral, usually indicate an increase in pulmonary blood flow secondary to a left-to-right shunt (Fig. 53-13A). The vessels in the lower as well as the upper lung fields are dilated. Although pulmonary arteries and veins also become abnormally prominent in patients with heart failure, the vessels are not usually sharply outlined, and additional signs of pulmonary venous hypertension or interstitial edema are present (Chapter 58).

The vessels to the lower lobes carry about 60 to 70% of the pulmonary blood flow and are normally of greater caliber than the vessels to the upper lobes. As pulmonary venous pressure increases, the lower lobe vessels become constricted, so more blood is distributed to the upper lobes, which makes their vessels more prominent. This redistribution of the pulmonary vasculature is a reliable sign of pulmonary venous hypertension (see Fig. 53-13B), although it is often difficult to recognize unless quite marked. With a sufficient further increase in venous pressure, pulmonary edema develops.

Pulmonary Edema

Normally, extravascular circulation of fluid in the lungs from the capillaries through the interstitium and back to the blood stream by way of the lymphatics is constant. When pulmonary venous pressure increases, more and more fluid leaks from the capillary bed, the capacity of the lymphatics to remove the fluid is exceeded, and the interstitium becomes waterlogged. Because the interlobular septa in the outer portions of the lung bases are oriented parallel to the x-ray beam on an erect film, when thickened, they are seen as parallel, short horizontal lines extending to the pleural surfaces (Kerley B lines). Kerley A lines also represent thickened interlobular septa, but they are longer and are seen in the upper lung fields. These lines are within the depth of the lung and do not usually reach the pleural surface. Most of the other septa, even when thickened, are too fine to be identified as individual structures. However, the summation pattern creates random "noise" on the film that obscures the shadows of the pulmonary vessels (Fig. 53-14). A ground-glass appearance of the lung fields without identifiable vascular markings within them is characteristic of interstitial pulmonary edema (Chapter 58). The patient is generally severely tachypneic at this stage, but rales may not be

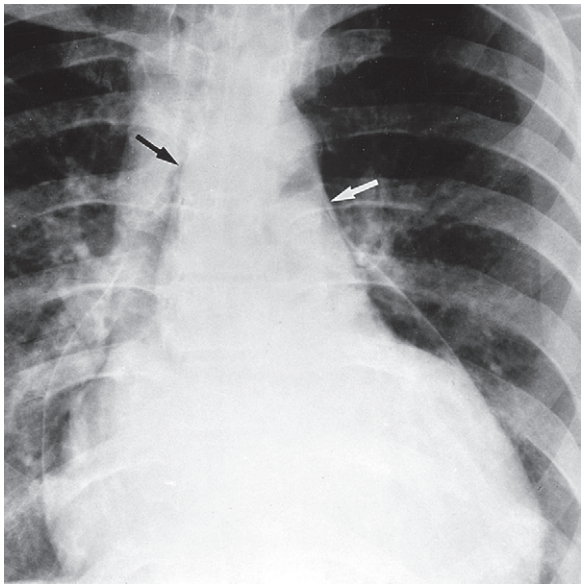

FIGURE 53-10. Superior pericardial reflection with effusion after a tap. During pericardiocentesis, some of the fluid withdrawn was replaced with air. The normal pericardium is now outlined between the intrapericardial air and the air in the lungs and is seen as a thin linear shadow along the outer border of the cardiac silhouette. The film is made in the erect position, and the air has risen to the highest point of the pericardial cavity *(arrows),* above the level of the pulmonary hila and almost reaching the aortic arch.

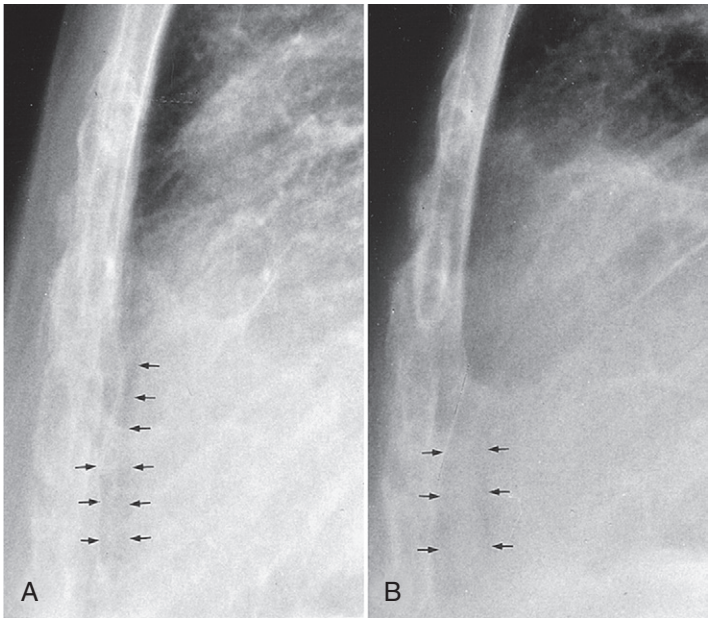

FIGURE 53-12. Pericardial effusion with posterior displacement of the epicardial fat line. The *two lines of arrows* point to the substernal fat and the subepicardial fat layers. **A,** Normal. The fine line of soft tissue density between the fat layers represents the epicardium, the pericardium, and the fluid between them. **B,** Same patient with a pericardial effusion. The epicardial fat line is displaced posteriorly, and the pericardial stripe is abnormally wide.

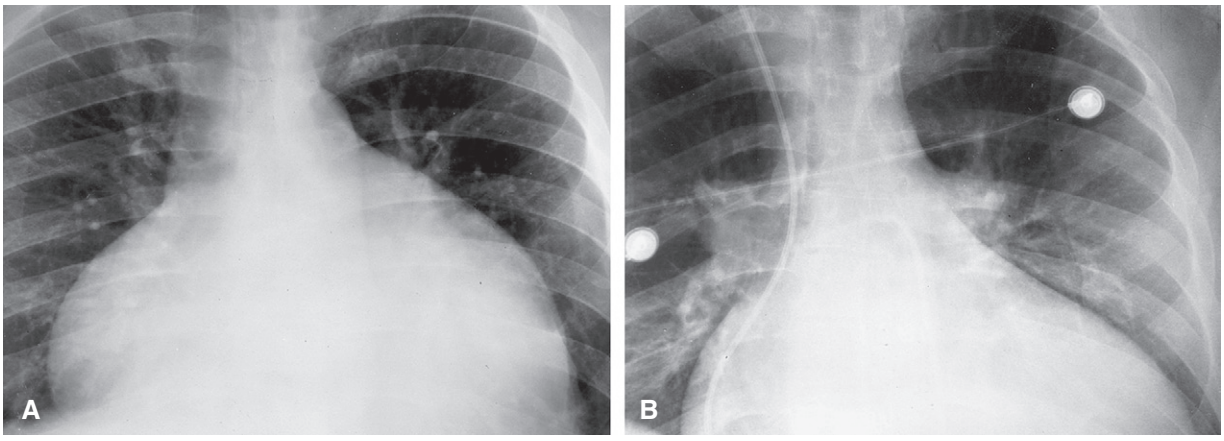

FIGURE 53-11. Hilum overlay sign. A, Pericardial effusion. The heart is diffusely enlarged. Its silhouette extends outward and is obscuring the hilar shadows in each lung. **B,** Dilated cardiomyopathy. The heart is diffusely enlarged. The failing left ventricle has caused congestion of the hilar vessels, and they are more prominent than normal.

present. Interstitial edema also causes thickening of the bronchial walls and peribronchial connective tissue, best seen when they are projected on end. This "peribronchial cuffing" is best visualized in the superior portion of the pulmonary hila, where the anterior segmental bronchus of the upper lobes is viewed on end. When the interstitium can no longer accommodate the excess fluid, it spills into the alveoli (Fig. 53-15). At this point, as air bubbles through the fluid, the typical auscultatory findings of pulmonary edema appear.

Pulmonary Arterial Hypertension

Resistive pulmonary hypertension can result from a left-to-right intracardiac shunt, mitral valve disease, or extracardiac disease, such as repeated episodes of pulmonary embolization (Chapter 98). The central pulmonary arteries become grossly dilated. Instead of gradually tapering as they bifurcate, a sudden, sharp change in the caliber of the vessels is noted. The size and number of the smaller arterial branches decrease, and they take on the appearance of a "pruned tree" (see Fig. 53-6). With severe pulmonary hypertension, the right heart chambers may dilate. The radiographic appearance of pulmonary hypertension is relatively specific but not sensitive, and clinically significant pulmonary hypertension can be present with a normal-appearing pulmonary vascular bed.

The Cardiac Veins

Almost all coronary blood returns to the heart through the coronary sinus. The orifice of the coronary sinus is in the base of the right atrium just above the entrance of the inferior vena cava and behind the tricuspid valve. Three major cardiac veins drain through the coronary sinus. The great cardiac vein runs upward in the anterior portion of the interventricular sulcus to the atrioventricular sulcus, where it turns to the right (Fig. 53-16) and is joined by the posterior vein of the left ventricle. The drainage area of the latter vein roughly corresponds to the distribution of the circumflex coronary artery. These combined veins continue in the atrioventricular sulcus around the back of the heart as the coronary sinus, which empties into the right atrium. The third vein, the middle cardiac vein, courses in the posterior portion of the interventricular sulcus together with the posterior descending branch of the right coronary artery and joins the coronary sinus near its entrance into the right atrium.

Although percutaneous ventricular pacing initially was limited to the right ventricle, an electrode can now be safely placed percutaneously into a cardiac vein. If a venous catheter in the right atrium curves anteriorly in the lateral view, it extends into the right ventricle. However, if it curves posteriorly, it almost certainly enters the coronary sinus. In the frontal projection, the courses of a catheter in the coronary sinus and a catheter in the right ventricle are almost identical, although one is located on the back of the heart and the

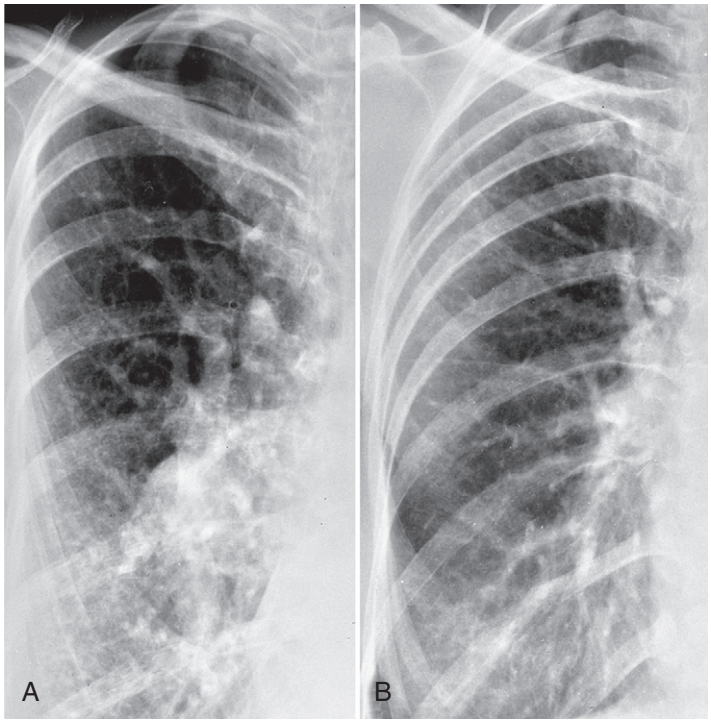

FIGURE 53-13. Pulmonary vasculature. A, Atrial septal defect, left-to-right shunt. All pulmonary vessels, to the lower lobes as well as to the upper lobes, are dilated, which is indicative of increased blood flow. **B,** Mitral stenosis, pulmonary venous hypertension with redistribution of the pulmonary vasculature. The lower lobe vessels are constricted and the upper vessels, which now carry more blood, are of greater caliber.

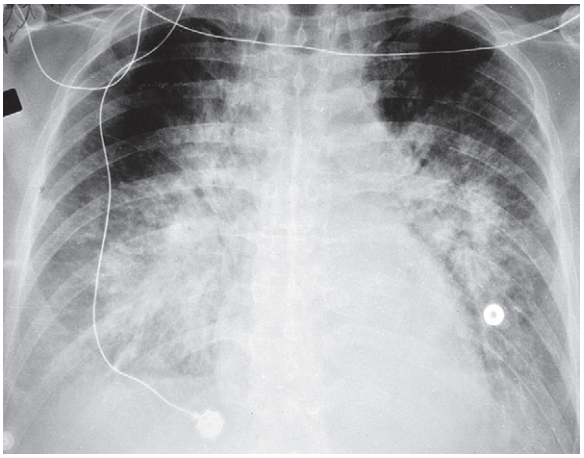

FIGURE 53-15. Alveolar pulmonary edema, acute myocardial infarction. Patchy areas of consolidation can be seen in the perihilar regions of both lungs. Dilation of the heart after a massive myocardial infarction may not be seen for the first 24 to 48 hours.

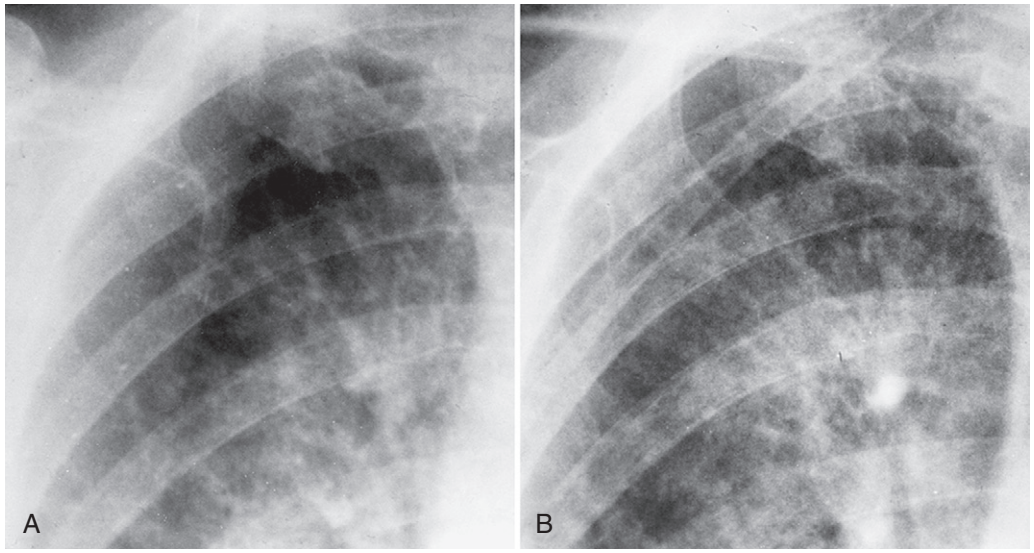

FIGURE 53-14. Interstitial pulmonary edema. A, Close-up of the right upper lobe; portable film of a patient with an acute myocardial infarction. The pulmonary vessels are well outlined. **B,** Two days later, the patient became tachypneic. No abnormal auscultatory findings were present in the lungs. Radiographically, the lung fields are noisy, with numerous random shadows obscuring the outline of the pulmonary vessels. The appearance and the time sequence of the changes are characteristic of interstitial pulmonary edema.

other is more anterior in the right ventricular cavity. Because the coronary sinus courses directly above the attachment of the posterior leaflet of the mitral valve (Fig. 53-17), it can be used for the percutaneous placement of a device to constrict the mitral orifice, thereby producing the same effect as a surgical mitral annuloplasty (Chapter 75).

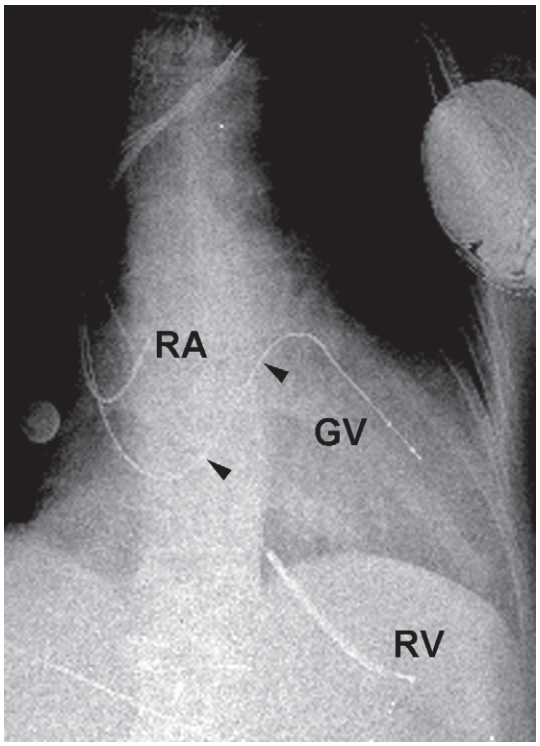

FIGURE 53-16. Biventricular pacemaker, frontal view. The left ventricular lead extends retrograde through the coronary sinus into the great cardiac vein (GV), running in the anterior interventricular sulcus. The section of the coronary sinus between the *arrowheads* is the portion adjacent to the insertion of the posterior mitral leaflet. RA = right atrial lead; RV = right ventricular lead.

THE HEART AND PORTABLE FILMS

Not uncommonly, cardiac patients are too ill to be transported, so their studies must be performed with portable equipment at the bedside. The resulting images are less sharp and have less contrast, and the degree of magnification of the intrathoracic structures can vary considerably. Portable images can also vary from one to the next because the positioning of the patient and the film and the distance between the patient and the x-ray tube are all dependent, in practice, on visual estimation of the technologist. Despite these differences, the same principles of interpretation also apply to portable images, with a few important caveats:

1. The size of the heart, especially relative to the width of the chest, is magnified on a portable image, so the cardiothoracic ratio is not particularly useful. Furthermore, small changes in cardiac size from one portable film to the next have little significance because of the likelihood of variations in technique. Conversely, if the heart appears smaller on a portable than on an erect film, the decrease in size is almost certainly real.
2. If the technologist tilts the x-ray tube even slightly toward the patient's head, the heart will appear even larger and will be projected over the hilar vessels, thereby mimicking the "hilum overlay" sign of a pericardial effusion. Thus, this sign is not useful with portable images.
3. Free pleural fluid collects in the dependent portions of the pleural space, at first in the costophrenic sulci. With fixed equipment in which the x-ray beam is horizontal, the lateral costophrenic sulci are usually obliterated by the fluid, and the upper level of the fluid can be seen. When the patient is supine or slightly tilted, the fluid flows out of the costophrenic sulci and layers along the posterior chest wall. The x-ray beam, although still at right angles to the patient, is no longer horizontal, so the fluid, now viewed en face, appears as an ill-defined haze.
4. Portable films are frequently used to confirm the position of various inserted devices. Without any sense of depth, however, all that is really known is that the object is "projected over" the region of interest; it could actually be some distance away.

ELECTROCARDIOGRAPHY

LEONARD GANZ

Electrocardiography, which has changed surprisingly little since it was initially introduced by Einthoven in the early 1900s, allows recording of myocardial activation from several vantage points on the body's surface, thereby permitting analysis of electrical activation in different myocardial regions. Surface electrocardiography may be supplemented with intracardiac recordings, which are particularly helpful in the diagnosis and management of cardiac arrhythmias (Chapter 62).

NORMAL FUNCTION AND ELECTROCARDIOGRAM

Normal Cardiac Activation

Electrical activation of the heart depends on the spread of a depolarizing wave front from pacemaker cells through cardiac muscle, as well as specialized conducting tissues (Fig. 54-1). Under normal circumstances, cells in the sinoatrial (SA) nodal complex in the high lateral aspect of the right atrium have the highest spontaneous depolarization rate and are therefore the dominant cardiac pacemaker (Chapter 61). This electrical wave front spreads throughout the right and left atria; specialized conducting tracts called *Bachmann's* bundle speed the depolarizing wave front to the left atrium. Electrical atrial activation triggers atrial muscular contraction, which pumps blood through the tricuspid and mitral valves into the right and left ventricles. Normally, the atrioventricular (AV) node, where conduction delay is physiologic, serves as the only electrical connection linking the atria and ventricles; the AV valve rings are insulated. The depolarizing wave front exits the AV node into the bundle of His, a specialized conducting tissue capable of rapid conduction. The bundle of His bifurcates into right and left bundle branches; the left bundle branch divides into the left anterior and left posterior fascicles. The bundle branches, as well as their more distal ramifications of specialized conducting tissue, are called the *Purkinje system*. From these specialized conducting tissues, the depolarizing wave front enters into and then moves through ventricular muscle. As in the atria, ventricular electrical activation begets muscular contraction, which pumps blood through the semilunar valves into the pulmonary and systemic circulations. After electrical activation, or depolarization, a period of electrical recovery, or repolarization, is necessary before repeated activation.

At the cellular level, a complex orchestration of ion channels opening and closing determines the membrane potential throughout this process. The flow of ions into and out of the myocardial cells inscribes an action potential, which reflects depolarization and repolarization, as well as spontaneous depolarization of pacemaker cells (Chapter 61).

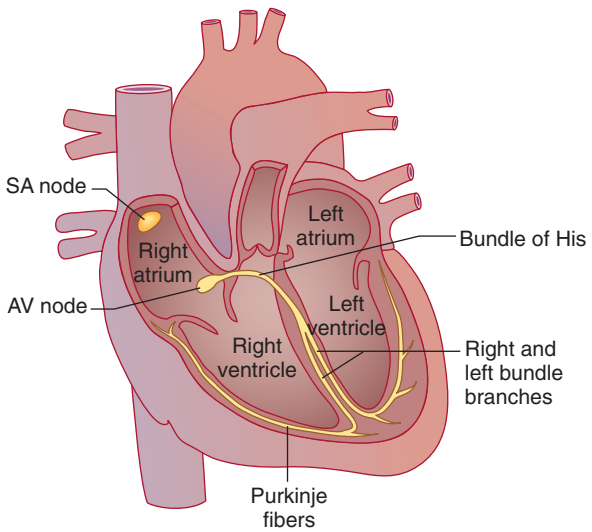

FIGURE 54-1. Cardiac conduction system. The normal conducting system consists of pacemaker cells in the sinoatrial (SA) nodal complex, specialized intra-atrial conducting tracts (including Bachmann's bundle), the atrioventricular (AV) node, the His-Purkinje system, and working atrial and ventricular myocardium.

The Electrocardiographic Waves

Labeled alphabetically, beginning with the P wave, the basic waves of the electrocardiogram (ECG) correspond to these electrical events (Fig. 54-2). The P wave represents atrial muscular depolarization; in severe hyperkalemia, atrial electrical activation may be unaccompanied by atrial muscular activation, and no P wave is inscribed. The QRS complex represents ventricular muscular depolarization; because of the disparity between ventricular and atrial muscle mass, the QRS complex is typically much larger in voltage amplitude than the P wave is. Recorded from multiple vantage points, the QRS complex harbors tremendous information about the structure and function of ventricular tissue. Under normal circumstances, the PR interval, which is the segment from the onset of the P wave to the onset of the QRS complex, represents the delay between atrial and ventricular depolarization. The ST segment and T wave (and occasionally the U wave) reflect ventricular repolarization, a process of electrical recovery that must take place before the ventricle can be depolarized again. Atrial muscle also requires repolarization before the next depolarizing wave front. Because ventricular mass far exceeds atrial muscular mass, the low-amplitude atrial repolarization wave is buried underneath the QRS complex and is rarely manifested on the ECG.

Electrocardiography Standards

A standard ECG is recorded on paper with 1-mm ("small" boxes) as well as 5-mm ("big" boxes) gridlines. Voltage amplitude is measured on the vertical axis (typically 10 mm equaling 1 mV) and time on the horizontal axis. Because the usual ECG recording speed is 25 mm per second, each 1-mm gridline ("small" box) represents 0.04 second (40 msec), and each 5-mm gridline ("big" box) equals 0.2 second (200 msec). These parameters are the usual calibration or standardization. Necessary for proper interpretation, the standardization parameters are typically printed on the ECG.

A standard ECG is recorded over a 10-second period, although a rhythm or monitor strip can be recorded for substantially longer if necessary. Multiple leads are typically recorded simultaneously from the top to the bottom of the page. The usual groupings of leads include I, II, and III; aVR, aVL, and aVF; V_1, V_2, and V_3; and V_4, V_5, and V_6 (see later). Each group of leads is recorded for 2.5 seconds. A single lead (or multilead) rhythm strip is recorded below for the entire 10 seconds. Thus, as the ECG is scanned from left to right, one sees 10 seconds of cardiac activity, with each complex recorded simultaneously in multiple leads.

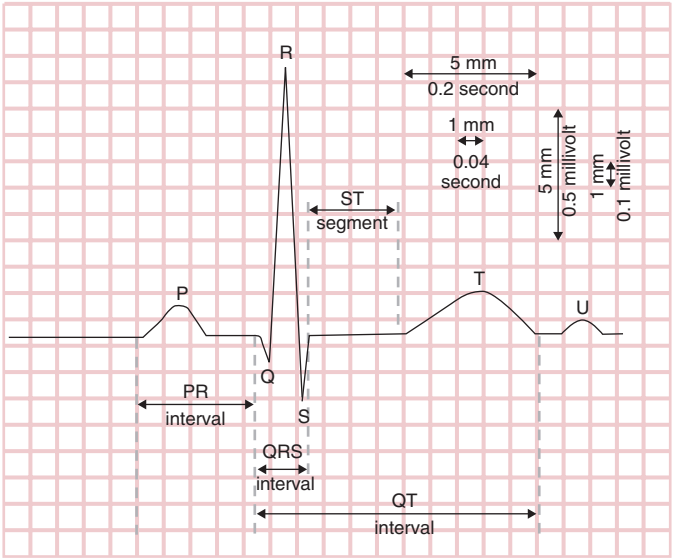

FIGURE 54-2. Inscription of a normal electrocardiogram (ECG). Sinoatrial nodal depolarization is not visible on the surface ECG; the P wave corresponds to atrial mechanical contraction. The PR interval denotes conduction through the atrial muscle, atrioventricular node, and His-Purkinje system. The QRS complex reflects ventricular muscle depolarization. The ST segment and T wave correspond to ventricular repolarization. Atrial repolarization also occurs, but the signal is of low amplitude and buried underneath the QRS complex. Note the gridlines. On the horizontal axis, each 1-mm line ("small" box) denotes 0.04 second (40 msec); a "big" box denotes 0.2 second (200 msec). On the vertical axis, 1 mm ("small" box) corresponds to 0.1 mV; 10 mm (two "big" boxes) therefore denotes 1 mV.

TABLE 54-1 NORMAL ELECTROCARDIOGRAPHIC INTERVALS

Heart rate	50-100 beats per minute
P wave duration	<0.12 sec (120 msec)
PR interval	0.09 (90 msec) to 0.20 sec (200 msec)
QRS duration	0.075 (75 msec) to 0.11 sec (110 msec)
QTc	0.45 sec (450 msec) males, 0.46 sec (460 msec) females
QRS axis	−30 to + 90 degrees

Normal Intervals

Each of the various ECG waves and intervals has normal ranges, defined from large numbers of electrocardiographic recordings in (presumably) healthy subjects (Table 54-1; see Fig. 54-2).

The RR interval (or PP interval), which is the measurement from R wave to R wave (or P wave to P wave), allows calculation of the heart rate. Because there are 60,000 msec in a minute, the heart rate (HR) in beats per minute can be easily calculated from the RR or PP interval in milliseconds:

$$HR = \frac{60{,}000}{RR}$$

Although traditionally the normal resting heart rate has been defined as 60 to 100 beats per minute, a range of 50 to 90 at rest may actually be more reflective of normal physiology. When the heart rate is grossly irregular, as in atrial fibrillation (Chapter 64), the RR interval can be averaged over a number of cardiac cycles to estimate the heart rate. Because a standard ECG records 10 seconds in time, the heart rate (beats per minute) will equal the number of QRS complexes recorded on a standard ECG multiplied by 6.

P Wave Duration

The P wave duration, from the beginning to the end of a P wave, is typically less than 0.12 second (120 msec, three small boxes) in length. A broader P wave reflects an intra-atrial or interatrial conduction delay, or both. Abnormalities in P wave amplitude, morphology, and axis may reflect atrial enlargement.

PR Interval

The PR interval, which is measured from the onset of the P wave to the onset of the QRS complex, is normally between 0.09 and 0.2 second (90 to 200 msec). One-to-one AV conduction with a PR interval greater than 0.2 second has traditionally been called first-degree AV block, but *delayed AV conduction* may be a more appropriate term. Conduction through the atrial tissue, the AV node, and the His-Purkinje system contributes to the PR interval. When the PR interval is prolonged, delay is usually present in the AV node, although other sites of delay are possible. Prolongation of the PR interval is associated with an increased risk of atrial fibrillation, need for a pacemaker, and higher overall mortality. A short PR interval may reflect ventricular preexcitation (Wolff-Parkinson-White syndrome), a junctional rhythm, or other conditions.

QRS Complex

The QRS complex, which reflects ventricular muscular electrical activation, carries important information in patients with coronary artery disease, cardiomyopathy, metabolic abnormalities, and other conditions. Capital letters (Q, R, S) denote large-amplitude deflections (≥5 mm or 0.5 mV), whereas lowercase letters (q, r, s) signify low-amplitude deflections (<5 mm or 0.5 mV). Q, q, S, and s waves are negative excursions from the isoelectric baseline, whereas R and r waves are positive deflections. Q and q waves are initial negative deflections, and S and s waves are negative deflections that follow a positive deflection (R or r wave); a QS complex is an entirely negative deflection. An R′ or r′ wave refers to a second positive deflection after an S (or s) wave. The duration of the QRS complex reflects the time required for ventricular depolarization. Ventricular activation usually requires at least 0.075 second (75 msec, nearly two small boxes). There is some debate regarding the upper limit of the normal range for QRS duration; a recent consensus document specified 0.11 second (110 msec, nearly three small boxes). If the QRS duration is prolonged, an intraventricular or interventricular conduction delay (IVCD), or both, is present. Particular patterns of IVCD have been termed *bundle branch block* (see later).

QT Interval

The QT interval, which reflects ventricular repolarization, is measured from the onset of the QRS complex to the end of the T wave. Accurate assessment of the repolarization interval is important inasmuch as patients with prolonged repolarization, either congenital or acquired, may be at risk for torsades de pointes ventricular tachycardia (Chapter 65). The QT interval must be corrected to allow comparison of this interval at differing heart rates. Bazett's formula defines a corrected QT interval (QTc):

$$QTc = \frac{QT}{\sqrt{RR}}$$

Bazett's formula works reasonably well at heart rates in the normal range but overcorrects at high rates and undercorrects at low rates. Although more complex regression formulas have been developed to correct the QT interval at different heart rates, none has achieved widespread clinical use. Irregular rhythms (notably atrial fibrillation) complicate calculation of the QTc. Calculating multiple QTc intervals and then taking the average is reasonable; alternatively, the QTc after the longest RR interval can be considered the "worst-case scenario" of the repolarization interval.

The presence of a U wave complicates measurement of the QT (and therefore QTc) interval because it is not always clear where the T wave ends and whether the U wave should be included in a QTU interval. If the isoelectric baseline is reached between the T and U waves, the U wave is not generally included in the QT interval. If the T wave "merges" into the U wave without reaching the isoelectric baseline, the U wave is included in the QT (or QTU) interval. Short QTc intervals are unusual. The QTc in a given patient may vary somewhat over the course of the day and tends to be slightly longer in young and middle-aged women than in men. The upper limit of a normal QTc is somewhat debatable, but a cutoff of 0.45 second (450 msec) in men and 0.46 second (460 msec) in women was proposed recently in a consensus document. The QT interval is quite sensitive to drug effects, as well as to electrolyte and metabolic derangements.

Electrocardiographic Leads

Recording a single ECG lead allows calculation of the heart rate and, frequently, accurate diagnosis of the heart rhythm. When the ECG is recorded from multiple skin leads simultaneously, the direction (or vector) of activation as the electrical wave front moves through the heart can be inferred. Although a number of different lead systems are possible (and some are actually used in research settings), standard electrocardiography uses 12 leads from 12 vantage points, recorded with 10 electrodes, 6 on the chest wall and 4 on the limbs. In reality, only three limb leads are actually used to generate recordings; the right leg lead serves as an electrical ground. The limb leads, called the *frontal plane leads,* generate bipolar and augmented unipolar lead recordings. The chest or precordial electrodes record unipolar recordings. Bipolar leads record the potential difference between two skin electrodes. In unipolar recordings, the lead of interest, the exploring electrode, is compared with a reference electrode. By convention, a positive deflection is recorded if the electrical wave front is moving toward the positive electrode in a bipolar pair or toward the exploring electrode in a unipolar lead.

The bipolar limb leads measure potential differences between electrodes on pairs of limb electrodes. Lead I compares the right arm (negative) and left arm (positive), lead II the right arm (negative) and left leg (positive), and lead III the left arm (negative) and left leg (positive) (Fig. 54-3). Because the direction of both atrial and ventricular depolarization is away from the right arm and toward the left arm, a positive P wave and QRS complex are generally recorded in lead I. Similarly, the P wave and QRS complexes are positive in leads II and III in normal SA to AV conduction because atrial and ventricular activation proceeds in a craniocaudal direction. The bipolar limb leads closely resemble Einthoven's original string galvanometer recordings.

Leads aVR, aVL, and aVF are augmented unipolar leads in which the potential in each limb is compared with a reference electrode. For lead aVR, the potential of the right arm is compared with a reference composed of the left arm and left leg electrodes. Lead aVL compares the left arm potential with a reference combining the right arm and left leg; aVF compares the left leg with a right and left arm reference. Because atrial and ventricular activation normally moves from right to left and in a craniocaudal direction, the P wave and QRS complex are negative in lead aVR but positive in lead aVF. In lead aVL, P waves and QRS complexes are generally upright, although an rS complex may be recorded, particularly in young patients.

The precordial electrodes are positioned at specific points on the chest wall (Fig. 54-4A). These unipolar leads compare electrical potential between the

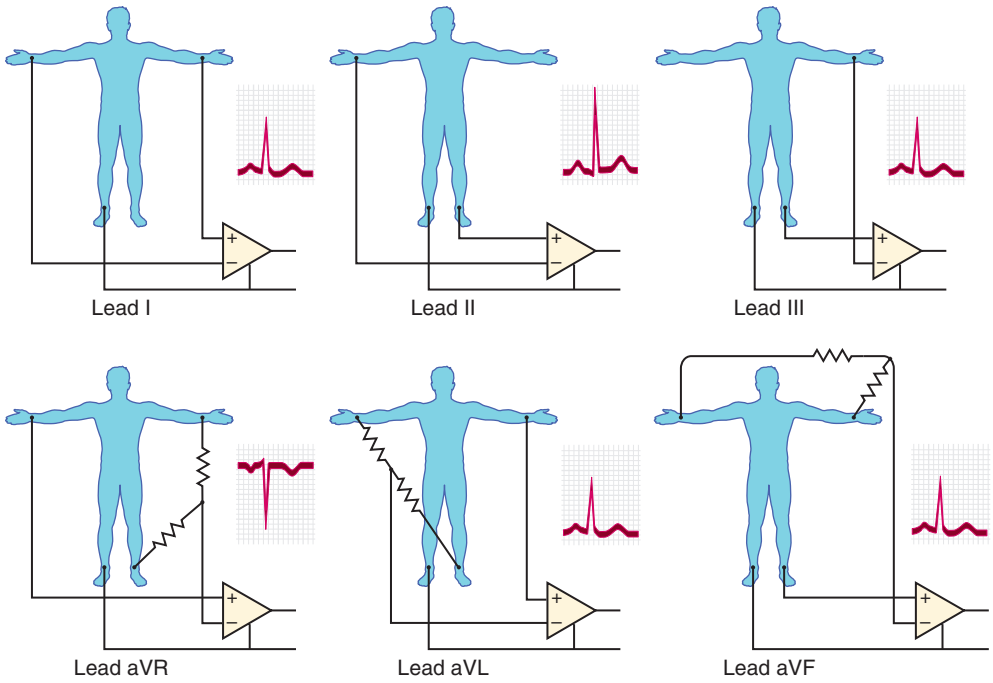

FIGURE 54-3. Normal cardiac activation as manifested in the limb leads. Under normal circumstances, P waves and QRS complex are typically upright in leads I, II, III, and aVF and inverted in aVR. In lead aVL, P waves are usually upright, although QRS complexes may be either upright or inverted. The right leg electrode serves to ground the system.

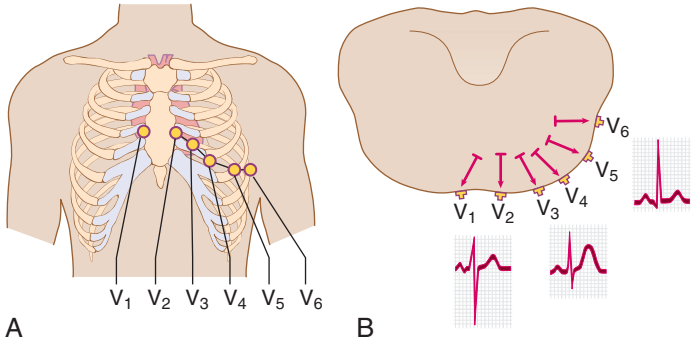

FIGURE 54-4. Precordial leads. A, Positioning of the precordial leads on the chest wall. **B,** Normal cardiac activation as manifested in the precordial leads. Note the small r wave and deep S wave in lead V_1, the transition at around V_3 or V_4, and the "septal" q wave and large R wave in lead V_6.

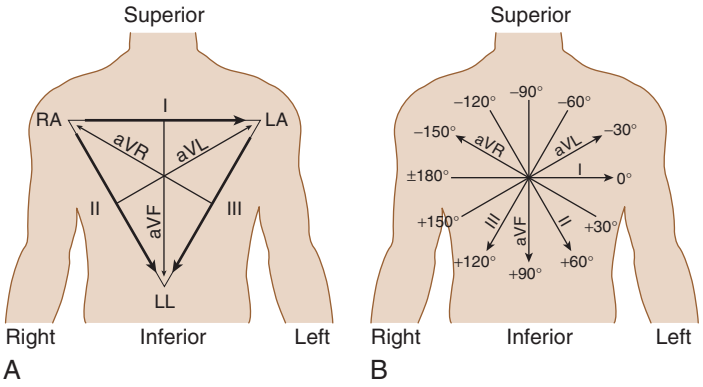

FIGURE 54-5. Axis of electrical activation. A, Vectors for the limb leads (LL) in the frontal plane. **B,** Hexaxial reference for determining the frontal plane axis. Note that the vectors for leads I, II, and III are in the same direction as in **A,** but now, like the augmented limb leads, these standard limb lead vectors have been moved so that they emanate from the center of the figure. LA = left atrium; RA = right atrium.

chest electrode and a reference electrode called the *Wilson central terminal.* The Wilson central terminal combines the right arm, left arm, and left leg potentials through 5000-Ω resistors. The six precordial leads define atrial and ventricular activation with respect to a somewhat transverse plane through the chest wall (see Fig. 54-4B). In this plane, atrial activation moves from right to left. Initial ventricular activation involving the septum is directed from left to right; left ventricular depolarization, which dominates right ventricular depolarization because of the differential in myocardial mass, then moves apically and laterally. In lead V_1, to the right of the sternum, the P wave is biphasic (reflecting right and then left atrial activation). Initial ventricular activation of the septum inscribes an r wave, whereas subsequent activation away from lead V_1 records a dominant S wave. In lead V_6, the P wave is positive. Initial septal depolarization inscribes a tiny "septal" q wave (usually ≤0.02 second), and subsequent ventricular depolarization records a dominant R wave.

Right-sided chest leads should be recorded when right ventricular abnormalities are suspected. RV_3, the mirror image of lead V_3, is routinely recorded in pediatric patients because of the possibility of congenital heart disease. In adults, ST elevation in lead RV_3 is quite specific for acute right ventricular infarction in those being evaluated for an acute inferior wall myocardial infarction.

Axis

An axis of electrical activation can be defined in the frontal plane axis by combining the bipolar and augmented unipolar limb leads (Fig. 54-5A). By convention, the axis parallel to lead I, toward the left arm, is called 0 degrees. A frontal plane axis between −30 and +90 degrees is normal; other axes are abnormal (Fig. 54-6). Right axis deviation is a normal variant in children and

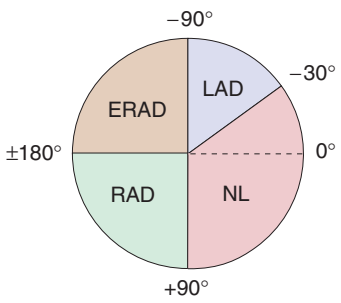

FIGURE 54-6. Chart of frontal plane axes. Normal (NL) = −30 to +90 degrees; left axis deviation (LAD) = −30 to −90 degrees (moderate, −30 to −45 degrees; marked, −45 to −90 degrees); right axis deviation (RAD) = +90 to +180 degrees (moderate, +90 to +120 degrees; marked, +120 to +180 degrees); extreme right axis deviation (ERAD) = −90 to ±180 degrees. Mild RAD is considered normal in children, adolescents, and young adults.

adolescents. The frontal plane axis can be estimated by identifying the limb lead in which the QRS complex is most nearly isoelectric (similar positive and negative deflections); the axis is perpendicular to this lead (see Fig. 54-5B). Because two lines pointing 180 degrees apart can be drawn perpendicular to any given line, examination of the other limb leads defines the direction in which the axis points. If the QRS complex is positive in any given limb lead, the axis will be oriented toward that limb lead, not away from it. Alternatively, the axis is in the normal range if the QRS complexes are primarily positive in both leads I and II.

An axis per se is not defined in the precordial leads. Rather, because the typical progression from leads V_1 to V_6 is from a predominantly negative to a positive QRS complex, the transition point is usually defined as the point at which the amplitude of the R wave begins to exceed the amplitude of the S wave.

APPROACH TO INTERPRETING THE ELECTROCARDIOGRAM

A stepwise approach to interpreting the ECG ensures that no features of the tracing will be overlooked (Table 54-2).

Normal Electrocardiogram

Figure 54-7 is an example of a normal ECG. Sinus rhythm occurs at about 78 beats per minute, with minor variations in the RR intervals (sinus arrhythmia). The PR interval, QRS duration, and QTc are all normal. The QRS complex is most nearly isoelectric in lead aVL, so the QRS axis will be perpendicular to lead aVL. Because aVL points to −30 degrees, the QRS axis must be approximately −120 or +60 degrees. Because the QRS complex is positive in leads I and II (large R waves), the QRS axis is approximately +60 degrees. The transition in the precordial leads is between leads V_3 and V_4. The P wave is biphasic in lead V_1 and then positive in the other precordial leads. "Septal" q waves, reflecting not lateral infarction but rather normal early septal depolarization, are present in leads V_5 and V_6. Tiny q waves, a normal variant, are seen in the inferior leads.

TABLE 54-2 STEPWISE APPROACH TO INTERPRETING THE ELECTROCARDIOGRAM

Estimate the heart rate
Define the heart rhythm (regular vs. irregular; relationship of P waves to QRS complexes)
Measure intervals (PR, QRS duration, QT)
Calculate/estimate QTc
Estimate QRS axis
Examine P wave morphology, duration, and axis
Examine QRS progression and transition in precordial leads
Examine QRS complexes in regional groupings (septal leads [V_1,V_2], anterior leads [V_2, V_3, V_4], lateral leads [I, aVL, V_5, V_6], inferior and posterior leads [II, III, aVF, V_1, V_2])
Examine ST segments in regional groupings
Examine T waves in regional groupings

Abnormal Electrocardiogram

Electrocardiography in patients with coronary artery disease is reviewed in Chapters 71 to 73 and arrhythmias in Chapters 61 to 66.

Conduction Abnormalities and Axis Deviation

Abnormalities of the specialized conduction system (i.e., His-Purkinje system) reflect slow or absent conduction in a particular structure, but fascicular blocks do not prolong QRS duration beyond 120 msec (Table 54-3). An IVCD is generally defined as a QRS duration of more than 0.11 second (110 msec). When the QRS has a duration of at least 0.12 second (120 msec), it often has the configuration of a specific bundle branch block (Fig. 54-8).

Chamber Hypertrophy

A number of criteria for defining left ventricular hypertrophy (LVH; Fig. 54-9) and right ventricular hypertrophy (RVH) have been proposed. All of the LVH criteria suffer from poor sensitivity (ranging from 30 to 50%), although the specificity is good (85 to 95%). The Cornell voltage criterion, developed with an echocardiographic standard for LVH, simply adds the S wave amplitude in V_3 and the R wave amplitude in aVL; a total greater than

TABLE 54-3 FASCICULAR AND BUNDLE BRANCH BLOCKS

	QRS DURATION	AXIS	QRS MORPHOLOGY	ST SEGMENTS AND T WAVES
LAFB	<0.12 sec (120 msec)	−45 to −90 degrees	Delayed transition across the precordium qR aVL	Normal
LPFB	<0.12 sec (120 msec)	+90 to +180 degrees	Delayed transition across the precordium rS in I, aVL qR in III, aVF	Normal
RBBB	≥0.12 sec (120 msec)	Normal	rsr′, rsR′, rSR′ in V_1 (and usually V_2); wide S in V_6 and I	Discordant in V_1 and V_2
RBBB with LAFB	≥0.12 sec (120 msec)	−45 to 90 degrees	rsr′, rsR′, rSR′ in V_1 (and usually V_2); wide S in V_6 and I	Discordant in V_1 and V_2
RBBB with LPFB	≥0.12 sec (120 msec)	+ 90 to +180 degrees	rsr′, rsR′, rSR′ in V_1 (and usually V_2); wide S in V_6 and I	Discordant in V_1 and V_2
LBBB	≥0.12 sec (120 msec)	Variable	rS or QS in V_1 (S wide and notched); wide notched R without q in V_5, V_6, and I Wide notched R with or without small q in aVL	Discordant in V_1 to V_6

LAD = left axis deviation; LAFB = left anterior fascicular block; LBBB = left bundle branch block; LPFB = left posterior fascicular block; RBBB = right bundle branch block.

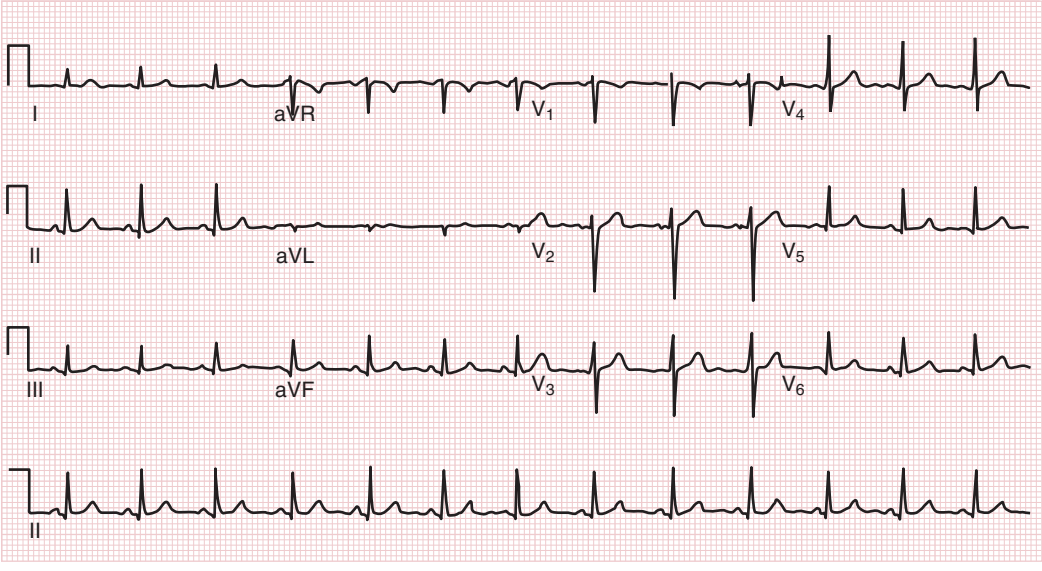

FIGURE 54-7. Normal electrocardiogram. The heart rate is approximately 78 beats per minute, with minor irregularity. Sinus arrhythmia is present. The axis is approximately +60 degrees. The PR, QRS, and QT intervals are approximately 140, 90, and 360 msec, respectively. P wave morphology, duration, and axis are normal. The transition is between leads V_3 and V_4. No abnormal Q waves are present. ST segments are isoelectric, and T waves are concordant with QRS complexes.

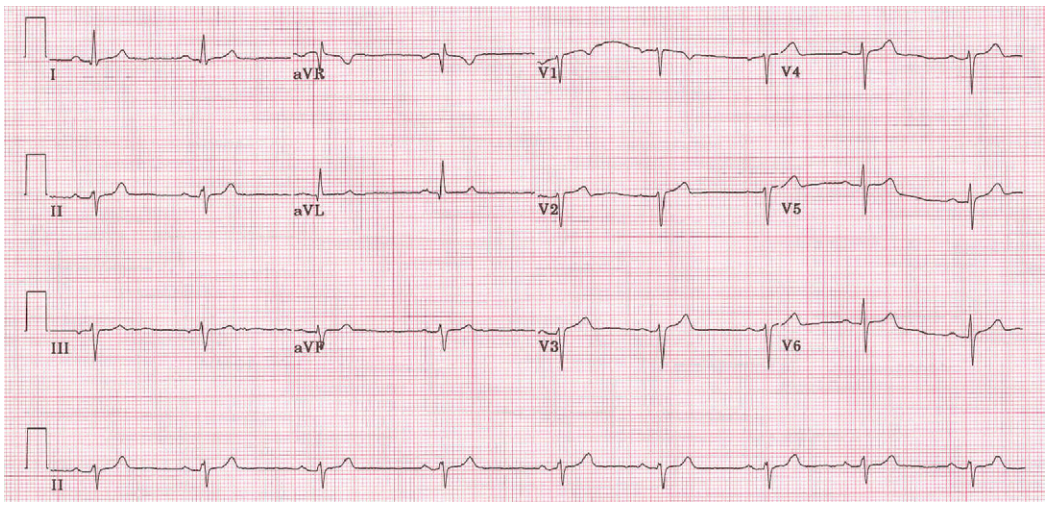
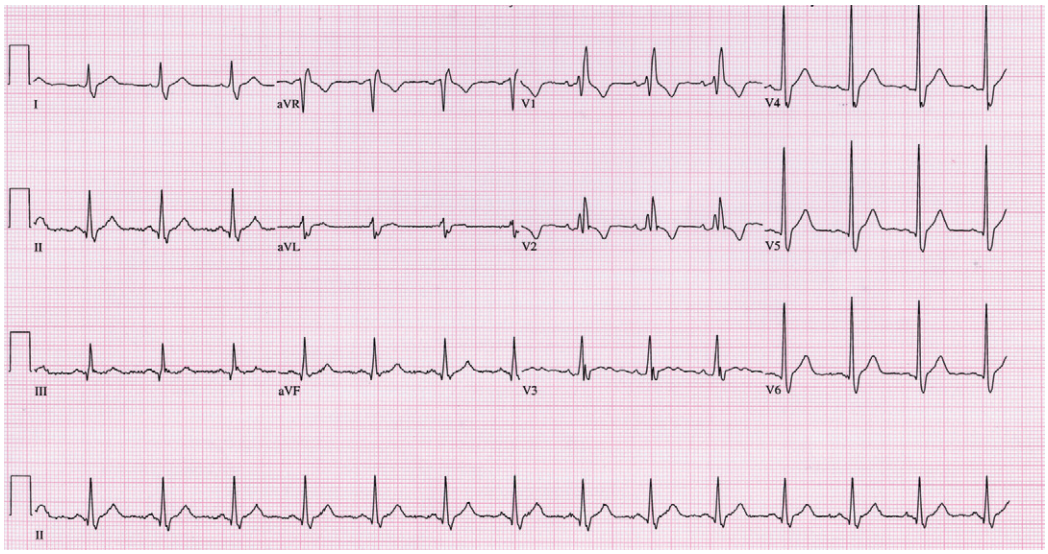
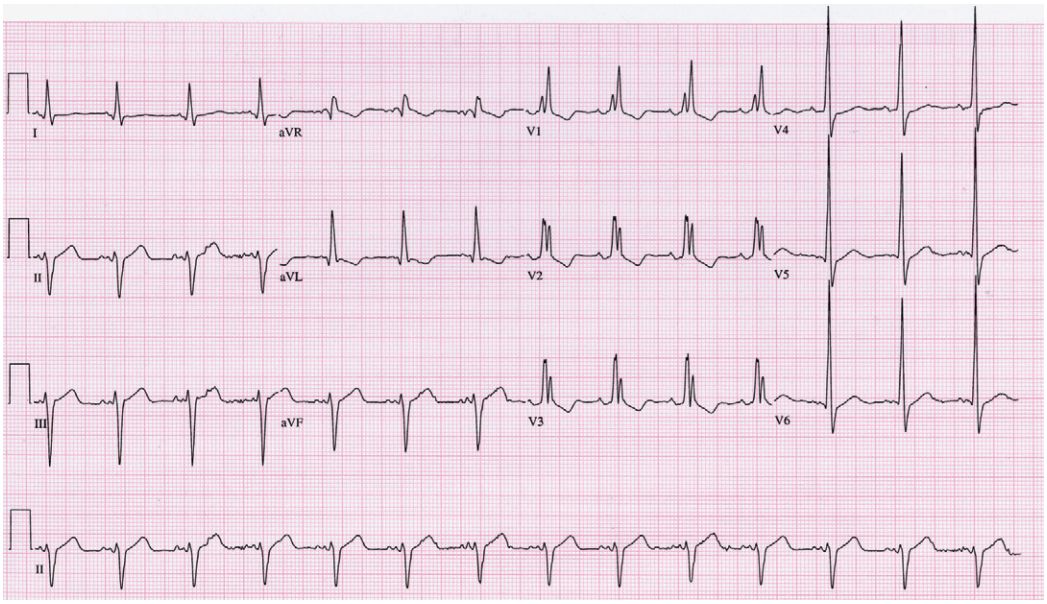


A

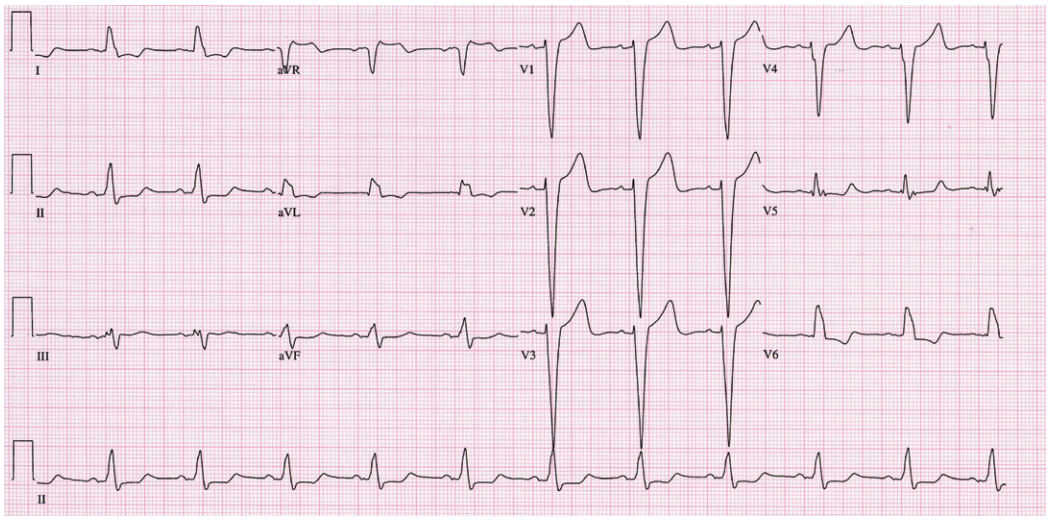


B



C

FIGURE 54-8. Fascicular and bundle branch blocks. A, Left anterior fascicular block (LAFB). Left axis deviation is present; the axis is approximately –60 degrees. The QRS duration is normal, and there is a delay in R wave progression across the precordial leads (late transition). Small q waves are present in leads I and aVL and small r waves in leads II, III, and aVF. **B,** Right bundle branch block (RBBB). The QRS is widened, with an rsR′ pattern in lead V_1 and a wide terminal S wave in lead V_6. ST segments are downsloping, and T waves are discordant with the QRS complex in the right precordial leads. The axis is normal, and signs of normal septal activation (q waves in lead V_6) are present. **C,** RBBB and LAFB. In addition to features diagnostic of RBBB, an axis of –60 degrees is present.



D

FIGURE 54-8, cont'd. **D,** Left bundle branch block (LBBB). The QRS is widened, with a broad, notched complex in leads I, aVL, and the left precordial leads. Small r waves and broad, deep S waves are present in the right precordial leads. With LBBB, the axis is usually normal or deviated to the left. ST segments and T waves are discordant with the QRS complex throughout the precordium.

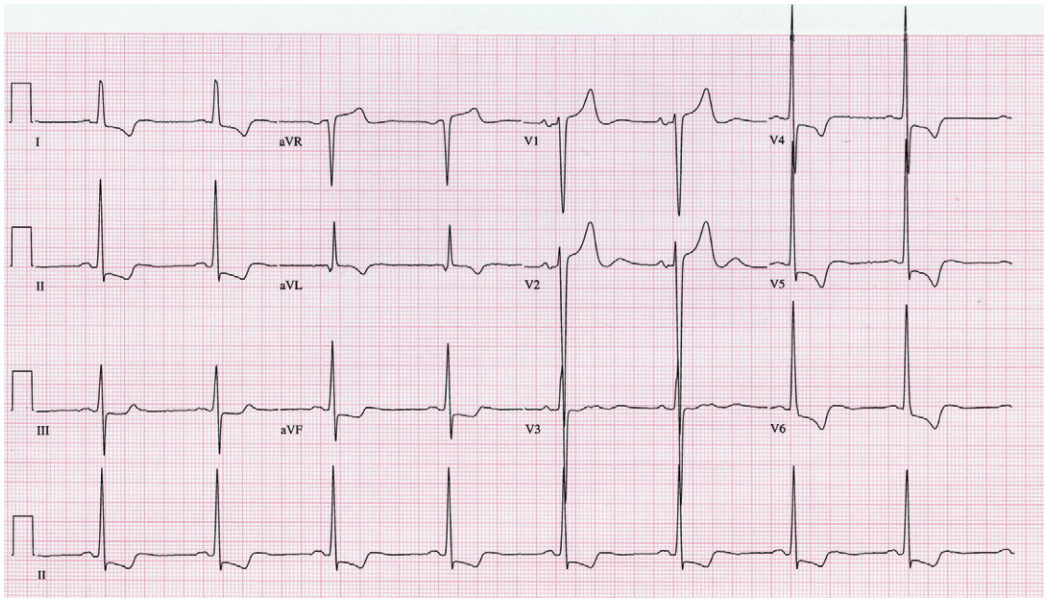


FIGURE 54-9. Left ventricular hypertrophy. Note the striking S wave amplitude in the right precordial leads and R wave amplitude in the left precordial leads. Repolarization abnormalities are present in the left precordial leads, as well as the limb leads. The S wave amplitude in V_3 (2.4 mV) plus the R wave amplitude in aVL (1.0 mV) total 3.4 mV, easily satisfying the Cornell voltage criteria in this 76-year-old hypertensive man. Sinus bradycardia (50 beats per minute) is present as well.

2.0 mV in women and 2.8 mV in men implies LVH. In many clinical settings, the Cornell criterion has replaced the more complicated Romhilt-Estes criteria, which assign points for QRS amplitude, repolarization abnormalities ("strain" pattern), left axis deviation, and other electrocardiographic features. RVH is much less common than LVH. Electrocardiographic criteria for diagnosing RVH have even lower sensitivity (10 to 20%) than for LVH, although the specificity is similar. The Sokolow-Lyon criterion for RVH adds the R wave amplitude in lead V_1 to the S wave amplitude in lead V_5 or V_6; a sum of 1.05 mV or greater implies RVH.

Low QRS Voltage

Low QRS voltage is defined as limb lead voltage less than 5 mm (0.5 mV) in all leads or precordial voltage less than 10 mm (1 mV) in all leads. The differential diagnosis is broad (Table 54-4), and no underlying explanation is defined in many cases.

TABLE 54-4 CAUSES OF LOW QRS VOLTAGE

Normal variant
Pericardial effusion
Myocardial infarction
Cardiomyopathy
Hypothyroidism
Obesity
Sarcoidosis
Amyloidosis
Chronic obstructive pulmonary disease
Anasarca

Repolarization Abnormalities

Abnormalities of the ST segment or T waves, or both, are extremely common (Table 54-5). Electrolyte and other metabolic abnormalities, drug effects (particularly digoxin and antiarrhythmic drugs), and secondary effects caused by LVH or bundle branch block are all commonly encountered. Early repolarization, a relatively common pattern of ST segment elevation previously thought to be benign, occurs more commonly in patients with idiopathic ventricular fibrillation than in controls and has also been associated with an increased risk of cardiac mortality.

Pitfalls of Automated Computerized Electrocardiographic Readings

Automatic interpretations of ECG tracings are generally quite accurate for calculating heart rates, axes, and intervals. Interpretation of the significance of repolarization abnormalities may be less accurate, and diagnosis of rhythms

TABLE 54-5 CAUSES OF REPOLARIZATION ABNORMALITIES

Athlete's heart
Early repolarization (normal variant)
Myocardial ischemia/injury
Pericarditis
Electrolyte abnormalities
Left ventricular hypertrophy
Intraventricular conduction delay/bundle branch block
Drug effects (digitalis, antiarrhythmic drugs, etc.)
Long QT syndrome
Stroke/neurologic catastrophe

is the striking weakness of these programs. Thus, over-reading of the computerized interpretation by the physician and comparison with previous tracings, when available, remain mandatory.

ECHOCARDIOGRAPHY

CATHERINE M. OTTO

Echocardiography is the clinical standard for evaluating cardiac function in patients with known or suspected heart disease. This chapter reviews the basic principles of echocardiography, echocardiographic approaches, quantitative measurements, and clinical indications. The specific use of echocardiography and additional images is shown in other chapters on individual types of cardiovascular diseases.

ECHOCARDIOGRAPHIC IMAGING

Principles

Echocardiography is based on the use of a piezoelectric crystal that converts electrical to mechanical energy, and vice versa, allowing both transmission and reception of an ultrasound signal. The frequency of ultrasound waves used for diagnostic imaging ranges from 2 to 10 MHz, with lower frequencies having greater tissue penetration and higher frequencies providing better image resolution. Each transducer consists of a complex array of piezoelectric crystals arranged to provide images in a fanlike two-dimensional image, with the narrow top of this sector scan indicating the origin of the ultrasound signal. Transducers also include an acoustic lens that determines the focal depth, height, and width of the ultrasound beam.

Images are generated based on the reflection of ultrasound from acoustic interfaces: for example, the boundary between the blood in the left ventricle and the myocardium. The time delay between transmission and reception is used to determine the depth of origin of the ultrasound reflection. The depths of the reflected signals from multiple ultrasound beams are combined to generate a two-dimensional image. The speed of signal analysis allows acquisition of two-dimensional ultrasound images at frame rates of 30 to 60 per second. Ultrasound is strongly attenuated by bone and air, so echocardiography relies on acoustic "windows" where, for example, ultrasound can penetrate to the heart while avoiding the ribs and lungs. With transthoracic imaging, the patient is positioned to bring the cardiac structures close to the chest wall, usually in a left lateral decubitus position, and the transducer is placed on the chest, using gel to provide acoustic coupling between the transducer and skin. Standard acoustic windows are parasternal, apical, subcostal, and suprasternal notch.

Standard Image Planes

From the parasternal window, the image plane is adjusted manually by an experienced physician or sonographer to provide long and short axis views. Standard cardiac imaging planes are aligned relative to the axis of the heart, with the long axis defined as the plane that intersects the cardiac apex and the middle of the aortic valve. Short axis views are perpendicular to this long axis, with standard image planes at the cardiac base (aortic valve level), mitral valve, and midventricular levels. From the apical window, the transducer is rotated to provide three views oriented 60 degrees from each other, producing a four-chamber, a two-chamber, and a long axis view (Fig. 55-1).

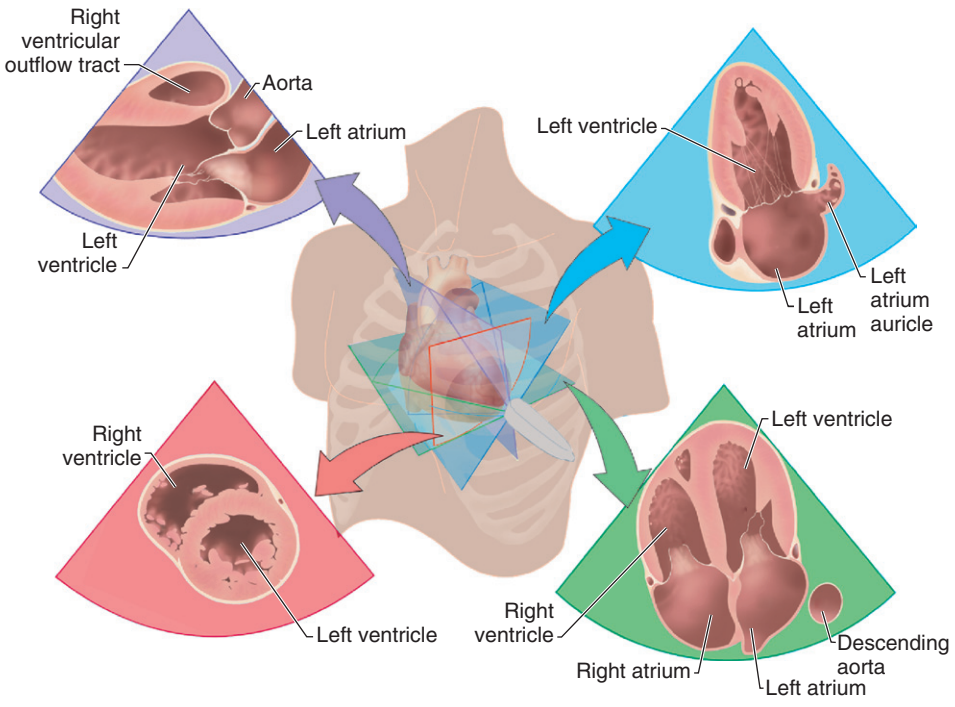

FIGURE 55-1. The four basic image planes used in transthoracic echocardiography. A parasternal transducer position or "window" is used to obtain long and short axis views. The long axis view *(purple outline)* extends from the left ventricular apex through the aortic valve plane. The short axis view is perpendicular to the long axis view, resulting in a circular view of the left ventricle *(red outline)*. The transducer is placed at the ventricular apex to obtain the two-chamber *(blue outline)* and four-chamber *(green outline)* views, each of which is about a 60-degree rotation from the long axis view and perpendicular to the short axis view. The four-chamber view includes both ventricles and both atria. The two-chamber view includes the left ventricle and left atrium; sometimes the atrial appendage is visualized. (From Otto CM. *Textbook of Clinical Echocardiography,* 4th ed. Philadelphia: Elsevier Saunders; 2009:32, Fig. 2-1.)

Measurements

Echocardiography provides accurate cardiac dimensions from two-dimensional or two-dimensional-guided linear depth (M-mode) recordings. The measurements typically provided include left ventricular (LV) end-diastolic and end-systolic internal dimensions, LV wall thickness, left atrial anterior-posterior diameter, and aortic sinus dimension. LV ejection fraction (EF) is determined by visual estimation or, more accurately, by tracing the endocardial borders at end diastole and end systole in two orthogonal views. End-diastolic and end-systolic ventricular volumes (EDV and ESV, respectively) are calculated using validated formulas, and the EF is determined as follows:

$$EF = (EDV - ESV)/EDV$$

Limitations

Echocardiography is a very accurate, widely available, and widely used imaging approach. However, the quality of images can be suboptimal because of poor tissue penetration (e.g., excessive adipose tissue, position of the lungs relative to the heart), although images are nondiagnostic in fewer than 5% of patients with current instrumentation. Reflections are stronger when the interface is perpendicular to the ultrasound beam, so structures that are parallel to the beam may not be visible, an artifact called *echo dropout*. This potential limitation may be avoided by the use of appropriate imaging planes and the integration of data from multiple transducer positions. Ultrasound artifacts, such as beam width, shadowing, and reverberations, may be misinterpreted by inexperienced observers.

DOPPLER ECHOCARDIOGRAPHY

Principles

Ultrasound energy that is backscattered from moving red blood cells is shifted to a higher frequency when the blood is moving toward the transducer and a lower frequency when it is moving away. The magnitude of this Doppler shift corresponds to the velocity of blood flow.

Modalities

Pulsed Doppler allows measurement of flow velocity at a specific intracardiac site with the advantages of high spatial and temporal resolution. However, spatial localization is based on intermittent sampling at a time interval corresponding to the depth of interest. The sampling frequency, which is depth dependent, limits the maximum detectable velocity because of a phenomenon called *signal aliasing*. Normal intracardiac flow velocities are about 1 m/second, which can usually be recorded with pulsed Doppler.

Continuous-wave Doppler allows measurement of high velocities along the entire length of the ultrasound beam, but the origin of the high-velocity signal must be inferred from the two-dimensional images. With stenotic and regurgitant valves, blood flow velocities may be as high as 5 to 6 m/second, requiring the use of the continuous-wave Doppler mode. Both pulsed and continuous-wave Doppler velocities are displayed as a graph of velocity versus time, with the density of the spectral display corresponding to signal strength.

Color flow Doppler imaging is a modification of pulsed Doppler in which the flow velocity is displayed across a two-dimensional image using a color scale to indicate direction and velocity. The advantage is a visually appealing display of intracardiac flow patterns. Disadvantages are low temporal resolution (frame rates of 10 to 30 per second) and poor velocity resolution due to signal aliasing.

Tissue Doppler uses the Doppler principle to record the velocity of motion of the myocardial wall. Tissue Doppler recordings of the myocardium adjacent to the mitral annulus are used to evaluate diastolic ventricular function.

Measurements

A standard echocardiographic study includes pulsed Doppler measurement of antegrade flow velocities (transmitral and transaortic) and evaluation for valve regurgitation using continuous-wave and color Doppler modalities. Other Doppler measurements depend on the specific clinical indication.

Quantitative measurements using Doppler data are derived from two basic concepts: volume flow rate and the pressure-velocity relationship. Stroke volume (in cubic centimeters) can be calculated as the volume of a cylinder, where the base is the spatial cross-sectional area (CSA, in square centimeters) of flow, determined as the area of a circle from a two-dimensional diameter measurement. The height of the cylinder is the distance the average blood cell travels in one cardiac cycle, which is the velocity time integral (VTI, in centimeters) of flow. Therefore,

$$SV\,(cm^3) = CSA\,(cm^2) \times VTI\,(cm)$$

This approach has been validated for measurement of transaortic, transmitral, and transpulmonic flow. Measurement of volume flow rate at two different intracardiac sites allows quantitation of intracardiac shunts and valvular regurgitation.

The relationship between the pressure gradient (ΔP) across a narrowing and the velocity (v) of blood flow is described by the simplified Bernoulli equation:

$$\Delta P = 4v^2$$

This equation allows calculation of maximum and mean gradients across stenotic valves, estimation of pulmonary systolic pressure, and detailed evaluation of intracardiac hemodynamics with regurgitant valves.

ECHOCARDIOGRAPHIC APPROACHES

Several echocardiographic modalities are in clinical use. If it is unclear which modality is optimum in a specific clinical setting, consultation with the echocardiographer is appropriate.

Transthoracic echocardiography (TTE) is the standard clinical approach in most patients with suspected or known cardiac disease. Advantages are that it is noninvasive, has no known adverse effects, and provides detailed data on cardiac anatomy and physiology. Limitations include poor image quality in some patients, limited visualization of structures distant from the transducer (e.g., atrial septum, left atrial appendage), and the inability to visualize structures immediately distal to prosthetic heart valves (acoustic shadowing).

Transesophageal echocardiography (TEE) offers superior image quality because of a shorter distance between the transducer and the heart, the absence of interposed bone or lung, and the use of a higher-frequency transducer. TEE usually is well tolerated, but intubation of the esophagus entails some risk, and most clinicians do this procedure with the patient under conscious sedation. TEE is much more sensitive than TTE for detection of left atrial thrombus (95% vs. 50%), valvular vegetations (99% vs. 60%), and prosthetic mitral valve regurgitation (Fig. 55-2).

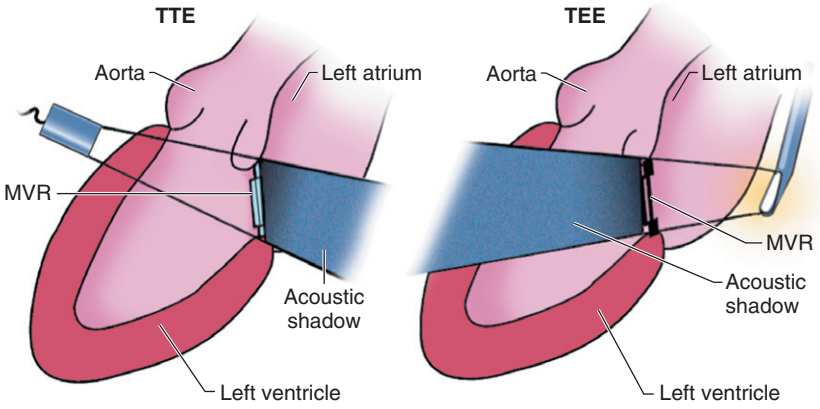

FIGURE 55-2. The problem of acoustic shadowing from a prosthetic mitral valve replacement (MVR). On the left, with transthoracic echocardiography (TTE), the acoustic shadow distal to the prosthetic valve obscures the left atrium, limiting assessment of valve regurgitation by Doppler techniques. On the right, with transesophageal echocardiography (TEE), the left atrium now can be evaluated for valvular regurgitation. However, the acoustic shadow now obscures the left ventricle. (From Otto CM. *Textbook of Clinical Echocardiography,* 4th ed. Philadelphia: Elsevier Saunders; 2009:117, Fig. 5-9.)

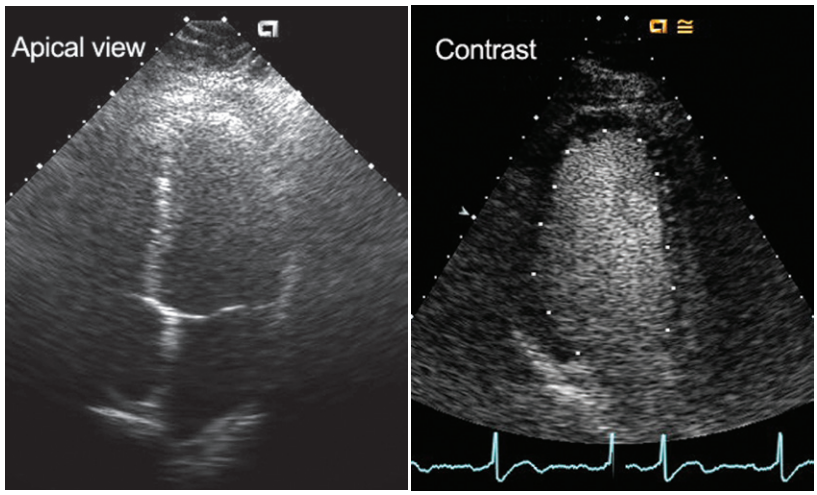

FIGURE 55-3. Poor-quality apical view (A) with marked improvement in definition of the left ventricular cavity after opacification using contrast echocardiography (B). The *dots* indicate the left ventricular endocardial tracing for calculation of ejection fraction.

Handheld echocardiography refers to the use of smaller, less expensive ultrasound systems that can be carried by the physician, who can perform quick, limited examinations in the office or at the bedside. These laptop-sized echocardiography units range from the very simple, with only two-dimensional imaging and limited controls, to systems with high-quality imaging and all Doppler modalities. Handheld echocardiography does not replace a complete imaging study but can serve as an adjunct to the physical examination, particularly in the acute care setting, such as to distinguish ventricular dilation from a pericardial effusion or to estimate ventricular systolic performance.

Contrast echocardiography may be performed using intravenous injection of agitated saline to opacify the right-sided heart chambers. These microbubbles are relatively large and do not pass through pulmonary capillaries. Therefore, appearance of contrast in the left side of the heart within one or two beats after right heart opacification is consistent with an intracardiac shunt. Although most atrial-level shunts are predominantly left-to-right shunts, a small amount of right-to-left shunting occurs, which is the basis of this approach.

Contrast echocardiography also may be performed with commercially available microbubbles in the range of 1 to 5 μm. Because these microbubbles are smaller than the pulmonary capillaries, right heart opacification is followed by left heart opacification, which can enhance the evaluation of systolic function when image quality is suboptimal, especially during stress echocardiography (Fig. 55-3).

Three-dimensional echocardiography is increasingly available and is useful in some clinical settings, particularly for the evaluation of complex structural heart disease and for transcatheter interventions (Fig. 55-4).

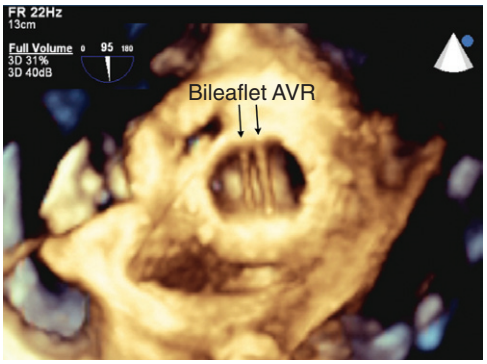

FIGURE 55-4. Real-time three-dimensional transesophageal echocardiographic imaging of a bileaflet aortic valve replacement (AVR) with the leaflets open during systole. The three-dimensional data set was cropped and rotated so that the viewer is looking at the valve from the aortic side. (From Otto CM. *Textbook of Clinical Echocardiography,* 4th ed. Philadelphia: Elsevier Saunders; 2009:91, Fig. 4-3.)

Stress echocardiography is a standard approach for evaluating patients with known or suspected coronary artery disease; it has a sensitivity (85 to 95%) and a specificity (80 to 90%) similar to those of radionuclide stress imaging (Chapters 56 and 71). Myocardial infarction results in thinning and akinesis of the affected wall. However, in the absence of infarction, resting myocardial function is normal, even when severe epicardial coronary disease is present. The increased myocardial demand associated with exercise or pharmacologic stress leads to myocardial ischemia, which results in a regional wall motion abnormality, often before the onset of chest pain or electrocardiographic changes (Fig. 55-5).

In patients who can exercise, standard views of the left ventricle are recorded at baseline and immediately after maximal treadmill or bicycle exercise. If endocardial definition is suboptimal, left-sided contrast is used. The rest and exercise images are compared in a side-by-side cine loop format. Myocardial ischemia is present if resting wall motion is normal but hypokinesis or akinesis is seen after exercise. The pattern of regional wall motion accurately identifies the area of myocardium at risk and is reasonably reliable for identification of the affected coronary artery. With three-vessel coronary disease, rather than a regional wall motion abnormality, the only clue on imaging may be an absence of the expected decrease in chamber size at peak exercise, caused by diffuse ischemia. Interpretation of an exercise echocardiogram includes exercise duration, hemodynamic response, symptoms, and electrocardiographic changes, in addition to the echocardiographic images (see Fig. 55-5).

In patients who are unable to exercise, stress testing is performed using a graded intravenous infusion of dobutamine, beginning at 5 to 10 μg/kg/minute and increasing every 3 minutes to a maximum dose of 40 μg/kg/minute. If needed, atropine is used to achieve 85% of the maximum predicted heart rate. In addition to evaluation for myocardial ischemia, dobutamine stress echocardiography can assess myocardial viability in areas of stunning or hibernation, based on an improvement in endocardial motion from baseline to low-dose dobutamine, with subsequent worsening of function at higher doses—the "biphasic" response.

Intracardiac echocardiography (ICE) is performed using an ultrasound probe on a catheter that is inserted into the right side of the heart through the femoral vein. ICE is used in the cardiac catheterization laboratory to guide percutaneous closure of a patent foramen ovale (PFO) and other procedures. In the electrophysiology laboratory, ICE helps guide catheter positioning and identify complications.

CARDIAC FUNCTION MEASUREMENTS

In addition to qualitative descriptions of cardiac anatomy and physiology, echocardiography provides precise and accurate quantitation of cardiac function, including ventricular systolic and diastolic function, an estimate of the severity of valve stenosis and regurgitation, and a noninvasive estimate of pulmonary pressures.

Systolic Ventricular Function

Overall LV systolic function is graded by visual estimation, with an approximate correspondence to EF as follows: normal (EF > 55%), mildly reduced (EF, 40 to 55%), moderately reduced (EF, 20 to 40%), severely reduced (EF < 20%). More precise quantitation is performed when clinically indicated by calculation of a biplane ejection fraction. Cardiac output calculations are not routine but may be helpful for noninvasive monitoring of therapy in patients with heart failure. Because EF measurements are affected by preload and afterload, measures that are less dependent on loading conditions, including

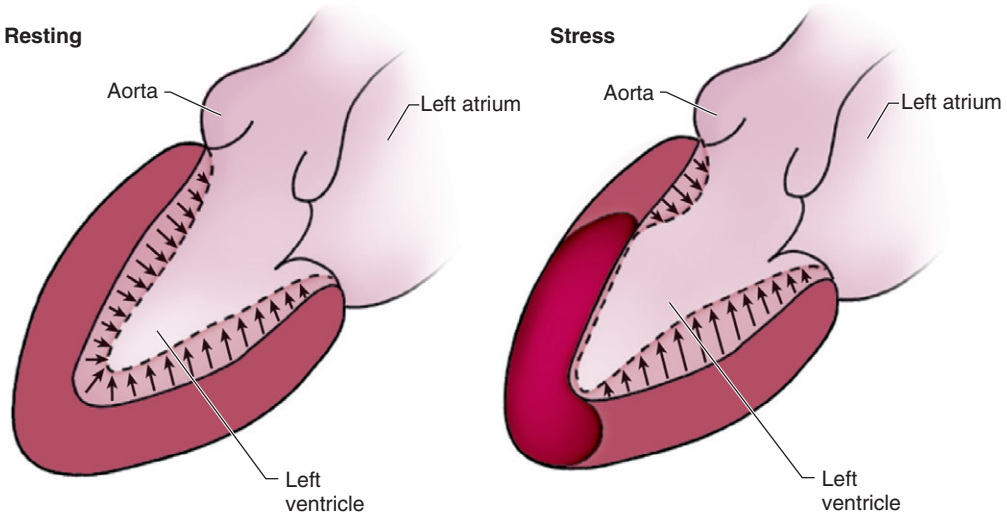

FIGURE 55-5. The concept of stress echocardiography in a patient with 70% stenosis in the proximal third of the left anterior descending (LAD) coronary artery. At rest *(left),* endocardial motion and wall thickening are normal. After stress *(right),* either exercise or pharmacologic, the middle and apical segments of the anterior wall become ischemic, showing reduced endocardial wall motion and wall thickening. If the LAD extends around the apex, the apical segment of the posterior wall also will be affected, as shown here. The normal segment of the posterior wall shows compensatory hyperkinesis. (From Otto CM. *Textbook of Clinical Echocardiography,* 4th ed. Philadelphia: Elsevier Saunders; 2009:191, Fig. 8-9.)

the end-systolic dimension or volume, are generally preferred for clinical decision making in situations such as the timing of surgery for chronic valvular regurgitation.

Diastolic Ventricular Function

Evaluation of diastolic ventricular function is challenging because the patterns of ventricular filling are affected by preload, heart rate, and coexisting valvular regurgitation in addition to the diastolic properties of the ventricle. However, echocardiography can classify diastolic function based on the combination of LV inflow, pulmonary vein flow, tissue Doppler velocities, and the isovolumic relaxation time. An estimate of LV filling pressure (e.g., LV end-diastolic pressure) also can be inferred using these approaches.

Valvular Stenosis

Echocardiography is the clinical standard for evaluation of aortic valvular heart disease (see Fig. 75-1). Cardiac catheterization can be reserved for cases in which echocardiography is nondiagnostic, clinical data are discrepant with echocardiographic findings, or coronary anatomy needs to be assessed (Chapter 75).

In patients with aortic stenosis, the most direct measure of stenosis severity is the antegrade velocity across the valve, indicating mild (<3 m/second), moderate (3 to 4 m/second), or severe (>4 m/second) valve obstruction. The maximum and mean transaortic pressure gradients also can be calculated using the Bernoulli equation. Accurate evaluation depends on a careful examination by an experienced echocardiographer.

Aortic valve area (AVA) is calculated using the continuity equation, based on the concept that volume flow rates proximal to and within the narrowed orifice are equal:

$$AVA \times VTI_{AS} = CSA_{LVOT} \times VTI_{LVOT}$$

or

$$AVA = (CSA_{LVOT} \times VTI_{LVOT})/VTI_{AS}$$

where LVOT = left ventricular outflow tract, VTI = velocity time integral, CSA = cross-sectional area, and AS = aortic stenosis (Fig. 55-6). It is especially important to calculate the AVA when LV systolic dysfunction accompanies aortic valve disease. In some patients, dobutamine stress echocardiography is helpful in distinguishing ventricular dysfunction caused by severe aortic stenosis from primary myocardial disease with concurrent moderate stenosis.

The evaluation of mitral stenosis (see Fig. 75-3) includes measurement of the mean transmitral gradient from the velocity curve and calculation of the valve area, both from two-dimensional planimetry of a short-axis image of the orifice and from the deceleration slope of the Doppler curve (pressure half-time method).

Valvular Regurgitation

The current approach to evaluating valvular regurgitation is based on the proximal geometry of the regurgitant jet, with measurement of the narrowest jet width (vena contracta; see Fig. 75-5). When further quantitation is needed, regurgitant volume (RV), regurgitant fraction (RF), and regurgitant orifice area (ROA) are calculated. Although color flow visualization of the flow disturbance may be helpful for detection of regurgitation and for understanding the mechanism of valve dysfunction, this approach should no longer be used to evaluate severity.

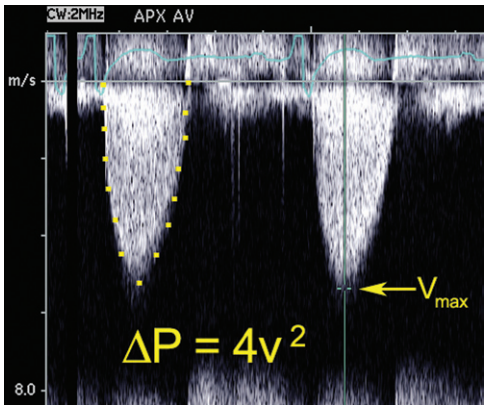

FIGURE 55-6. In a patient with aortic stenosis, the aortic jet velocity is recorded with continuous wave Doppler from the window that yields the highest velocity signal. Maximum velocity (V_{max}) is used to calculate the maximum systolic gradient. The Doppler curve is traced, as shown, to calculate the mean systolic gradient, using the Bernoulli equation, by which the pressure gradient (ΔP) equals four times the square of the velocity.

For aortic regurgitation, a narrow vena contracta (<3 mm) indicates mild regurgitation, whereas a wide vena contracta (>6 mm) indicates severe regurgitation. Additional evaluation of the severity of aortic regurgitation is based on the presence of holodiastolic flow reversal in the abdominal aorta and the density and slope of the continuous wave Doppler velocity curve. The approach to evaluating mitral regurgitation (see Fig. 75-5) is similar, beginning with measurement of the vena contracta. In addition to calculation based on transmitral versus transaortic volume flow rates, the proximal acceleration of flow into the regurgitant orifice allows evaluation with central regurgitant jets. Color flow shows a proximal isovelocity surface area (PISA).

Pulmonary Pressures

Estimation of pulmonary artery systolic pressure (PAP) is a standard component of a complete examination. The systolic pressure difference between the right ventricle and right atrium is calculated from the peak velocity in the tricuspid regurgitant (V_{TR}) jet, using the Bernoulli equation. Then, the right atrial pressure (RAP) is estimated from the size and appearance of the inferior vena cava. Because right ventricular and pulmonary artery systolic pressures are equal (in the absence of pulmonic stenosis),

$$PAP = 4(V_{TR})^2 + RAP$$

A small amount of tricuspid regurgitation is present in most patients, so pulmonary pressures can be estimated with this approach in more than 90%

of patients. Because this approach measures only pulmonary systolic pressure, not pulmonary vascular resistance, invasive evaluation may still be needed in some clinical situations (Chapter 68).

THE ECHOCARDIOGRAPHIC EXAMINATION

Clinical Indications

Echocardiography is an effective approach to the initial evaluation of many cardiac signs and symptoms (Table 55-1). Even when transesophageal imaging might be helpful, most clinicians begin with a transthoracic examination; exceptions are for the patient with a possible acute aortic dissection (Chapter 78), in whom TEE should be performed as quickly as possible, and in the evaluation of possible left atrial thrombosis before cardioversion without anticoagulation (Chapter 64). It is important to remember that resting echocardiography is not helpful for diagnosis of coronary artery disease; stress imaging is needed if this diagnosis is suspected (Chapter 71). In patients with known cardiac disease, echocardiography is used to evaluate severity, assess the results of medical and surgical interventions, and guide procedures (Table 55-2).

TABLE 55-1 COMMON SYMPTOMS AND SIGNS EVALUATED BY ECHOCARDIOGRAPHY

REASON FOR ECHOCARDIOGRAPHY	POSSIBLE ECHOCARDIOGRAPHIC FINDINGS OR DIAGNOSIS	REASON FOR ECHOCARDIOGRAPHY	POSSIBLE ECHOCARDIOGRAPHIC FINDINGS OR DIAGNOSIS
Chest pain	Coronary artery disease Acute myocardial infarction on resting echocardiography Stress echocardiography needed to detect coronary disease Aortic dissection Pericarditis Valvular aortic stenosis Hypertrophic cardiomyopathy	Cardiac murmur Systolic	Flow murmur (no valve abnormality) Aortic stenosis—valvular or subaortic Hypertrophic cardiomyopathy Mitral regurgitation Ventricular septal defect Pulmonic stenosis Tricuspid regurgitation
		Diastolic	Mitral stenosis Aortic regurgitation Pulmonic regurgitation Tricuspid stenosis
Heart failure	Left ventricular systolic dysfunction (global or segmental) Valvular heart disease Left ventricular diastolic dysfunction Pericardial disease Right ventricular dysfunction	Cardiomegaly on chest radiography	Pericardial effusion Dilated cardiomyopathy Specific chamber enlargement (e.g., left ventricle in chronic aortic regurgitation)
Palpitations	Left ventricular systolic dysfunction Mitral valve disease Congenital heart disease (e.g., ASD, Ebstein's anomaly) Pericarditis No structural cardiac disease	Systemic embolic event	Left ventricular systolic function and segmental wall motion abnormalities (aneurysms) Left ventricular thrombus Aortic valve disease Mitral valve disease Left atrial thrombus (TTE has low sensitivity, TEE required) Atrial septal defect or patent foramen ovale

ASD = atrial septal defect; TEE = transesophageal echocardiography; TTE = transthoracic echocardiography.

TABLE 55-2 INDICATIONS FOR ECHOCARDIOGRAPHY BY KNOWN DIAGNOSIS

CLINICAL DIAGNOSIS	KEY ECHOCARDIOGRAPHIC FINDINGS	LIMITATIONS OF ECHOCARDIOGRAPHY	ALTERNATIVE APPROACHES
VALVULAR HEART DISEASE (CHAPTER 75)			
Valve stenosis	Etiology of stenosis, valve anatomy Transvalvular ΔP, valve area Chamber enlargement and hypertrophy LV and RV systolic function Associated valvular regurgitation	Possible underestimation of the severity of stenosis Possible coexisting coronary artery disease	Cardiac catheterization; MRI
Valve regurgitation	Mechanism and etiology of regurgitation Severity of regurgitation Chamber enlargement LV and RV systolic function PA pressure estimate	TEE may be needed to evaluate mitral regurgitant severity and valve anatomy (especially before MV repair)	Cardiac catheterization; MRI
Prosthetic valve function	Evidence for stenosis Detection of regurgitation Chamber enlargement Ventricular function PA pressure estimate	Imaging of prosthetic valves is limited by shadowing and reverberations TEE is needed for suspected prosthetic MR due to "masking" of the LA on TTE	Cardiac catheterization
Endocarditis (Chapter 76)	Detection of vegetations (TTE sensitivity 70-85%) Presence and degree of valve dysfunction Chamber enlargement and function Detection of abscess Possible prognostic implications	TEE more sensitive for detection of vegetations (>90%) A definite diagnosis of endocarditis also depends on bacteriologic criteria TEE more sensitive for detecting an abscess	Blood cultures and clinical findings also are diagnostic criteria for endocarditis

TABLE 55-2 INDICATIONS FOR ECHOCARDIOGRAPHY BY KNOWN DIAGNOSIS—cont'd

CLINICAL DIAGNOSIS	KEY ECHOCARDIOGRAPHIC FINDINGS	LIMITATIONS OF ECHOCARDIOGRAPHY	ALTERNATIVE APPROACHES
CORONARY ARTERY DISEASE			
Acute myocardial infarction (Chapters 72 and 73)	Segmental wall motion abnormality reflects "myocardium at risk" Global LV function (EF) Complications: Acute MR vs. VSD Pericarditis LV thrombus, aneurysm RV infarct	Coronary artery anatomy itself is not directly visualized	Coronary angiography Radionuclide LV angiography Cardiac catheterization
Angina (Chapter 71)	Global and segmental LV systolic function Exclude other causes of angina (e.g., AS, HOCM)	Resting wall motion may be normal despite significant CAD Stress echocardiography is needed to induce ischemia and wall motion abnormality	Coronary angiography Stress thallium ETT
Pre-revascularization/ post-revascularization	Assess wall thickening and endocardial motion at baseline Improvement in segmental function after procedure	Dobutamine stress and/or contrast echocardiography is needed to detect viable but nonfunctioning myocardium	MRI PET Thallium ETT Contrast echocardiography
End-stage ischemic disease	Overall LV systolic function (EF) PA pressures Associated MR LV thrombus RV systolic function	—	Coronary angiography Radionuclide EF
CARDIOMYOPATHY (CHAPTERS 58-60)			
Dilated	Chamber dilation (all four) LV and RV systolic function (qualitative and EF) Coexisting atrioventricular valve regurgitation PA systolic pressure LV thrombus	Indirect measures of LVEDP Accurate EF may be difficult if image quality is poor	Radionuclide EF LV and RV angiography
Restrictive	LV wall thickness LV systolic function LV diastolic function PA systolic pressure	Must be distinguished from constrictive pericarditis	Cardiac catheterization with direct, simultaneous RV and LV pressure measurement after volume loading
Hypertrophic	Pattern and extent of LV hypertrophy Dynamic LVOT obstruction (imaging and Doppler) Coexisting MR Diastolic LV dysfunction	—	—
Hypertension (Chapter 67)	LV wall thickness and chamber dimensions LV mass LV systolic function Aortic root dilation	—	—
PERICARDIAL DISEASE (CHAPTER 77)			
	Pericardial thickening Detection, size, and location of PE 2D signs of tamponade physiology Doppler signs of tamponade physiology	Diagnosis of tamponade is a hemodynamic and clinical diagnosis Constrictive pericarditis is a difficult diagnosis Not all patients with pericarditis have an effusion	Intracardiac pressure measurements for tamponade or constriction MRI or CT to detect pericardial thickening
DISEASES OF THE AORTA (CHAPTER 78)			
Aortic root dilation	Etiology of aortic dilation Accurate aortic root diameter measurements Anatomy of sinuses of Valsalva (especially Marfan syndrome) Associated aortic regurgitation	—	CT, MRI, aortography
Aortic dissection	2D images of ascending aorta, aortic arch, descending thoracic and proximal abdominal aorta Imaging of dissection "flap" Associated aortic regurgitation Ventricular function	TEE more sensitive (97%) and more specific (100%) Cannot assess distal vascular beds	Aortography CT MRI TEE
CARDIAC MASSES (CHAPTER 60)			
LV thrombus	High sensitivity and specificity for diagnosis of LV thrombus Suspect with apical wall motion abnormality or diffuse LV systolic dysfunction	Technical artifacts can be misleading 5-MHz or higher frequency transducer and angulated apical views needed TEE is needed to detect LA thrombus reliably	LV thrombus may not be recognized on radionuclide or contrast angiography
LA thrombus	Low sensitivity for detection of LA thrombus, although specificity is high Suspect with LA enlargement, MV disease	—	TEE

TABLE 55-2 INDICATIONS FOR ECHOCARDIOGRAPHY BY KNOWN DIAGNOSIS—cont'd

CLINICAL DIAGNOSIS	KEY ECHOCARDIOGRAPHIC FINDINGS	LIMITATIONS OF ECHOCARDIOGRAPHY	ALTERNATIVE APPROACHES
Cardiac tumors	Size, location, and physiologic consequences of tumor mass	Extracardiac involvement is not well seen Cannot distinguish benign from malignant tumor or tumor from thrombus	TEE CT MRI (with cardiac gating) Intracardiac echocardiography
PULMONARY HYPERTENSION (CHAPTER 68)			
	Estimate of PA pressure Evidence of left-sided heart disease to account for increased PA pressures RV size and systolic function (cor pulmonale) Associated TR	Indirect PA pressure measurement Cannot determine pulmonary vascular resistance accurately	Cardiac catheterization
CONGENITAL HEART DISEASE (CHAPTER 69)			
	Detection and assessment of anatomic abnormalities Quantitation of physiologic abnormalities Chamber enlargement Ventricular function	No direct intracardiac pressure measurements Complicated anatomy may be difficult to evaluate if image quality is poor (TEE is helpful)	MRI with 3D reconstruction Cardiac catheterization TEE

From Otto CM. *Textbook of Clinical Echocardiography*, 4th ed. Philadelphia: Elsevier Saunders; 2009:475-478.

Normal Findings

Trace to mild regurgitation is considered "physiologic" and is seen with 70 to 80% of mitral valves, 80 to 90% of tricuspid valves, and 70 to 80% of pulmonic valves in normal individuals. The prevalence of aortic regurgitation increases with age, but it is found in only 5% of young normal adults; the presence of aortic regurgitation raises the possibility of subtle aortic valve or root abnormalities.

A PFO (Chapter 69) is present in 25 to 35% of normal individuals and may be identified by color Doppler or by contrast echocardiography. Use of the Valsalva maneuver enhances identification of a PFO because the slight elevation in right atrial pressure may lead to a brief right-to-left shunt. The significance of a PFO in patients without clinical events is unclear. Other common anatomic variants seen on echocardiography include aberrant chords (or "webs") in the left ventricle; small, linear, mobile echoes associated with the valves (Lambl's excrescences); and normal ridges in the left and right atrium.

Unexpected abnormal findings also may be found on studies requested for other indications. A bicuspid aortic valve is present in 1 to 2% of the population; most of these patients are asymptomatic until late in life, so many cases are diagnosed "incidentally" by echocardiography. Aortic valve sclerosis, which is a frequent unexpected echocardiographic diagnosis, is a marker of cardiovascular disease and an increased risk of myocardial infarction even if valve function is normal.

INTEGRATING THE ECHOCARDIOGRAPHIC AND CLINICAL FINDINGS

The echocardiographic request should indicate the specific reason for the study and any relevant symptoms or signs. The echocardiographic examination then can be tailored to answer the clinical question. The echocardiographic results should be interpreted in conjunction with other clinical data. If the echocardiographic data seem discrepant with the clinical data, the requesting physician should review the images with the echocardiographer to identify areas of uncertainty and to determine the next best diagnostic step.

56 NONINVASIVE CARDIAC IMAGING

CHRISTOPHER M. KRAMER AND GEORGE A. BELLER

NUCLEAR CARDIOLOGY

The techniques of nuclear cardiology permit the noninvasive imaging of myocardial perfusion under stress and resting conditions and of resting regional and global function by use of radionuclide imaging agents and gamma or positron cameras with associated computer processing. All these techniques are based on acquiring images of radioactivity emanating from tracers localized in heart muscle or in the blood pools of the left and right ventricles. Myocardial perfusion imaging is the most commonly performed nuclear cardiology technique, most often in conjunction with either exercise or pharmacologic stress intended to produce flow heterogeneity between relatively hypoperfused and normally perfused myocardial regions. Radionuclide angiography, in which technetium-99m (^{99m}Tc)-labeled red blood cells or other ^{99m}Tc-labeled agents are injected intravenously, is used for measurement of left ventricular ejection fraction and assessment of regional wall motion, especially to monitor changes in global left ventricular function in patients undergoing chemotherapy with cardiac toxic drugs. Positron emission tomography (PET) can assess regional myocardial metabolism to estimate myocardial viability, most often with fluorine-18–labeled 2-deoxyglucose (FDG), as well as myocardial perfusion by use of rubidium-82 (^{82}Rb). Hybrid cameras with computed tomography (CT) permit multimodality imaging of coronary anatomy and physiologic perturbations in flow or myocardial function.

Myocardial Perfusion Imaging

Imaging Agents

For the assessment of myocardial perfusion, ^{99m}Tc-labeled perfusion agents, which provide higher-quality images more quickly, are used more commonly than thallium-201 (^{201}Tl) for exercise or pharmacologic stress perfusion imaging to evaluate patients with suspected or known coronary heart disease (CHD). Of the various ^{99m}Tc-labeled agents, ^{99m}Tc-sestamibi and ^{99m}Tc-tetrofosmin are the most common. These ^{99m}Tc agents permit simultaneous assessment of regional and global left ventricular function and volumes with gated single-photon emission computed tomography (SPECT) technology.

Some laboratories use dual-isotope rest ^{201}Tl/stress ^{99m}Tc-sestamibi imaging, in which patients undergo ^{201}Tl imaging at rest and then, immediately

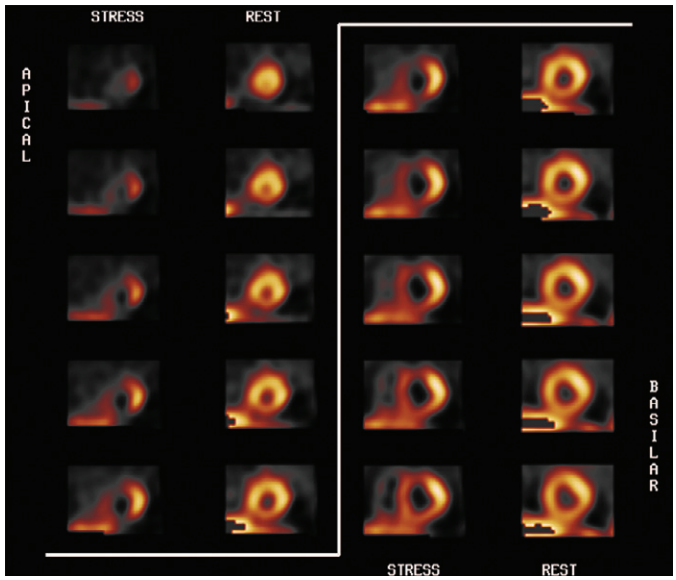

FIGURE 56-1. Short-axis images showing a moderately large, reversible defect of the apex, anterior wall, and septum. This defect is consistent with disease of the proximal left anterior descending coronary artery.

afterward, undergo ^{99m}Tc-sestamibi imaging during stress. Reversibility is identified by comparing the perfusion pattern on the stress ^{99m}Tc-sestamibi images with the pattern on the baseline resting ^{201}Tl images. The major advantage of this technique is the marked decrease in total imaging time, but the disadvantage is a substantially higher radiation dose. In patients with a low to intermediate pretest probability of CHD, a normal stress myocardial perfusion study obviates the need for a resting study, reducing both cost and radiation.

Detection of Coronary Heart Disease

The major indications for stress and rest myocardial perfusion imaging are to diagnose CHD, to assess prognosis, and to detect myocardial viability. Exercise or pharmacologic stress myocardial perfusion imaging in patients with chest pain yields a sensitivity for detecting CHD in the 85 to 90% range (Fig. 56-1). The specificity for excluding CHD is in the 85% range for ^{99m}Tc-sestamibi SPECT imaging and increases to 90% with gated SPECT. Exercise or pharmacologic stress SPECT perfusion imaging have sensitivities and specificities that are superior to those of exercise electrocardiogram (ECG) testing alone. The specificity of gated SPECT for detecting CHD with use of one of the ^{99m}Tc-labeled perfusion agents is 20 to 30% higher than that of ^{201}Tl SPECT in women.

Radionuclide stress perfusion imaging is of particular value compared with exercise ECG testing alone in (1) patients with resting ECG abnormalities, such as those seen with left ventricular hypertrophy, digitalis effect, Wolff-Parkinson-White syndrome, and intraventricular conduction abnormalities; and (2) patients who fail to achieve more than 85% of maximal predicted heart rate. Approximately 40% of patients with a low to intermediate pretest likelihood of CHD who manifest 1.0 mm or more of horizontal or downsloping ST segment depression have no evidence of CHD (false-positive findings). The addition of stress perfusion imaging can assist in differentiating true-positive from false-positive ST depression. Detection of proximal left anterior descending stenoses and proximal multivessel CHD is enhanced by identifying regional systolic thickening or wall motion abnormalities on the gated SPECT images compared with assessment based on perfusion alone. If possible, drugs such as long-acting nitrates, β-blockers, and rate-lowering calcium blockers should be discontinued for 24 hours before exercise stress testing that is performed to diagnose or to exclude CHD as the cause of chest pain.

Pharmacologic Stress Imaging

In patients who are unable to exercise to adequate heart rates and workloads on exercise stress testing protocols, pharmacologic stress testing with use of vasodilators (e.g., dipyridamole), adenosine, regadenoson, or inotropic agents (e.g., dobutamine) is an alternative to exercise for detecting physiologically significant coronary artery stenoses. Sensitivity and specificity for CHD detection are comparable for dipyridamole and adenosine. The addition of limited exercise to dipyridamole or adenosine imaging can prevent the vasodilator-induced hypotension, improve the ECG detection of ischemia, and enhance image quality by increasing the heart-to-liver ratio of tracer uptake. Dobutamine stress is preferred in patients who have bronchospasm or a history of asthma or who have consumed caffeine, which is an adenosine receptor antagonist, within 12 hours before testing. Patients who experience side effects such as hypotension and chest pain during dipyridamole or adenosine infusion should be treated with intravenous aminophylline, an adenosine antagonist that immediately reverses these side effects. Regadenoson has fewer side effects than adenosine. PET myocardial perfusion imaging, which is performed only with vasodilator stress, has a higher specificity and better ability to detect multivessel disease than SPECT.

Assessment of Prognosis

The extent of hypoperfusion on post-stress SPECT perfusion images provides important incremental prognostic information when added to clinical characteristics, the resting left ventricular ejection fraction, exercise ECG stress test variables, and even coronary artery anatomy. Nondiabetic patients with chest pain and a normal myocardial perfusion scan at peak exercise or under vasodilator stress have a subsequent cardiac death or infarction rate of less than 1% per year and are generally appropriate candidates for medical therapy (Chapter 71) or require further diagnostic evaluation for a noncardiac cause of chest pain (Chapters 50 and 139). Conversely, patients with high-risk imaging results may benefit from early referral for invasive strategies, including coronary revascularization (Chapter 74), even if symptoms are mild. Patients who show inducible ischemia involving more than 20% of the left ventricular myocardium may have a better outcome with coronary revascularization compared with medical therapy.

Transient ischemic left ventricular cavity dilation, by which the left ventricular cavity appears more dilated on stress images compared with rest images, is a particularly high-risk finding on SPECT. This finding occurs when subendocardial ischemia after stress causes a decrease in tracer uptake in the subendocardium, thereby yielding what appears to be a larger left ventricular cavity than was observed on the resting images.

Patients with abnormal pharmacologic stress studies have a worse prognosis than patients with comparable defect patterns seen on exercise scans, perhaps because their inability to exercise is also a prognostic factor. Assessment of regional left ventricular function on post-stress gated SPECT images enhances the detection of three-vessel CHD. Exercise or pharmacologic stress perfusion imaging also provides useful prognostic information for predischarge risk stratification in clinically low- to intermediate-risk patients who have experienced an uncomplicated myocardial infarction or unstable angina. Demonstration of defects remote from the zone of infarction (which indicate underlying multivessel disease), evidence for residual ischemia within the infarct zone, or both identify patients with an increased risk of reinfarction and subsequent cardiac death.

Exercise or pharmacologic stress perfusion imaging is superior to exercise ECG testing alone for detection of coronary restenosis in patients presenting with recurrence of symptoms after a percutaneous coronary intervention (Chapter 74). Stress perfusion imaging also has proved useful for identifying high-risk asymptomatic patients who have undergone previous coronary artery bypass graft surgery (Chapter 74) and patients who have intermediate or nonevaluable stenoses on coronary angiography.

Determination of Myocardial Viability with Single-Photon Emission Computed Tomography or Positron Emission Tomography

SPECT perfusion imaging is performed in the resting state to identify residual myocardial viability in zones corresponding to severe regional wall motion abnormalities in patients with CHD and depressed left ventricular function. When severe left ventricular dysfunction is caused by "hibernation" (a state of chronic reduced contractility because of substantial ischemia), and not by irreversible myocardial necrosis, areas of resting hypoperfusion that are viable and contributing to hibernation show initial defects on early images but no or less severe defects on 3-hour delayed images. If uptake ultimately exceeds 50 or 60% of peak uptake in these regions, there is a high probability (65 to 75%) that regional myocardial function will improve after successful revascularization, compared with only a 10 to 20% probability for myocardial zones showing less than 50% of peak uptake on resting images.

Regional myocardial metabolism can be assessed noninvasively by PET with FDG and a flow tracer such as [^{13}N]ammonia or ^{82}Rb. FDG is a glucose

analogue that is taken up initially in myocardial cells and is trapped by conversion to FDG-6-phosphate. FDG is cell membrane impermeable and remains within viable cells at high concentrations for more than 40 to 60 minutes. Increased FDG activity on clinical PET images in areas of diminished regional blood flow, as determined by [^{13}N]ammonia imaging, is characteristic of myocardial viability. These areas of blood flow/FDG mismatch usually show improved regional function after coronary revascularization. Regions of the heart that show both diminished perfusion and FDG uptake (a "match" pattern) represent predominantly nonviable myocardium, with only a 10 to 15% probability of showing improved systolic function after revascularization. Patients who have an ischemic cardiomyopathy with poor viability on either resting SPECT or PET have a worse outcome after coronary revascularization compared with patients with predominantly viable myocardium.

Imaging of Ventricular Function

Global and segmental left and right ventricular function can be evaluated accurately by gated cardiac blood pool imaging to provide a radionuclide angiogram or ventriculogram. The equilibrium radionuclide angiographic approach is performed after thorough mixing of ^{99m}Tc-labeled blood cells within the intravascular compartment. Because ^{99m}Tc remains within the blood pool, serial imaging studies can be acquired during several hours. Acquisition of the images is synchronized with the QRS complex on the ECG through a multigated approach by which each cardiac cycle is divided into multiple frames. A uniform diminution of left ventricular systolic function without segmental wall motion abnormalities suggests nonischemic dilated cardiomyopathy (Chapter 60), whereas depressed global left ventricular function associated with segmental wall motion abnormalities suggests ischemic heart disease.

CARDIAC COMPUTED TOMOGRAPHY

For CT, imaging with high spatial and temporal resolution and ECG gating during a breath-hold yields snapshots of the heart reconstructed from the same phase of the cardiac cycle. Multidetector computed tomography (MDCT), which has almost entirely replaced electron beam CT, can capture a three-dimensional image of the heart in one to two heartbeats on the latest generation scanners as well as provide coronary artery calcium scoring without the use of contrast and with only 1 to 3 millisievert (mSv) of radiation. MDCT coronary arteriography requires 60 to 100 mL of iodinated contrast and average radiation doses less than 5 mSv. However, without careful planning of the imaging approach, radiation doses on the order of 10 to 25 mSv have been reported on 64-detector scanners. β-Blockade is often used to achieve a heart rate of less than 60 beats per minute to optimize imaging, and irregular rhythms such as atrial fibrillation may diminish image quality.

Coronary Artery Calcium Scoring

Coronary calcium is an indicator of the burden of atherosclerotic plaque, and very high levels confer an increased risk of future cardiac events (Fig. 56-2). Calcium scores are generally calculated as an Agatston score, which corresponds to each coronary lesion's calcium area multiplied by the maximal CT attenuation value of that lesion, and then summed for the entire coronary tree. Calcium scores are age, gender, and race dependent and must be normalized by these factors. In a large prospective, population-based study, the coronary calcium score predicted coronary events independently of either standard risk factors or C-reactive protein and was a better predictor than the Framingham risk score. Calcium scores above 300 were associated with an increased risk of myocardial infarction and cardiac death at every risk level. The utility of calcium scoring is highest in intermediate-risk patients on the basis of Framingham risk data, and there is no evidence that a calcium score in otherwise low- or high-risk groups would change risk factor management. Importantly, there is no correlation between coronary calcium and the physiologic or anatomic significance of a stenosis. Consensus guidelines suggest that stress testing may be indicated in patients with high calcium scores (>300 to 400).

Computed Tomographic Coronary Angiography

MDCT is an excellent technique to diagnose anomalous coronary arterial anatomy in adults (Fig. 56-3). For detection of coronary artery disease, 64-detector scanners have consistently demonstrated sensitivities on a per-segment basis in the 95% range, specificities of 85 to 98%, positive-predictive values of 64 to 91%, and negative-predictive values of 99%. Thus, the technique appears to be an excellent way to exclude significant coronary artery disease (Fig. 56-4). Initial studies with 256- and 320-detector row scanners are even more promising. A limitation of the technique, however, is its lower specificity in heavily calcified vessels, which are more common in elderly patients. MDCT tends to overestimate the percentage of stenosis when compared with intravascular ultrasound. The accuracy for detecting stenoses in bypass grafts is quite high, although evaluation of native vessel coronary artery disease is limited in postbypass patients owing to extensive calcification and smaller size vessels. Stents less than 3 mm in diameter cannot be

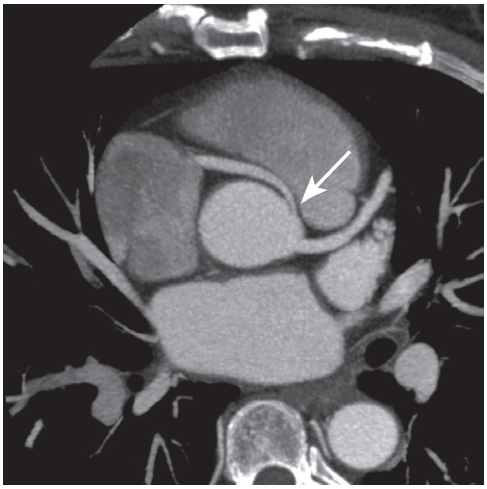

FIGURE 56-3. Contrast-enhanced computed tomographic angiogram in a young patient with chest pain and an anomalous right coronary artery (RCA). The RCA originates with a slit-like origin from the left coronary cusp *(arrow)* and passes anteriorly between the aorta and right ventricular outflow tract. The left main coronary artery originates normally from the left cusp.

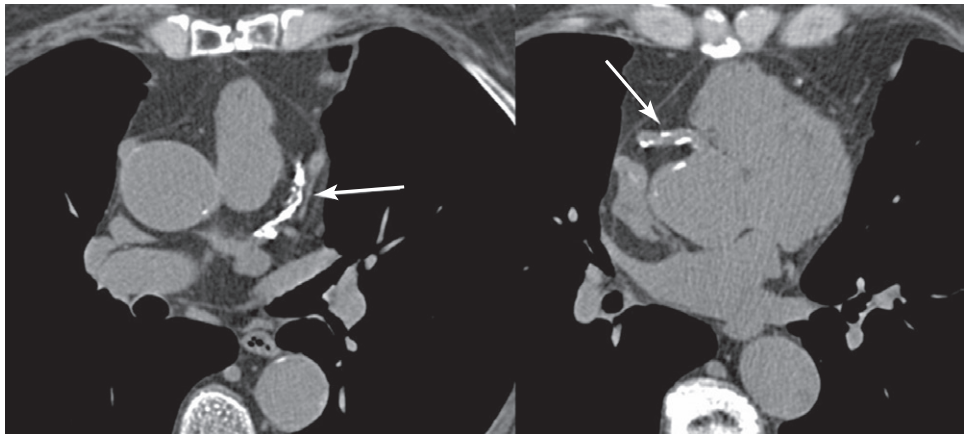

FIGURE 56-2. Non–contrast-enhanced computed tomography axial slices through the heart at two locations for coronary calcium scoring as risk assessment in an asymptomatic patient. On the *left,* the slice includes the left anterior descending artery with extensive calcification in its proximal portion *(arrow)*. On the *right,* the slice includes the right coronary artery with proximal spotty calcification *(arrow)*. This patient's calcium score was 457, putting him in a higher risk group regardless of his Framingham risk score.

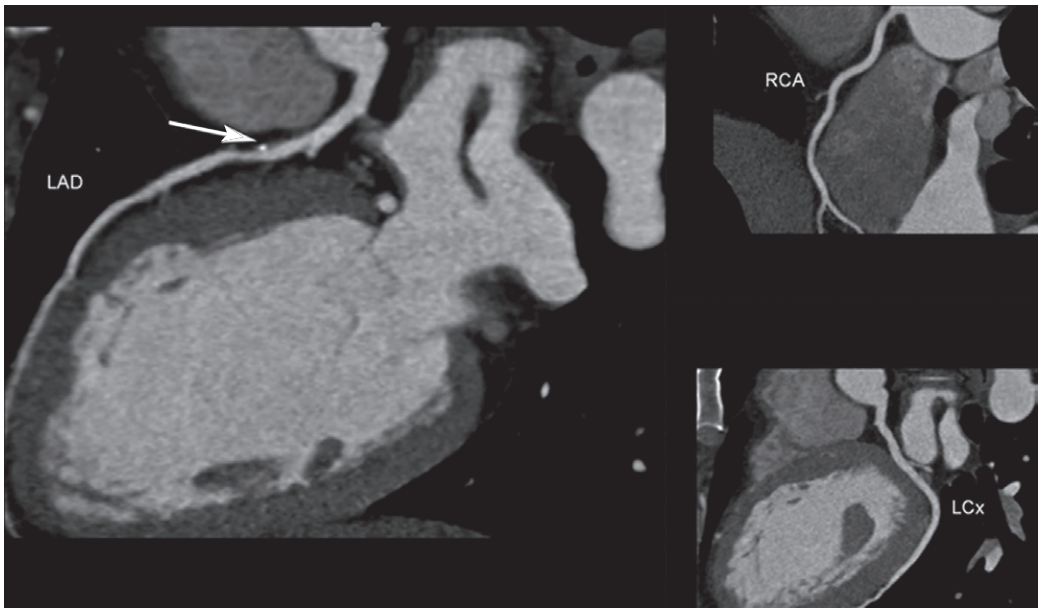

FIGURE 56-4. Contrast-enhanced computed tomographic coronary angiogram obtained on a dual source 64-detector scanner in a patient with atypical chest pain. The left anterior descending (LAD) artery has a nonobstructive lesion *(arrow)* containing both noncalcified (soft) plaque, which appears dark, and a focal area of calcification. The right coronary artery (RCA) and left circumflex coronary artery (LCx) are normal.

adequately evaluated by MDCT, although accuracy in larger stents is improving with the use of advanced postprocessing techniques.

MDCT coronary angiography is not recommended as a routine screening test, but it can be useful in selected situations, such as in low- or low-intermediate-risk patients who present to emergency departments with chest pain but without ECG changes or elevations of cardiac biomarkers (Chapter 50). The high negative-predictive value of MDCT often can exclude important CHD and avoid the need for other testing in this patient group. MDCT also may be useful in patients with equivocal or nondiagnostic stress testing or new-onset heart failure. The extent and severity of coronary disease found at CT coronary angiography correlate with subsequent all-cause mortality in a similar fashion to catheter-based coronary angiography.

Other Cardiac Applications

The same data acquired by MDCT for coronary artery imaging can be reformatted and used for functional cardiac imaging, including measurement of left ventricular volumes, ejection fraction, wall thickness, and global and segmental wall motion. In acute and chronic myocardial infarction, contrast-enhanced MDCT can demonstrate late enhancement in a manner similar to cardiovascular magnetic resonance imaging (CMR), albeit with a lower signal and contrast-to-noise ratio. MDCT also can complement echocardiography to evaluate cardiac anatomy in patients with congenital heart disease, especially in patients with contraindications to CMR. MDCT can evaluate pericardial thickness and calcification in patients with suspected constrictive pericarditis (see Fig. 77-10 in Chapter 77) and can evaluate native and prosthetic valvular structures and cardiac masses when imaging with other modalities is inadequate.

Cardiac CT is often used to image the left atrium and pulmonary venous anatomy for preprocedural planning for pulmonary vein ablations for atrial fibrillation (Chapter 66). Cardiac venous anatomy may be imaged to aid in the implantation of left ventricular pacemakers in the cardiac venous system for biventricular pacing for heart failure (Chapters 59 and 66).

CARDIOVASCULAR MAGNETIC RESONANCE IMAGING

Indications, Contraindications, and Pulse Sequences

CMR is a tremendously versatile and flexible imaging modality. CMR is typically performed on 1.5-Tesla (T) scanners, although problems with ECG gating and off-resonance effects previously encountered at higher field strength (3 T) have largely been overcome. Advantages of CMR include the lack of ionizing radiation, the variety of tissues that can be characterized, and the ability to image the heart in any arbitrary plane. Images typically are obtained using ECG gating and breath-hold techniques.

In addition to general restrictions regarding magnetic resonance (e.g., certain intracranial aneurysm clips, transcutaneous electrical nerve stimulation units, intra-auricular implants), patients with cardiac pacemakers and implantable cardioverter-defibrillators generally should *not* undergo CMR because of concern regarding reprogramming of the device, direct stimulation of the heart during gradient switching, or localized heating in the lead system. Newer pacemaker systems and defibrillator models may not be susceptible, but even in these cases, careful precautions must be taken, including close monitoring and device testing and reprogramming after the procedure. CMR is safe for all prosthetic heart valves, although image distortions immediately around the prosthesis will obscure nearby pathology. CMR is safe for patients with intracoronary stents, including at 3 T. Gadolinium-based contrast agents are now contraindicated in patients with a glomerular filtration rate of less than 30 mL/minute/1.83 m^2, owing to the recently identified complication of nephrogenic systemic fibrosis (Chapter 275) in a small subset of patients with severe chronic kidney disease, especially those on dialysis.

A comprehensive CMR study includes evaluation of cardiac structure, function, tissue characteristics, perfusion, and scarring or fibrosis. The components of the examination are tailored to the particular diagnostic question at hand.

Specific Clinical Applications

Coronary Disease

For detection of myocardial ischemia, gadolinium perfusion imaging during vasodilator stress with adenosine or regadenoson shows defects, generally in the subendocardium, that persist for at least 5 heartbeats during the first pass of contrast. Imaging is often repeated at rest after approximately 10 minutes to be sure any defect seen with stress was not either artifactual or due to an infarct (the latter is excluded in combination with late gadolinium enhancement). Head-to-head comparisons of vasodilator stress perfusion CMR and dobutamine stress CMR suggest a higher sensitivity for contrast-enhanced perfusion imaging and higher specificity for dobutamine wall motion imaging. MDCT has superior spatial resolution and accuracy compared with CMR for imaging of the coronary arteries. However, CMR coronary imaging is ideal for the diagnosis of anomalous coronary arteries.

CMR with late gadolinium enhancement is the gold standard technique for assessment of myocardial scar owing to myocardial infarction, with a better accuracy than nuclear imaging approaches, especially for smaller non–Q wave infarctions (Fig. 56-5). In acute myocardial infarction, CMR techniques assess the myocardium at risk and estimate the amount of salvaged myocardium owing to reperfusion. Areas of low signal in the subendocardial core of the infarction represent regions of microvascular obstruction with severe capillary destruction and are a marker of subsequent adverse left ventricular remodeling and poorer outcome.

Cardiomyopathies

CMR is increasingly used to identify the underlying etiology of cardiomyopathies and is the best test to diagnose arrhythmogenic right ventricular

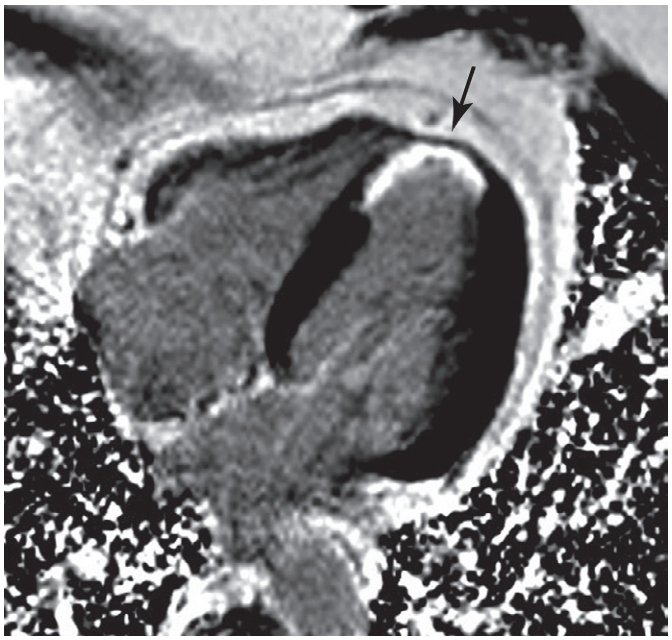

FIGURE 56-5. Late gadolinium-enhanced four-chamber long-axis image in a patient with a scar *(arrow)* from a prior anterior myocardial infarction.

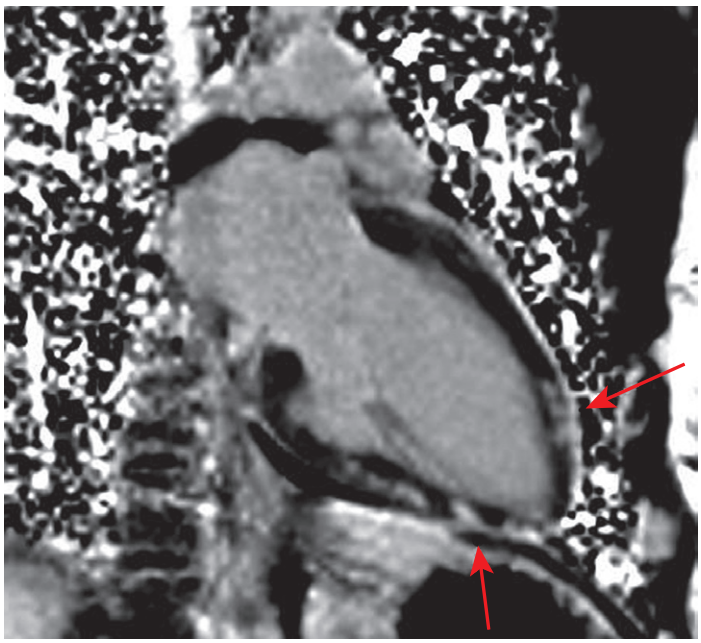

FIGURE 56-7. Gadolinium-enhanced image in a 22-year-old man shows patchy subepicardial enhancement *(arrows)*, characteristic of acute myocarditis.

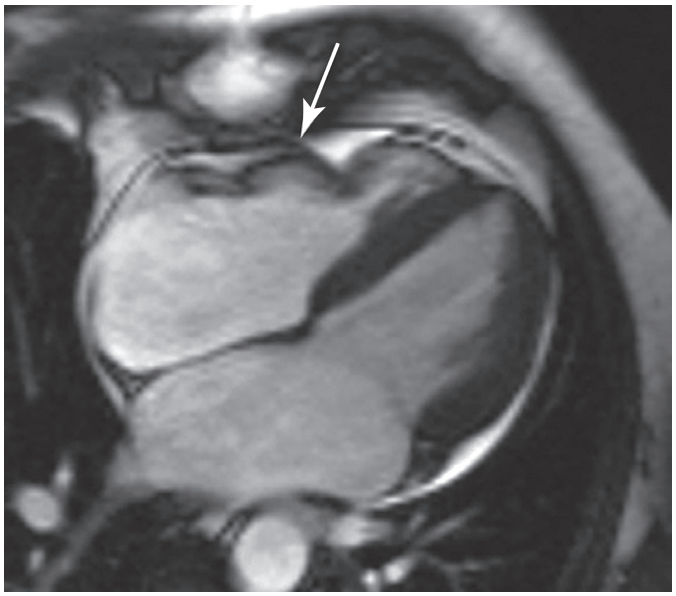

FIGURE 56-6. **Magnetic resonance image in a 27-year-old woman with arrhythmogenic right ventricular cardiomyopathy demonstrates regional right ventricular (RV) systolic dysfunction, which is the hallmark of the disease.** The *arrow* points to a region of RV dyskinesis at end systole, and the RV appears like an accordion at end systole.

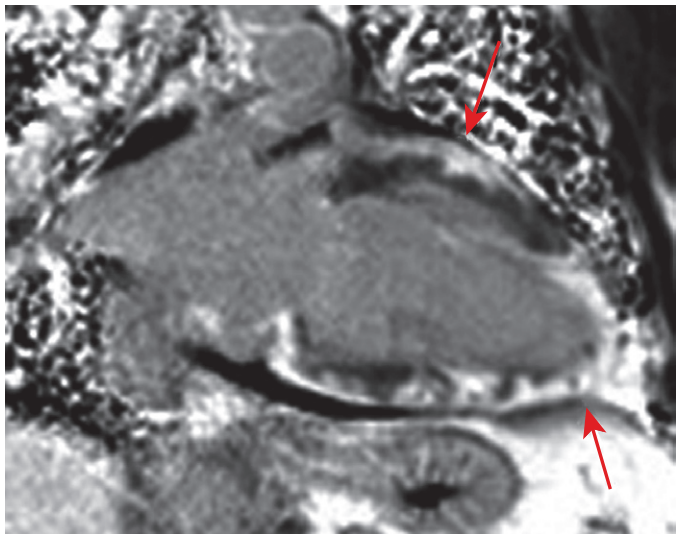

FIGURE 56-8. Late gadolinium-enhanced magnetic resonance image in a 47-year-old man with heart failure, heart block, and hilar lymphadenopathy shows patchy late gadolinium enhancement in a noncoronary distribution, including subepicardial anterior wall enhancement *(upper arrow)* and near transmural apical enhancement *(lower arrow)* consistent with myocardial sarcoidosis.

dysplasia (Fig. 56-6), which is associated with an increased risk of sudden death (Chapters 60 and 65). Arrhythmogenic right ventricular cardiomyopathy is characterized by regional or global right ventricular dilation and dysfunction. Late gadolinium enhancement may be seen but can be difficult to identify in the thin-walled right ventricle in this disease. Fat is a nonspecific finding.

In patients who present in acute heart failure or with chest pain, elevated troponins, but a negative coronary arteriogram, CMR is ideally suited to identify myocarditis (Chapter 60) noninvasively (Fig. 56-7), with changes most often in the basal lateral wall pattern seen as chronic midwall enhancement, which is a poor prognostic marker in the setting of dilated cardiomyopathy. CMR is more sensitive than echocardiography to measure regional wall thickness and left ventricular outflow tract gradients in patients with hypertrophic cardiomyopathy (Chapter 60). Cardiac amyloidosis (Chapters 60 and 194) can be seen as diffuse subendocardial enhancement, patchy enhancement, or simply difficulty in nulling normal myocardium. Patchy fibrosis is readily identified in cardiac sarcoidosis (Chapters 60 and 95) (Fig. 56-8) and may be more sensitive than endomyocardial biopsy. In iron overload conditions such as thalassemia (Chapter 165), multi-echo T1-weighted imaging of T2* can identify the extent of iron overload. Rarer causes of cardiomyopathy, such as ventricular noncompaction, Chagas' disease (Chapters 60 and 355), and takotsubo cardiomyopathy (Chapter 60), also have characteristic CMR findings. CMR is highly accurate for the noninvasive quantitative assessment of left and right ventricular volumes and ejection fraction but is rarely needed clinically for this purpose unless adequate echocardiography (Chapter 55) cannot be obtained.

Aortic Dissection, Pericardial Disease, and Masses

CMR is an excellent test to detect aortic dissection (see Fig. 78-5 in Chapter 78) or intraluminal aortic hematoma (see Fig. 78-6 in Chapter 78) in patients who are stable enough for it and have no contraindications. CMR is also an excellent test for the evaluation of chronic pericardial disease (Fig. 56-9) because it accurately identifies pericardial thickness as well as adherence of the pericardium to the epicardium in constrictive pericarditis. Real-time

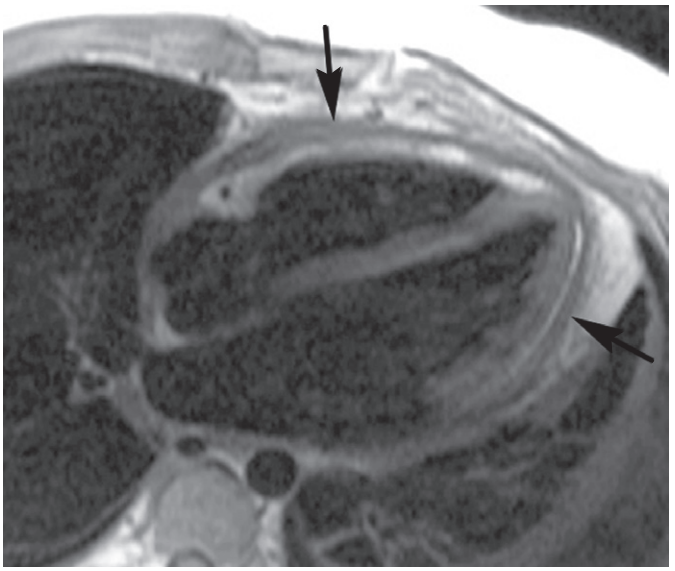

FIGURE 56-9. Magnetic resonance image of a 35-year-old man with dyspnea many years after mantle radiation for Hodgkin's lymphoma shows a thickened pericardium *(arrows)* circumferentially around the left and right ventricles.

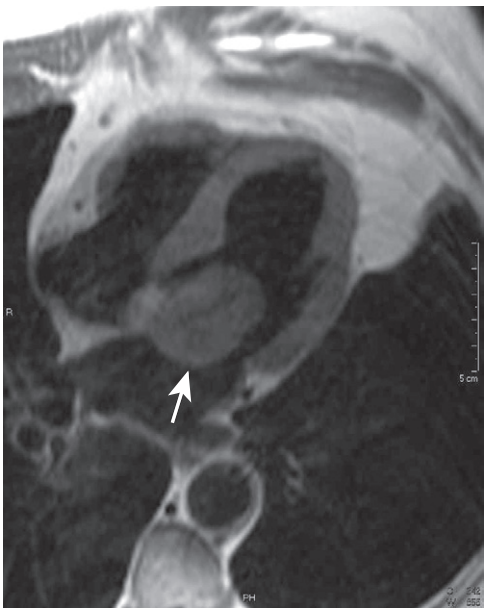

FIGURE 56-10. Diastolic magnetic resonance image of a large left atrial myxoma *(arrow)* showing that it is attached to the atrial septum and is prolapsing across the mitral valve.

imaging can demonstrate ventricular interdependence, a hallmark of this disease.

CMR is also an ideal tool to diagnose intracardiac (Fig. 56-10) and extracardiac masses such as myxomas, thrombus, and tumors, owing to its high spatial resolution and ability to perform tissue characterization.

Congenital Heart Disease

CMR is useful for the assessment of both simple and complex congenital heart disease (Chapter 69). Although atrial septal defects and ventricular septal defects in adults are generally well appreciated by echocardiography, phase velocity CMR readily quantifies blood flow through the major blood vessels, thereby facilitating accurate assessment of the ratio of pulmonary to systemic blood flow. CMR is particularly valuable for assessing abnormalities of the great vessels, such as aortic coarctation (Fig. 56-11), extracardiac anatomy, or anomalous pulmonary venous drainage, and in patients with complex congenital heart disease who have undergone prior corrective or palliative shunt surgery, such as in tetralogy of Fallot. CMR is uniquely able to measure right ventricular volumes accurately, an often important determination in this setting.

CATHETERIZATION AND ANGIOGRAPHY

MORTON KERN

Cardiac catheterization is insertion and passage of small plastic tubes (catheters) into arteries and veins to the heart to obtain radiographic images of coronary arteries and cardiac chambers (angiography and ventriculography) and to measure pressures in the heart (hemodynamics). Coronary angiography defines the site, severity, and morphology of atherosclerotic lesions, and it identifies collateral blood supply beyond occluded vessel segments. Cardiac catheterization is used not only to diagnose coronary artery, valvular (Chapter 75), and myocardial diseases (Chapter 60), but also to perform therapeutic (interventional) procedures to relieve obstructing arterial stenoses (Chapter 74), open narrowed valves, or close intracardiac defects (Chapter 69) through catheter-based, minimally invasive percutaneous techniques. These same diagnostic and therapeutic techniques are also used in the peripheral arterial circulation in a modified fashion to address carotid, renal, and peripheral vascular disease (Chapter 80), aortic aneurysms (Chapter 78), and vascular shunts (Table 57-1).

INDICATIONS AND CONTRAINDICATIONS FOR CARDIAC CATHETERIZATION

The indications to perform cardiac catheterization include the need to diagnose atherosclerotic coronary artery disease, abnormalities of cardiac muscle

TABLE 57-1 PROCEDURES THAT MAY ACCOMPANY CORONARY ANGIOGRAPHY

PROCEDURE	COMMENTS
Central venous access: femoral, internal jugular, subclavian	Uses IV access for emergency medications or fluids, temporary pacemaker; pacemaker not mandatory for most coronary angiography
Hemodynamic assessment, left heart pressures, aorta, and left ventricle	Routine for all studies
Right and left heart combined pressures	Not routine for coronary artery disease but mandatory for valvular heart disease and routine for heart failure, right ventricular dysfunction, pericardial disease, cardiomyopathy, intracardiac shunts, congenital abnormalities
Left ventriculography	Routine for all studies; may be excluded with high-risk patients and those with left main coronary or aortic stenosis, severe congestive heart failure, or renal failure
Internal mammary selective angiography	Routine for coronary bypass conduit
Pharmacologic studies: Complication of coronary spasm, use of ergonovine or acetylcholine conducted in specialized centers Use of vasodilators	Conducted routinely for coronary angiography with nitroglycerin and commonly nitric oxide used for pulmonary hypertension
Aortography	Routine for aortic insufficiency, aortic dissection, and aneurysm and may be performed with or without aortic stenosis; routine to locate bypass graft conduits not visualized by selective angiography
Cardiac pacing electrophysiologic studies	Arrhythmia evaluation routine
Interventional and special techniques	Percutaneous coronary angioplasty including balloon stenting, Rotablator, and coronary atherectomy Intracoronary pressure flow assessment of lesion severity routine Balloon catheter valvuloplasty, myocardial biopsy, atrial septal defect or patent foramen ovale defect closure, transseptal or direct left ventricular function to assess valvular heart disease and invasive interventional electrophysiologic catheter ablation
Vascular closure devices	Routinely available for patients prone to femoral artery access bleeding

From Kern MJ, ed. *The Cardiac Catheterization Handbook*, 5th ed. St. Louis: Mosby; 2010.

TABLE 57-2 INDICATIONS AND CONTRAINDICATIONS FOR CARDIAC CATHETERIZATION

INDICATIONS

1. Identification of the extent and severity of coronary artery disease and evaluation of left ventricular function
2. Assessment of the severity of valvular or myocardial disorders such as aortic stenosis and/or insufficiency, mitral stenosis and/or insufficiency, and various cardiomyopathies to determine the need for surgical correction
3. Collection of data to confirm and complement noninvasive studies
4. Determination of the presence of coronary artery disease in patients with confusing clinical presentations or chest pain of uncertain origin

ABSOLUTE CONTRAINDICATIONS

1. Inadequate facilities
2. Patient refusal

RELATIVE CONTRAINDICATIONS

1. Severe uncontrolled hypertension
2. Ventricular arrhythmias
3. Recent acute stroke
4. Severe anemia
5. Active gastrointestinal bleeding
6. Allergy to radiographic contrast
7. Acute renal failure
8. Uncompensated congestive failure (patient cannot lie flat)
9. Unexplained febrile illness and/or untreated active infection
10. Electrolyte abnormalities (e.g., hypokalemia)
11. Severe coagulopathy
12. Pregnancy
13. Uncontrolled arrhythmias, hypertension
14. Uncooperative patient or patient refusal

function, valvular abnormalities, and congenital heart disease (Table 57-2). Contraindications to cardiac catheterization are few. Absolute contraindications involve only inadequate facilities or equipment for catheterization. Relative contraindications depend on the urgency of the procedure and conditions.

TECHNIQUE OF CATHETERIZATION

After the procedure and its indications, risks, and benefits are explained to the patient, the patient is placed on the cardiac catheterization table and centered under the C-arm of the radiographic gantry (E-Fig. 57-1). After sterile preparation and draping, local anesthetic is administered over the vascular access site (most commonly the femoral but, alternatively, the radial artery). The artery is punctured, and a vascular sheath is inserted, through which the angiographic catheter is advanced over a soft spring-tipped 0.035-inch guidewire that permits safe, atraumatic passage of the catheter to the heart. The specially shaped catheters are seated and connected to a manifold to measure pressure and inject radiographic contrast media.

Coronary arteriography records the images from multiple angles by rotating the C-arm. The images are displayed and preserved on digital imaging systems.

After coronary angiography, the catheter is exchanged for a ventriculography catheter that is inserted into the left ventricle. After left ventricular (LV) pressure is measured, radiographic contrast media (approximately 35 to 45 mL) is injected under high pressure (1000 psi) to assess LV wall motion, chamber size, presence of mitral valve regurgitation, and the shape of the aortic root. The LV ejection fraction (normal is 50 to 70%), a measure of the heart function, is computed as a percentage of the diastolic volume ejected.

After the diagnostic angiograms are completed, the need for coronary revascularization (Chapter 74) is assessed. If suitable symptomatic coronary artery obstructions are present, percutaneous coronary intervention (PCI) may be performed at the same time, if discussed and consented to in advance. Alternatively, the patient may be referred for later PCI or for coronary artery bypass graft (CABG) surgery.

At the conclusion of the catheterization procedure, the catheters are removed. For the femoral artery, hemostasis is achieved either by manual compression, which requires the patient to remain stationary in bed for 4 hours, or by use of a vascular closure device while the patient remains in bed for 1 to 2 hours. For the radial approach, the arterial sheath is removed with the simple application of a specialized compression wrist band; the patient can ambulate immediately.

COMPLICATIONS OF CARDIAC CATHETERIZATION

For the diagnostic cardiac catheterization, risks are less than 0.2% for death, less than 0.5% for myocardial infarction, less than 0.07% for stroke, less than 0.5% for serious arrhythmia, and less than 1% for major vascular complications, including thrombosis and bleeding requiring transfusion or pseudoaneurysm (Table 57-3). Vascular complications occur more frequently with the femoral artery approach than with the radial artery approach; the brachial artery approach, which is used only when neither femoral nor radial access is possible, has the highest rate of vascular complications, and the radial artery has the lowest.

Patients are not routinely anticoagulated for a diagnostic catheterization, and special preparations must be made for patients who are receiving anticoagulants, patients who have diabetes or renal insufficiency, and patients who may have a potential allergy to radiographic contrast media. For the anticoagulated patient, provisions to withhold warfarin or heparin must be made

TABLE 57-3 COMPLICATIONS OF CARDIAC CATHETERIZATION

MAJOR COMPLICATIONS

1. Death
2. Cerebrovascular accident
3. Myocardial infarction, shock
4. Ventricular tachycardia/fibrillation

RARE BUT SERIOUS COMPLICATIONS

1. Aortic dissection
2. Cardiac perforation
3. Tamponade
4. Congestive heart failure
5. Contrast reaction/anaphylaxis
6. Nephrotoxicity
7. Arrhythmias, including heart block, asystole, supraventricular tachyarrhythmias
8. Hemorrhage, including local or retroperitoneal
9. Infection
10. Protamine reaction
11. Vascular complications, including thrombosis, embolus, vascular injury, pseudoaneurysm

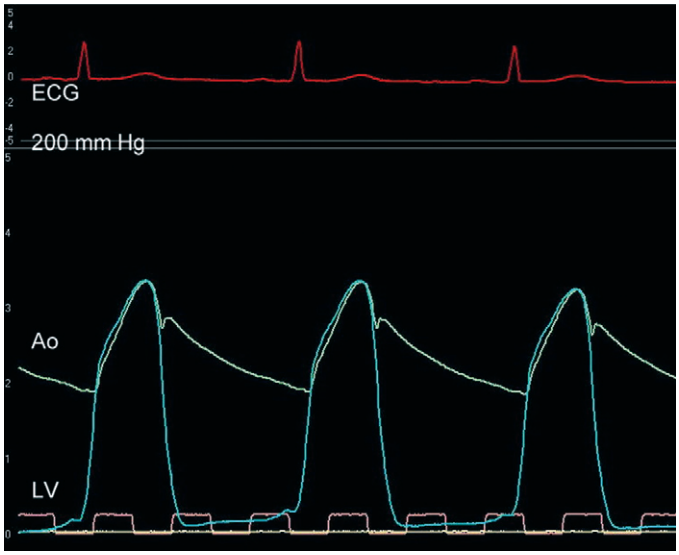

FIGURE 57-1. Normal left ventricular (LV) and aortic (Ao) pressures measured with high-fidelity pressure transducers.

to reduce the potential for femoral puncture site bleeding complications (e.g., retroperitoneal hematoma or pseudoaneurysm). For example, a patient taking warfarin after an aortic valve replacement would have the warfarin withheld for about 3 days before the catheterization, the international normalized ratio would be monitored, and the patient might be administered bridging heparin to the time of the procedure; warfarin would be restarted after the procedure.

For elective catheterizations in patients with insulin-dependent diabetes, half of the usual morning dose of insulin generally is given the morning of the procedure to provide reasonable diabetic coverage and to avoid hypoglycemia. Metformin should be withheld before study. Medications for hypertension and other medical conditions are continued up to and including the morning of the procedure.

Contrast-induced nephropathy, which generally becomes clinically apparent 2 to 3 days after the catheterization, is uncommon. Patients with diabetes or renal insufficiency and patients who are dehydrated from any cause are at a three- to five-fold increased risk for contrast-induced renal failure. For patients with renal insufficiency and those at high risk for contrast-induced renal failure because of diabetes or dehydration, hydration and treatment with *N*-acetylcysteine (Mucomyst, 600 mg evening and morning of procedure) are used routinely in most catheterization laboratories in an attempt to reduce the risk for contrast-induced renal failure.

Contrast media reactions are rare, with an overall incidence of 5% or less, but potentially serious. Adverse reactions occur in 10 to 12% of patients with a history of allergy and in 15% of patients with reported reaction on a previous contrast radiographic examination. There are three types of contrast allergies: cutaneous and mucosal manifestations, smooth muscle and minor anaphylactoid responses, and cardiovascular and major anaphylactoid responses involving laryngeal or pulmonary edema. Pretreatment with corticosteroids is helpful in reducing all types of reactions except urticaria. Patients reporting previous allergic reactions to contrast media should be premedicated with prednisone (60 mg orally the evening before and morning of the procedure) and diphenhydramine (25 to 50 mg orally the morning of the procedure). Patients with known prior anaphylactoid reactions should be pretreated with steroids in the same dose as above. Routine treatment with a histamine-2 blocker (e.g., cimetidine) does not appear to have any benefit.

Hypotension during and after cardiac catheterization may occur from a vasovagal response, bleeding (often occult), myocardial ischemia or infarction, or cardiac tamponade. Vasovagal hypotension is treated with volume and atropine (0.5 to 1.0 mg intravenously). Hypotension due to cardiac tamponade, which may occur during or after PCI, requires reversal of anticoagulation and urgent pericardiocentesis (Chapter 77).

Pulmonary congestion may develop in patients with marginal LV function or critical valvular heart disease. Congestion compromising respiratory and hemodynamic function is an emergency treated with oxygen, diuretics, nitroglycerin, inotropic agents, and intraaortic balloon pumping as indicated (Chapter 107).

Chest pain during coronary angiography is unusual, but myocardial ischemia with pain and ST segment changes may occur during PCI (Chapter 74). Treatment with nitroglycerin, heparin, and antiplatelet medications usually controls myocardial ischemia before revascularization (Chapter 72). Minor arrhythmias (e.g., atrial or ventricular premature beats, brief episodes of supraventricular tachycardia) are common and usually resolve without treatment. Ventricular tachycardia or fibrillation is a rare occurrence but requires prompt defibrillation (Chapter 63).

HEMODYNAMIC DATA OBTAINED DURING CARDIAC CATHETERIZATION

Hemodynamic data are the pressure and flow measurements generated by the heart and recorded during the catheterization procedure. A pressure wave is created by cardiac muscular contraction and is transmitted from the cardiac chamber through the arterial circuit (Fig. 57-1). The pressure waves are measured using the fluid-filled catheters with a pressure transducer, which converts the mechanical pressure to an electrical signal that is displayed on a video monitor.

Simultaneous pressure measurements across the heart valves are used to diagnose valve function. Hemodynamic data also include sampling multiple blood oxygen saturations throughout the right and left sides of the heart for intracardiac shunt identification. Cardiac output is commonly measured by a thermodilution technique. Hemodynamic data permit calculation of vascular and pulmonary resistances and cardiac valve areas (see Table 52-1 in Chapter 52). Complete hemodynamic data requiring right and left heart catheterization are indicated to evaluate dyspnea of any cause; to confirm echocardiographic findings when data are not concordant with clinical or other testing results; and to determine the status of valvular heart disease, cardiomyopathy, and constrictive or restrictive coronary physiology.

Complications of right heart catheterization are rare. The most common problem is transient arrhythmia resulting from mechanical stimulation by the catheter as it passes through the right ventricular outflow tract. In patients with left bundle branch block, a temporary pacemaker may be needed if right bundle branch block occurs during right-sided heart catheterization.

Examples of Hemodynamics for Valvular Heart Disease

The severity of a valvular stenosis is based on the pressure gradient and flow across the valve. In patients with suspected aortic stenosis, a transvalvular pressure gradient should be obtained whenever there is conflicting clinical or echocardiographic data. The pressure recordings most commonly used to assess the aortic valve gradients are the left ventricle and the femoral artery through a side arm of the femoral artery sheath (Fig. 57-2). The normal aortic

valve area is 2.5 to 3.5 cm^2 in adults. Severe aortic valve stenosis is associated with valve areas smaller than 1.0 cm^2.

In patients with mitral stenosis, the valve gradient usually is measured using the LV and pulmonary capillary wedge pressures (Fig. 57-3). The most accurate method to compute the mitral stenosis gradient uses the left atrial (obtained by transseptal puncture) and LV pressures. The normal mitral valve area is 4 to 6 cm^2. Valve areas smaller than 1.0 to 1.2 cm^2 are considered severe mitral stenosis.

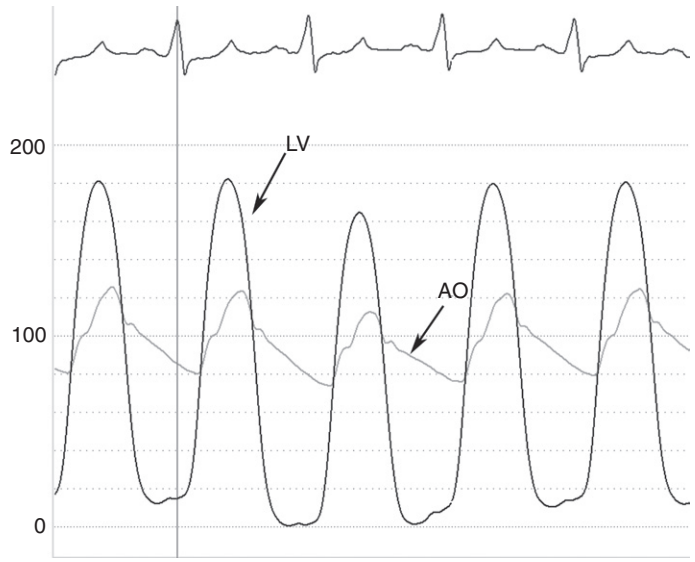

FIGURE 57-2. Hemodynamics of aortic stenosis. Left ventricular (LV) and aortic (AO) pressures are measured simultaneously. Aortic pressure is measured from a central position.

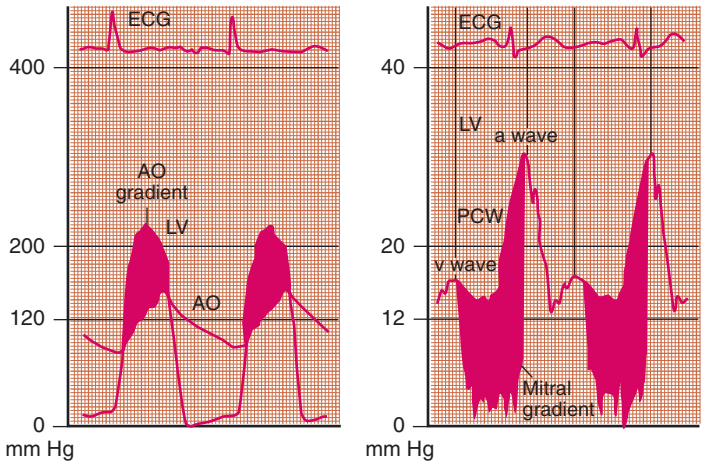

FIGURE 57-3. Examples of the hemodynamic findings in aortic and mitral stenosis. *Left panel,* Simultaneous recording of aortic (AO) and left ventricular (LV) pressure shows a 50-mm Hg systolic pressure gradient. *Right panel,* There is a 15-mm Hg diastolic gradient between the pulmonary capillary wedge pressure (PCW) and the LV pressure. The a wave in the PCW tracing is larger than the v wave, indicating increased resistance to LV filling in this patient. ECG = electrocardiogram.

In patients with mitral regurgitation, the hemodynamics often show a characteristic large v wave on the pulmonary capillary wedge (PCW) tracing (Fig. 57-4). The grading of mitral regurgitation is on a semiquantitative 1 to 4 severity scale based on the amount of contrast seen passing backward from the left ventricle through the incompetent mitral valve into the left atrium. Grade 1 angiographic mitral regurgitation demonstrates a brief puff of contrast filling the left atrium and emptying immediately; grade 2 shows contrast filling the left atrium on 3 beats with moderate density; grade 3 shows contrast filling immediately and moderate density persisting for 2 to 3 beats; and grade 4 shows contrast filling the entire left atrium, often including the appendage, with a density equal to that of the left ventricle for several beats after injection.

CORONARY ANGIOGRAPHY

Coronary angiography visualizes the epicardial arteries, branches, collaterals, and anomalies to diagnose and treat in patients with coronary artery disease (Fig. 57-5). In anticipation of PCI, the angiogram documents not only the presence and location of stenoses but also proximity to major and minor side branches, luminal abnormalities (e.g., thrombi), areas of calcification, and collateral supply, which will influence the decision and techniques used for revascularization. For the two-dimensional radiographic images to depict the three-dimensional coronary tree, multiple angulations of the radiographic imaging system are required.

Assessment of Coronary Stenoses

The degree of a stenosis is most often reported as the estimated percentage diameter luminal reduction of the most severely narrowed segment compared with the adjacent angiographically normal vessel segment, seen in the worst radiographic projection (Fig. 57-6). Because the operator uses visual estimations, an exact evaluation is impossible with less than 20% variation between readings of two or more experienced angiographers. The severity of a stenosis alone should not always be assumed to be associated with abnormal physiology (flow) and ischemia. Moreover, coronary artery disease is a diffuse process, so minimal luminal irregularities on angiography may represent significant, albeit nonobstructive, coronary artery disease at the time of angiography. The precise physiologic impact or morphologic detail of stenosis can be made with specialized catheters and sensor-tipped guidewires. For example, intermediately severe lesions (40 to 70% narrowed) without prior evidence of ischemia can be assessed using a pressure sensor guidewire to measure the translesional pressure during maximal blood flow (e.g., hyperemia induced by adenosine). This pressure measurement, which is called the *fractional flow reserve* (FFR), represents the percentage of normal flow across the stenosis. FFR values higher than 0.80 are considered nonischemic and do not require revascularization. Conversely, if the FFR is lower than 0.80, PCI may be undertaken. The lesion's length, true diameter, eccentricity, and degree of calcium involvement can be determined by intravascular ultrasound catheter-based imaging (IVUS); such information can help guide subsequent PCI (Fig. 57-7).

Coronary Artery Anomalies

Coronary artery anomalies may be present in patients with chest pain syndromes or in young individuals who have survived sudden death. The

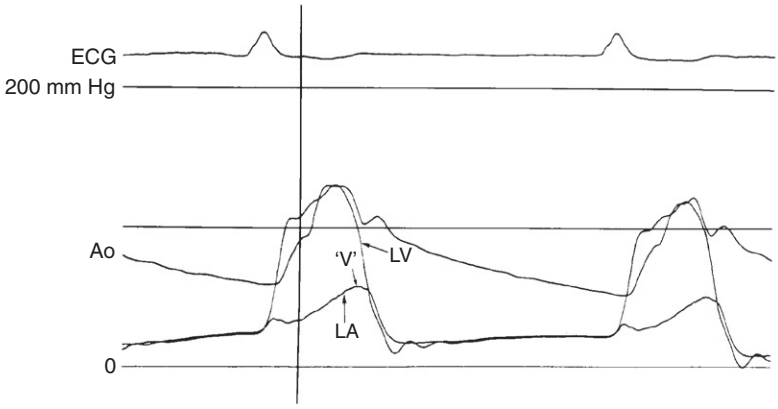

FIGURE 57-4. Hemodynamic tracings in a patient with mitral regurgitation characterized by giant v wave ('V') in the left atrial pressure (LA). This v wave corresponds to marked increase in flow and volume into the left atrium. Ao = aortic pressure; LV = left ventricular pressure.

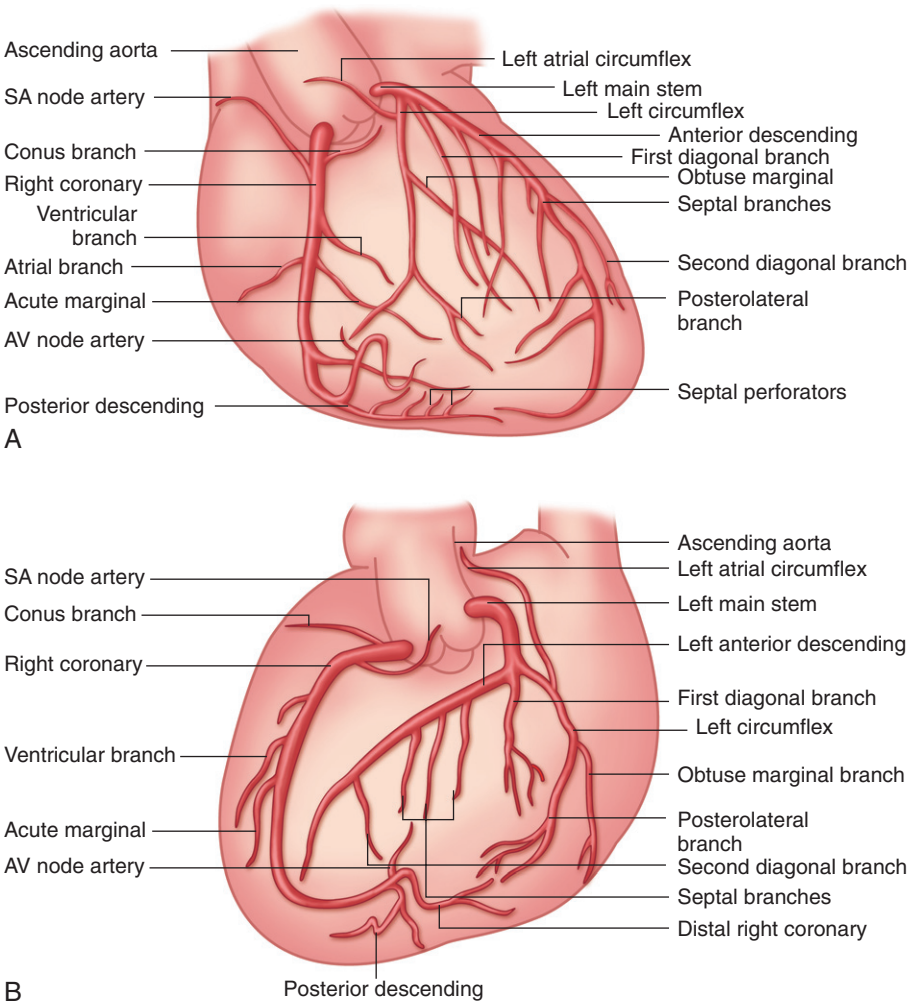

FIGURE 57-5. Coronary vessels. The right anterior oblique (**A**) and left anterior oblique (**B**) views are shown. The major arteries are the left main, left anterior descending, circumflex, and right coronary arteries. AV = atrioventricular; SA = sinoatrial. FIGURE 57-6. Example of a significant stenosis in the right coronary artery.

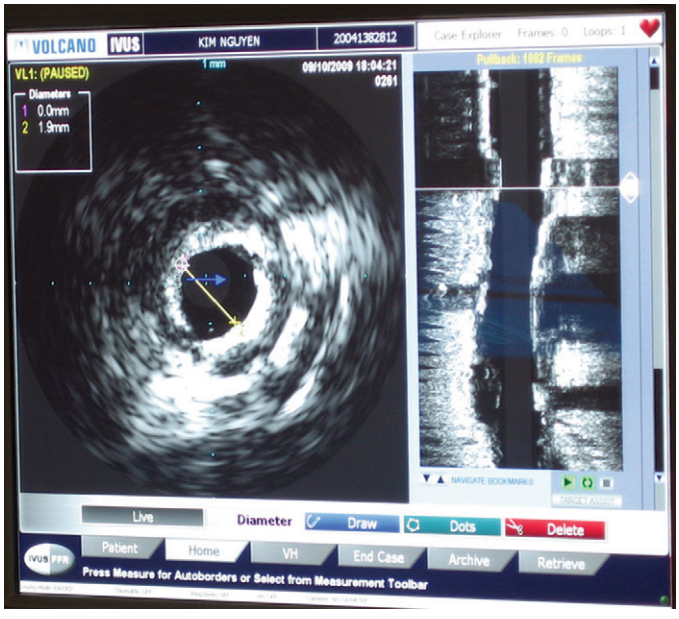

FIGURE 57-7. Angiographic monitor display of intravascular ultrasound (IVUS) image of coronary artery during percutaneous coronary intervention. Precise dimensions of the artery and lumen are provided.

angiographic appearance of coronary anomalies is not always straightforward, and computed tomographic angiography (Chapter 56) has become the diagnostic modality best suited to delineate the origin and course of the anomaly (Fig. 57-8).

At the time of coronary angiography, the misdiagnosis of an unsuspected anomalous origin of a coronary artery is a potential problem. Because the natural history of a patient with an anomalous origin of a coronary artery may depend on the anatomic pathway of the anomalous vessel, it is important to define accurately the origin and course of the vessel. Even experienced angiographers have difficulty delineating the true course of the anomalous vessel.

The most critical coronary anomaly is when the left main coronary artery arises from the right cusp and traverses a course between the aorta and pulmonary artery. The artery's initial course through the aortic wall creates a narrow oval opening; with aortic stretch during exercise, coronary blood flow is limited.

Ventriculography

The left ventriculogram, an integral part of nearly every coronary angiographic study, provides information on the motion of the walls of the heart (Fig. 57-9), LV volumes during systole and diastole, the LV ejection fraction, the rate of ejection, the quality of contractility, the presence of hypertrophic myopathy, and valvular regurgitation. The normal pattern of LV contraction is a coordinated, uniform, almost concentric inward motion of all points along the ventricular inner surface during systole. Uncoordinated contractions are named according to their severity (e.g., moderate or severe hypokinesis, akinesis, and aneurysm-dyskinesis). Focal abnormal wall motion indicates the presence of ischemia, infarction, or aneurysm.

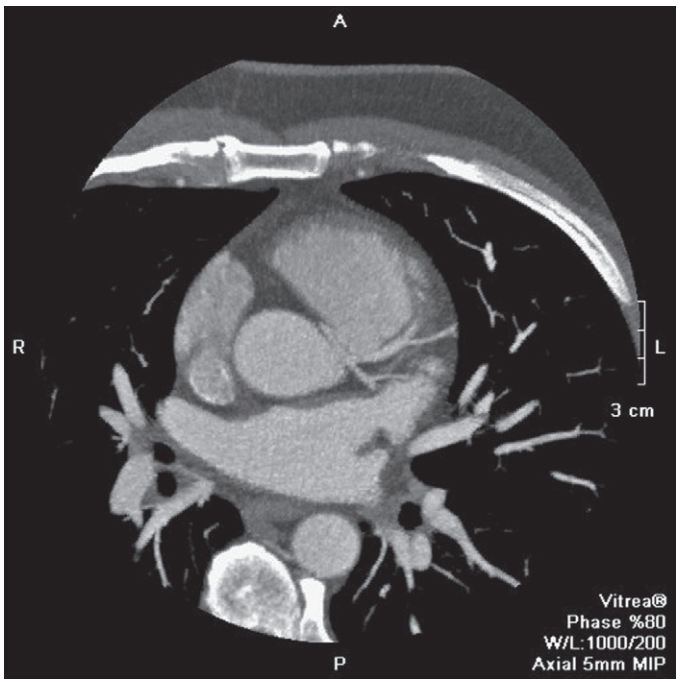

FIGURE 57-8. Frame from a computed tomographic angiographic study showing the origin of the left main coronary artery arising from the right sinus of Valsalva and coursing anteriorly between the aorta and pulmonary artery.

ADDITIONAL PROCEDURES PERFORMED IN THE CATHETERIZATION LABORATORY

Noncardiac Angiography

Other cardiovascular angiographic studies that may accompany coronary angiography and left ventriculography include aortography (Chapter 78), pulmonary angiography (Chapter 98), and peripheral vascular angiography of iliac and lower extremity arteries (Chapters 80 and 81) or renal arteries (Chapter 127).

Electrophysiologic Studies and Ablation Techniques

An electrophysiologic study (EPS) is an invasive procedure that involves the placement of multipolar catheter electrodes at various intracardiac sites (Chapter 62). The general purposes of an EPS are to characterize the electrophysiologic properties of the conduction system, induce and analyze the mechanism of arrhythmias, and evaluate the effects of therapeutic interventions. Electrode catheters are routinely placed in the right atrium, across the tricuspid valve annulus in the area of the atrioventricular node and His bundle, the right ventricle, the coronary sinus, and sometimes the left ventricle. EPS is routinely used in the clinical management of patients who have supraventricular and ventricular arrhythmias (Chapters 64 and 65).

Transseptal Heart Catheterization

Transseptal access using a long catheter with a needle to puncture the thin atrial septal membrane at the fossa ovalis permits placement of a catheter into the left atrium and then the LV. It is an established technique used to acquire precise, high-quality hemodynamic data for patients with aortic stenosis, mitral valve disease (both stenosis and regurgitation), and hypertrophic cardiomyopathy (outflow tract obstructive gradient) and to provide access for valvuloplasty techniques (Chapter 75). The risks of transseptal catheterization, which include punctures of the aortic root, the coronary sinus, or the posterior free wall of the atrium, are potentially lethal problems.

Endomyocardial Biopsy

Endomyocardial biopsy procedures use venous access from the internal jugular vein or femoral vein to insert a flexible metal bioptome to obtain four to six 1-mm^3 pieces of right ventricular myocardium. There are two definitive indications for endomyocardial biopsy: monitoring for cardiac transplant rejection (Chapter 82) and detection of anthracycline cardiotoxicity (Chapter 60). Other indications in selected patients include diagnosis of cardiomyopathy and myocarditis and differentiation between restrictive and constrictive cardiomyopathies.

Other Procedures

Pericardiocentesis (Chapter 77) and PCI (Chapter 74) are performed in the catheterization laboratory for specific indications. Other procedures include balloon valvuloplasty for stenotic heart valves (Chapter 75) and closure of an atrial septal defect or patent foramen ovale (Chapter 69), which is confirmed by typical oxygen saturations detected at catheterization. Percutaneous implantation of prosthetic heart valves is a newer procedure that may become routine for many laboratories in the future.

58 HEART FAILURE: PATHOPHYSIOLOGY AND DIAGNOSIS

BARRY M. MASSIE

HEART FAILURE

DEFINITION

Heart failure is a heterogeneous syndrome in which abnormalities of cardiac function are responsible for the inability of the heart to pump blood at an output sufficient to meet the requirements of metabolizing tissues or the ability to do so only at abnormally elevated diastolic pressures or volumes. The heart failure syndrome is characterized by signs and symptoms of intravascular and interstitial volume overload (shortness of breath, rales, elevated jugular venous pressure, and edema) or manifestations of inadequate tissue perfusion (impaired exercise tolerance, fatigue, signs of hypoperfusion, renal dysfunction), or both. Heart failure may occur as a result of (1) impaired myocardial contractility (systolic dysfunction, commonly characterized as reduced left ventricular [LV] ejection fraction [EF]); (2) increased ventricular stiffness or impaired myocardial relaxation in the absence of systolic dysfunction (diastolic dysfunction, which is commonly associated with a relatively normal LVEF and is often termed *heart failure with preserved EF*); (3) a variety of other cardiac abnormalities, including obstructive or regurgitant valvular disease, intracardiac shunting, or disorders of heart rate or rhythm; or (4) states in which the heart is unable to compensate for increased peripheral blood flow or metabolic requirements. In adults, LV involvement is almost always present even if the manifestations are primarily those of right ventricular (RV) dysfunction (fluid retention without dyspnea or rales). Heart failure may result from an acute insult to cardiac function, such as a large myocardial infarction (MI), or, more commonly, from a chronic process. The focus in this chapter is on the syndrome of *chronic* heart failure, including its presentation in an acutely decompensated state. The most common causes of de novo acute heart failure, such as MI (Chapter 73), valvular disease (Chapter 75), myocarditis (Chapter 60), and cardiogenic shock (Chapter 107), are discussed elsewhere.

EPIDEMIOLOGY

Both the incidence and the prevalence of heart failure are growing, as is the resulting burden of deaths and hospitalizations. Although these trends primarily reflect the strong association between heart failure and advancing age, they also are influenced by the rising prevalence of precursors such as hypertension, diabetes, dyslipidemia, and obesity in industrialized societies and the improved long-term survival of patients with ischemic and other forms of heart disease. The annual incidence of heart failure rises from less than 1 per 1000 patient years among those younger than 45 years, to 10 per 1000 patient years for those older than 65 years, to 30 per 1000 patient years (3%) for those older than 85 years. Prevalence figures follow a similar exponential pattern, increasing from 0.1% before 50 to 55 years of age to almost 10% after age 80 years. About 20% of U.S. adults will develop heart failure in their lifetimes. Overall in the United States, the estimated prevalence of heart failure is 5.8 million patients, with an annual incidence of 670,000 new cases per year. Heart failure results in 1.1 million hospital discharges and causes or contributes to 280,000 deaths per year. Although the relative incidence and prevalence of heart failure are lower in women than men, women constitute at least half of the cases because of their longer life expectancy. Any condition that causes myocardial necrosis or produces chronic pressure or volume overload can induce myocardial dysfunction and heart failure. In developed countries, the causes of heart failure have changed greatly over several decades. Valvular heart disease, with the exception of calcific aortic stenosis, has declined markedly, whereas coronary heart disease has become the predominant cause in men and women, being responsible for 60 to 75% of cases. Hypertension, although less frequently the primary cause of heart failure than in the past, continues to be a major factor in 75%, including most of the patients with coronary disease.

Prevention of Heart Failure

Treatment of hypertension, with a focus on the systolic pressure, reduces the incidence of heart failure by 50%. This intervention remains effective even in patients older than 75 years (Chapter 67). Any intervention that reduces the risk of a first or recurrent MI (Chapter 51) will also reduce the incidence of heart failure. In patients with reduced LVEF, angiotensin-converting enzyme (ACE) inhibitors, aldosterone blockers, and β-blockers prevent or delay progressive LV dysfunction and dilation and the onset or worsening of heart failure. Well-timed intervention for progressive valvular disease affords another opportunity to prevent eventual heart failure (Chapter 75).

Stages of Heart Failure

The recognition that most patients who develop heart failure have underlying risk factors or predisposing clinical conditions that precede its development, usually by many years, has led to a greater emphasis on early detection and treatment of predisposing factors, on the staging of heart failure (Fig. 58-1), and on early intervention. *Stage A* heart failure includes patients who are at risk for development of heart failure but do not as yet have either symptoms or apparent structural abnormalities of the heart; this includes patients with hypertension, atherosclerotic disease, diabetes, obesity, or the

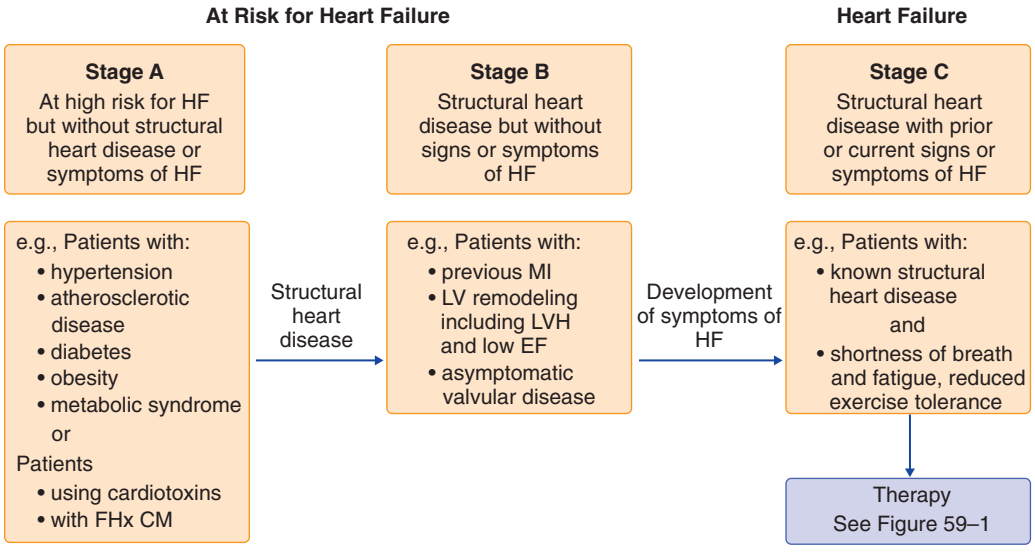

FIGURE 58-1. Stages of heart failure. EF = ejection fraction; FHx CM = family history of cardiomyopathy; HF = heart failure; LV = left ventricle; LVH = left ventricular hypertrophy; MI = myocardial infarction. (Modified from Hunt SA. ACC/AHA 2005 guideline update for the diagnosis and management of chronic heart failure in the adult: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines [Writing Committee to Update the 2001 Guidelines for the Evaluation and Management of Heart Failure]. *J Am Coll Cardiol.* 2005;46:e1-e82.)

metabolic syndrome and individuals with ongoing excessive alcohol intake, use of cardiotoxic drugs, a familial history of cardiomyopathy, or a known genetic abnormality associated with cardiomyopathy (Chapter 60). *Stage B* encompasses asymptomatic patients who have demonstrable structural abnormalities that predispose to heart failure, such as prior MI, LV hypertrophy diagnosed by electrocardiography or echocardiography, reduced LVEF or LV dilation, or asymptomatic but hemodynamically significant valvular heart disease. *Stage C* heart failure includes patients who have exhibited symptoms or signs of heart failure. These patients may have improved to the point of being relatively asymptomatic, but they still are classified as stage C and usually continue to receive treatment with agents that are known to improve their natural history, such as β-blockers and inhibitors of the renin-angiotensin-aldosterone system.

PATHOBIOLOGY

Differing Mechanisms of Heart Failure

Heart failure is a syndrome that may result from many cardiac and systemic disorders (Table 58-1). Some of these disorders, at least initially, do not involve the heart, and the term *heart failure* may be confusing. Even in high-output states, however, the patient may present with the classic findings of exertional dyspnea and edema *(high-output heart failure)* that resolve if the underlying disorder is eliminated. If they persist, these conditions may impair myocardial performance secondarily as a result of chronic volume overload or direct deleterious effects on the myocardium. Other conditions, including mechanical abnormalities, disorders of rate and rhythm, and pulmonary abnormalities, do not primarily affect myocardial function but are frequent causes of heart failure.

Abnormalities of Cardiac Function

Systolic Function

In the normal left ventricle, stroke volume increases over a wide range of end-diastolic volumes (the Frank-Starling effect). If contractility (or the inotropic state of the myocardium) is enhanced, such as during exercise or catecholamine stimulation, this increase is correspondingly greater (Table 58-2). In the failing heart with depressed contractility, there is relatively little increment in systolic function with further increases in LV volume, and the ventricular function curve is shifted downward and flattened (Chapter 52). In the clinical setting, systolic dysfunction is characterized by depressed stroke volume despite elevated ventricular filling pressures. The resulting symptoms are those of pulmonary or systemic congestion, activity intolerance, and organ dysfunction.

Assessment of systolic function clinically is more problematic. The most useful measure is the LVEF (stroke volume/end-diastolic volume, usually expressed as a percentage), which reflects a single point on the ventricular function curve. The EF is *load dependent*, however, meaning that alterations in afterload (see later discussion) can affect it independently of contractility. In addition, mitral regurgitation, which facilitates ejection into the low-pressure left atrium, may lead to an overestimation of systolic function by the EF. Nonetheless, with the exceptions indicated earlier, when the EF is normal (>50 to 55% in most laboratories), systolic function is usually adequate. LVEFs that are mildly (40 to 50%), moderately (30 to 40%), or severely (<30%) depressed are associated with reduced survival and, in the severe range, with reduced functional reserve, if not overt symptoms of heart failure. Cardiac output, in contrast, is a poor measure of systolic function because it can be affected markedly by heart rate, systemic vascular resistance, and the degree of LV dilation.

Diastolic Function

Diastole is the portion of the cardiac cycle between aortic valve closure and mitral valve closure. Diastole consists of three phases: (1) active relaxation, (2) the conduit phase, and (3) atrial contraction. If relaxation is delayed or if the myocardium is abnormally stiff (e.g., an excessively steep relationship between change in pressure and change in volume [$\Delta P/\Delta V$]), passive filling may be impaired and atrial pressures are abnormally elevated. In this setting of a noncompliant ventricle (compliance is the inverse of stiffness—the change in volume for a given change in pressure), atrial contraction is responsible for a disproportionately large amount of diastolic filling.

The importance of abnormalities of diastolic function in the pathogenesis of heart failure is increasingly appreciated. Because relaxation is energy dependent, it frequently is impaired in the presence of ischemia or hypoxemia. Recurring myocardial ischemia, myocardial hypertrophy, and aging all are associated with interstitial fibrosis and impaired diastolic function.

TABLE 58-1 PATHOGENESIS OF HEART FAILURE

IMPAIRED SYSTOLIC (CONTRACTILE) FUNCTION
Ischemic damage or dysfunction
Myocardial infarction
Persistent or intermittent myocardial ischemia
Hypoperfusion (shock)
Chronic pressure overloading
Hypertension
Obstructive valvular disease
Chronic volume overload
Regurgitant valvular disease
Intracardiac left-to-right shunting
Extracardiac shunting
Nonischemic dilated cardiomyopathy
Familial/genetic disorders
Toxic/drug-induced damage
Immunologically mediated necrosis
Infectious agents
Metabolic disorders

TABLE 58-2 MAJOR DETERMINANTS OF CARDIAC PERFORMANCE

Ventricular systolic function (contractility)
Ventricular diastolic function
Relaxation
Stiffness
Ventricular preload
Ventricular afterload
Cardiac rate and conduction
Myocardial blood flow

Ventricular Preload

In the intact heart, preload is best characterized by the end-diastolic volume or pressure, which are indirect indicators of end-diastolic fiber length (Chapter 52). The performance of the normal left ventricle is highly preload dependent, but the failing heart operates at high preloads and on the flat part of the LV function curve (see Fig. 52-3 in Chapter 52). In contrast to the normal ventricle, an increase in preload does not improve systolic function but worsens pulmonary congestion further. Preload reduction by diuresis or by reduction of venous return with venodilating agents generally has a beneficial effect on symptoms of heart failure.

Ventricular Afterload

LV afterload frequently is equated with arterial pressure or systemic vascular resistance, but a more accurate measurement of afterload is systolic wall stress (Chapter 52), defined as follows:

$$\text{Systolic wall stress} = (\text{Pressure} \times \text{radius of left ventricle}) \div (2 \times \text{thickness of left ventricle})$$

At any given arterial pressure, afterload is increased with a dilated, thin-walled ventricle and decreased with a smaller or thicker ventricle. Increased afterload has an effect similar to that of depressed contractility, so afterload reduction can improve cardiac performance.

Heart Rate and Rhythm

Heart rate affects cardiac performance by two mechanisms. First, increasing the heart rate enhances the inotropic state by upregulating cytosolic calcium concentrations. Second, heart rate is an important determinant of cardiac output and is the primary mechanism by which cardiac output is matched to demand in situations such as exercise. Because stroke volume is relatively fixed in the failing heart, heart rate becomes a major determinant of cardiac output. Chronic tachycardia impairs ventricular performance, however, and cardiac function can decline rapidly with sustained tachyarrhythmias (as seen in atrial fibrillation, atrial flutter, chronic atrial tachycardia, and even inappropriate sinus tachycardia).

Optimal cardiac performance depends on a well-coordinated sequence of contraction. Normal atrioventricular conduction times (0.16 to 0.20 second) enhance the contribution of atrial contraction to LV filling, which is particularly important in the noncompliant ventricle. Patients with heart failure frequently have intraventricular conduction abnormalities, which result in dyssynchronous contractions, such that the septum and parts of the anterior wall begin contracting only after systole has ended in other regions. Cardiac resynchronization therapy can prevent the onset of heart failure in patients with significant ventricular dyssynchrony, usually manifest electrically as a left bundle branch block.

Myocardial Blood Flow and Oxygen Requirements

In the normal heart, myocardial blood flow is closely coupled to oxygen requirements, and it is not ordinarily considered a determinant of cardiac performance. However, myocardial ischemia is associated with a rapid decline in contractile function that may persist long beyond the episode (myocardial stunning). Chronically inadequate blood flow may lead to a reduction in contractility, which reestablishes the balance between oxygen delivery and demands (hibernation). Low arterial diastolic pressures may interfere with the autoregulatory reserve of the coronary circulation, which is limited at diastolic pressures of less than 60 mm Hg. Endothelial dysfunction, which is common in patients with heart failure, also may limit blood flow. At the same time, tachycardia, increased afterload, and substantial LV hypertrophy increase myocardial oxygen requirements. Inadequate myocardial blood flow plays an important role in the pathogenesis of cardiac dysfunction, sometimes even in patients without obstructive coronary disease.

Genetic Causes of Dilated Cardiomyopathy

Although much less is known about the genetics of dilated cardiomyopathy than that of hypertrophic cardiomyopathy (Chapter 60), several forms of familial cardiomyopathy have been recognized, most of which are inherited in an autosomal dominant pattern. Mutations of genes encoding for nuclear membrane proteins (emerin, lamin) or for contractile or cytoskeletal proteins (desmin, a cardiac myosin, vinculin) have been identified. Cardiomyopathy also is associated with muscular dystrophies (Duchenne's, Becker's, and limb-girdle dystrophies; Chapter 429) and other forms of myopathy. As research in this area burgeons, it is estimated that genetic abnormalities may be involved in 20 to 30% of cases of idiopathic dilated cardiomyopathy.

TABLE 58-3 NEUROHORMONES THAT MAY BE INCREASED IN CHRONIC HEART FAILURE

Norepinephrine	Natriuretic peptides
Epinephrine	Endothelin
Plasma renin activity	Endorphins
Angiotensin II	Calcitonin gene–related peptide
Aldosterone	Growth hormone
Prostaglandins	Cortisol
Vasopressin	Proinflammatory cytokines
Neuropeptide Y	Neurokinin A
Vasoactive intestinal peptides	Substance P

Heart Failure Syndrome

Chronic heart failure is a multifaceted syndrome with diverse presentations (Fig. 58-2). The initial manifestations of hemodynamic dysfunction are a reduction in stroke volume and a rise in ventricular filling pressures, perhaps in the basal state but consistently under conditions of increased systemic demand for blood flow. These changes have downstream effects on cardiovascular reflexes and systemic organ perfusion and function, which in turn stimulate a variety of interdependent compensatory responses involving the cardiovascular system, neurohormonal systems, and alterations in renal physiology. It is this constellation of responses that leads to the characteristic pathophysiology of the heart failure syndrome. Recognition of the role of neurohormonal activation in heart failure has grown with the increasing understanding of its pathophysiology and with evidence that blockade of some of these responses can have a profound effect on the natural history of the disease (Table 58-3). The number of hormonal systems that are known to be activated in heart failure continues to grow.

Neurohormonal Responses

Sympathetic Nervous System

Initial activation of the sympathetic nervous system probably results from reduced pulse pressures, which activate arterial baroreceptors, and renal hypoperfusion. Evidence for its activation comes from elevated levels of circulating norepinephrine, direct sympathetic nerve recordings showing increased activity, and increased release of norepinephrine by several organs, including the heart. As cardiac function deteriorates, responsivity to norepinephrine diminishes, as evidenced by baroreceptor desensitization and downregulation of cardiac adrenergic receptors and signal transduction. This desensitization may further stimulate sympathetic responses.

The adaptive role of norepinephrine is to stimulate heart rate and myocardial contractility and to produce vasoconstriction. These actions reverse the depression of cardiac output and blood pressure. Increased levels of plasma norepinephrine are associated with a worse prognosis, although it is unclear

whether this is a cause-and-effect relationship. There is also convincing, albeit circumstantial, evidence that norepinephrine has adverse effects on the myocardium. In this regard, β-adrenoceptor blockade, which once was considered dangerous in heart failure because it would interfere with important compensatory mechanisms, consistently improves LV function and prognosis. The roles of other catecholamines in heart failure remain undefined.

Renin-Angiotensin-Aldosterone System

Elements of the renin-angiotensin-aldosterone system are activated relatively early in heart failure. The presumptive mechanisms of induction include renal hypoperfusion, β-adrenergic system stimulation, and hyponatremia. All may be activated further by diuretic therapy. Angiotensin II increases blood pressure by vasoconstriction; it enhances glomerular filtration by increasing renal pressure and maintaining glomerular flow through its intrarenal hemodynamic effects. Aldosterone causes sodium retention, which restores normal cardiac output by enhancing intravascular volume. These adaptations have deleterious consequences, however. Excessive vasoconstriction can depress LV function, and sodium retention increases already elevated ventricular filling pressures. There also is experimental evidence indicating that angiotensin II may have pathologic effects on the myocardium and may induce vascular hypertrophy, whereas aldosterone induces myocardial fibrosis. The striking success of ACE inhibitors and aldosterone blockers in improving the natural history of heart failure suggests that the adverse effects of renin-angiotensin-aldosterone activation may outweigh the benefit in patients with or at risk of heart failure.

Other Neurohormonal Systems

Levels of several natriuretic peptides are elevated consistently in heart failure, and they may counterbalance the vasoconstricting and sodium-retaining actions of the renin-angiotensin-aldosterone and sympathetic nervous systems. However, the renal responses to these natriuretic hormones are often downregulated in patients with heart failure, so they do not have the same natriuretic effects in patients with chronic heart failure that they manifest in normal individuals. Elevated circulating and tissue levels of vasodilating prostaglandins may improve glomerular hemodynamics, and inhibitors of prostaglandin synthesis (including aspirin and other nonsteroidal anti-inflammatory agents) interfere with the hemodynamic and renal actions of ACE inhibitors.

Endothelin and arginine vasopressin are elevated in many patients with heart failure, and interference with their actions may promote vasodilation and aquaresis. Arginine vasopressin induces vasoconstriction through a vascular (V-1) receptor and reduces free water clearance through a renal tubular (V-2) receptor. Endothelin causes prolonged vasoconstriction, reductions in glomerular filtration, and pulmonary arteriolar constriction. Although endothelin is a theoretically attractive target for therapy, clinical trials with endothelin antagonists have been negative or even shown harm, thereby indicating that interdiction of neurohormonal activation is not uniformly beneficial.

Cytokine Activation

Circulating levels of many proinflammatory cytokines, including tumor necrosis factor-α (TNF-α), interleukin-1β, and interleukin-6, are elevated in patients with relatively severe heart failure and may be involved in the syndrome of cardiac cachexia. These cytokines also may induce contractile dysfunction, myocardial fibrosis, and myocyte necrosis, perhaps by mediating some of the deleterious responses to catecholamines and angiotensin II. Nonetheless, trials using antagonists of TNF-α have not shown clinical benefit.

Altered Renal Physiology

In most patients with chronic heart failure, the kidneys are anatomically and structurally normal. Reduced blood pressure, diminished stroke volume, and reduced renal perfusion pressure and flow are sensed as reduced blood volume by the high-pressure baroreceptors and the juxtaglomerular apparatus, which maintain cardiovascular homeostasis. In chronic heart failure, these receptors become desensitized, generating reduced afferent responses. The low-pressure intracardiac pressure and volume receptors also are desensitized. Thirst and fluid intake may be increased as a result of activation of the cerebral thirst center. Although heart failure usually is associated with a normal or increased blood volume, it paradoxically is characterized by activation of the same homeostatic responses as those that act in hemorrhage and shock; the result is abnormal retention of sodium and water. In advanced heart failure, which is usually characterized by low cardiac output or hypotension (or coexisting renal vascular disease), the glomerular filtration rate may become so severely reduced that sodium and fluid retention becomes refractory to diuretic therapy.

Left Ventricular Remodeling and Progression of Heart Failure

After an initial insult precipitates heart failure, progressive alterations occur in myocardial structure and function owing to continuing damage by the underlying process and responses to hemodynamic stresses and neurohormonal activation. The left ventricle progressively dilates and changes from the normal ellipsoid shape to a more spherical geometry. This "remodeling" is accompanied by changes in the cardiac interstitium that lead to altered orientation of the myofibrils and progressive fibrosis. The result is more discoordinate and less effective contraction. Inhibitors of the renin-angiotensin-aldosterone system and β-blockers slow, halt, or reverse this remodeling process, preventing LV dilation, geometric distortion, and deterioration in contractile function.

CLINICAL MANIFESTATIONS

Heart failure may manifest acutely in a de novo manner, chronically, or as recurring exacerbations of chronic heart failure.

Acute Decompensation of Heart Failure

Most episodes of acute worsening of heart failure occur in patients with previously recognized symptoms of chronic heart failure. Patients with such decompensations usually present with shortness of breath, generally after a period of fluid retention or signs of congestion, as manifested by worsening edema and some degree of worsening dyspnea (Fig. 58-3).

Occasionally, the initial presentation may be more acute, with rapid progression to resting dyspnea or pulmonary edema, or both. The acute presentation is often associated with severe hypertension and is particularly characteristic of patients who have diastolic dysfunction and whose stiff left ventricle tolerates fluid retention poorly. In patients without a preceding history of heart failure, other precipitating factors, such as acute MI (Chapter 73), tachyarrhythmias (Chapters 64 and 65), previously unrecognized or new valvular abnormalities (Chapter 75), toxic damage (including alcohol excess), or acute myocarditis (Chapter 60), should be considered. Rapid diagnosis by noninvasive testing and early cardiac catheterization is essential. In patients whom myocarditis is suspected, particularly when the clinical presentation suggests giant cell myocarditis, early endomyocardial biopsy is recommended. Treatment is cause specific and may include early coronary revascularization, valve repair or replacement, or supportive care (e.g., inotropic support, intra-aortic balloon pumping, ventricular assist devices). If the condition does not improve, cardiac transplantation (Chapter 82) may be the best option for appropriate candidates.

Chronic Heart Failure

Left-Sided and Right-Sided Heart Failure

Most adult patients with heart failure have abnormalities of the left ventricle as the underlying cause. Nonetheless, the clinical presentation may be

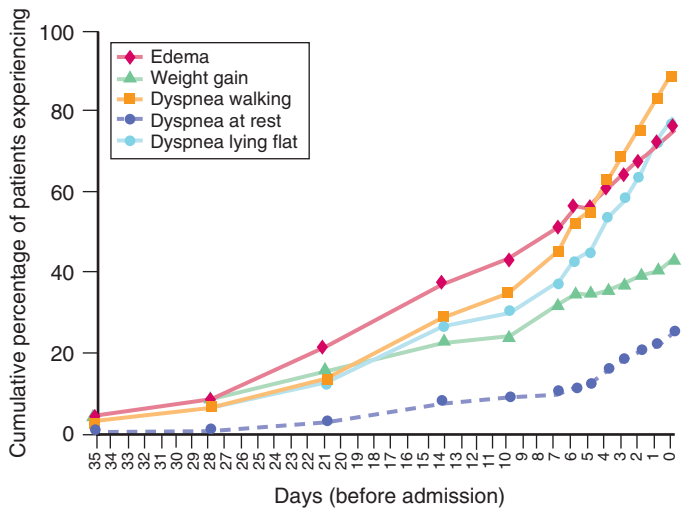

FIGURE 58-3. Number of days from onset of worsening of selected symptoms of heart failure to admission to hospital: cumulative percentage of patients. (Reprinted with permission from Schiff GD, Fung S, Speroff T, et al. Decompensated heart failure: symptoms, patterns of onset, and contributing factors. *Am J Med.* 2003;114:625-630.)

variable, sometimes suggesting predominantly or even exclusively RV dysfunction. The manifestations of LV dysfunction are related to elevated filling (diastolic) pressures, which are transmitted backward to the left atrium and pulmonary veins, or inadequate cardiac output. The former results in dyspnea (sometimes at rest but usually with activity) and, when severe, pulmonary edema (classically associated with rales and possibly pleural effusions). The cardiac output may be insufficient to support peripheral organ function, causing exertional muscle fatigue, impaired renal function and salt excretion, or depressed mentation.

Right-sided heart failure results from either chronic RV pressure overload (e.g., pulmonary hypertension resulting from cor pulmonale, pulmonary vascular disease or pulmonary embolism) or intrinsic dysfunction of the right ventricle or its valves. However, the most common cause of RV pressure overload is left-sided heart dysfunction, which results in pulmonary hypertension. If the symptoms and signs of left-sided heart failure are absent or difficult to elicit, the physician inappropriately may seek a primarily right-sided pathology. The primary manifestations of right-sided failure are related to chronically elevated right atrial and systemic venous pressures: jugular venous distention, peripheral edema, ascites, hepatic and bowel edema, and varied gastrointestinal complaints. These patients are especially vulnerable to renal dysfunction because elevated venous pressures may cause renal medullary ischemia and depress renal function.

Heart Failure with Preserved Ejection Fraction

Myocardial mechanisms that lead to the syndrome of heart failure can be differentiated into conditions that depress LV systolic function and conditions that occur despite normal or relatively preserved contractility. Although it is arbitrary, an LVEF threshold of 45 to 50% often is used for this distinction

Until the widespread use of noninvasive assessments of LV function, heart failure with preserved EF was considered unusual in the absence of valvular abnormalities or other specific and uncommon causes. It is now recognized that at least 40-50% of patients with heart failure have relatively normal EFs. In the ongoing Cardiovascular Health Study, a population-based study of more than 5000 patients aged 65 years and older, more than 70% of the patients developing heart failure had normal or only mildly impaired EFs. As the population ages and as interventional and pharmacologic approaches reduce infarct sizes and prevent LV remodeling, it is likely that heart failure with preserved EF will become increasingly common.

Although there are many potential causes of heart failure with preserved EF, most patients have current hypertension or a history of treated hypertension; the resulting LV hypertrophy and fibrosis are probably responsible for increased chamber stiffness. Ischemic heart disease also may contribute to heart failure with preserved systolic function, probably by virtue of subendocardial fibrosis or as a result of acute, intermittent ischemic dysfunction. Diabetes mellitus is often present, especially in women. Age itself is a crucial predisposing factor because it causes loss of myocytes (apoptosis), increased fibrosis with shifts to more rigid forms of collagen, and loss of vascular compliance.

The mortality rate of patients with heart failure with preserved systolic function is somewhat lower than the rate for those with low EFs but still is high, often owing to the significant comorbid conditions that are common in these older-aged individuals. Hospitalization and rehospitalization rates for these patients are comparable to those for patients with reduced EFs. Unfortunately, clinical trials have yet to identify any therapeutic interventions that improve the outcomes of the patients with heart failure with preserved systolic function.

Although patients who have heart failure with preserved systolic function are often considered to have *diastolic dysfunction,* other explanations for this presentation must be considered, some of which are reversible or warrant specific therapy (Table 58-4). The first two questions to consider are whether the patient's symptoms are caused by heart failure of any type and whether important valvular abnormalities are present. LVEF measurements may be inaccurate, particularly if their technical quality is suboptimal. Regurgitant valve disease may lead to a dissociation between the LVEF and underlying myocardial dysfunction because afterload may be low in this setting. There also are many conditions in which LV function is impaired transiently, but subsequently measured EFs may be normal. Intermittent ischemia, presenting as episodic heart failure *(flash pulmonary edema)*, is the most important of these conditions because revascularization may be indicated. Severe hypertension with subsequent control and transient tachyarrhythmias also may have temporary effects on EF. Some patients with alcoholic cardiomyopathy exhibit rapid recovery in EF when they cease drinking.

TABLE 58-4 CAUSES OF (AND ALTERNATIVE EXPLANATIONS FOR) HEART FAILURE WITH PRESERVED LEFT VENTRICULAR EJECTION FRACTION (>45-50%)

Inaccurate diagnosis of heart failure (e.g., pulmonary disease, obesity)
Inaccurate measurements of ejection fraction
Systolic function overestimated by ejection fraction (e.g., mitral regurgitation)
Episodic, unrecognized systolic dysfunction
Intermittent ischemia
Arrhythmia
Severe hypertension
Alcohol abuse
Diastolic dysfunction
Abnormalities of myocardial relaxation Ischemia Hypertrophy
Abnormalities of myocardial compliance Hypertrophy Aging Fibrosis Diabetes Infiltrative disease (amyloidosis, sarcoidosis) Storage disease (hemochromatosis) Endomyocardial disease (endomyocardial fibrosis, radiation, anthracyclines)
Pericardial disease (constriction, tamponade)

TABLE 58-5 FACTORS THAT MAY PRECIPITATE ACUTE DECOMPENSATION OF CHRONIC HEART FAILURE

Discontinuation of therapy (patient noncompliance or physician initiated)
Initiation of medications that worsen heart failure (calcium antagonists, β-blockers, nonsteroidal anti-inflammatory drugs, antiarrhythmic agents)
Iatrogenic volume overload (transfusion, fluid administration)
Dietary indiscretion
Alcohol consumption
Increased activity
Pregnancy
Exposure to high altitude
Arrhythmias
Myocardial ischemia or infarction
Worsening hypertension
Worsening mitral or tricuspid regurgitation
Fever or infection
Anemia

The remaining patients most likely have diastolic dysfunction as the underlying disorder. The noninvasive measurement of diastolic function remains problematic. The most commonly used test, Doppler echocardiography, is neither sensitive nor specific for diastolic dysfunction. Particularly in elderly patients, Doppler mitral valve filling patterns show impaired early diastolic filling in most subjects, whether or not they have evidence of heart failure. Diastolic dysfunction is basically a diagnosis of exclusion based on accompanying conditions and circumstantial evidence.

Factors Precipitating Acute Decompensation of Chronic Heart Failure

Many patients with chronic heart failure maintain a stable course, and then abruptly present with acutely or subacutely worsening symptoms. Although this decompensation may reflect unrecognized gradual progression of the underlying disorder, many precipitating events must be considered and, if present, addressed (Table 58-5). An important focus is on changes in medications (by patient or physician), diet, or activity. Superimposed new or altered

cardiovascular conditions, such as arrhythmias, ischemic events, hypertension, or valvular abnormalities, should be considered. Systemic processes, such as fever, infection, declining renal function, or anemia, also can cause cardiac decompensation.

DIAGNOSIS

The diagnosis of heart failure is straightforward when a patient presents with classic symptoms and accompanying physical findings. In patients with chronic heart failure, however, the diagnosis is often delayed or missed entirely because no single sign or symptom is diagnostic.

CLINICAL EVALUATION

The most frequent symptoms, dyspnea and fatigue, are not specific for heart failure, especially in older individuals, but their presence always should lead to a more complete evaluation. The more specific symptoms of orthopnea, paroxysmal nocturnal dyspnea, and severe edema are much less common. Although the physical examination may be helpful, characteristic physical findings may be absent. The chest radiograph (Chapter 53), on which many physicians rely, adds relatively little to the clinical evaluation except when pulmonary edema is present (see Fig. 53-15 in Chapter 53).

The key to making the timely diagnosis of chronic heart failure is to maintain a high degree of suspicion, particularly in high-risk patients with coronary artery disease, chronic hypertension, diabetes, a history of heavy alcohol use, or advanced age. If such patients present with any of the symptoms or physical findings suggestive of heart failure, additional testing (see later discussion) should be undertaken, typically beginning with echocardiography (Chapter 55).

The common symptoms of heart failure are well known but are frequently absent and variably specific for this condition. The symptoms generally reflect, but may be dissociated from, the hemodynamic derangements of elevated left-sided and right-sided pressures and impaired cardiac output or cardiac output reserve.

Dyspnea

Dyspnea (Chapter 83), or perceived shortness of breath, is the most common symptom of heart failure. In most patients, dyspnea is present only with activity or exertion. The underlying mechanisms are multifactorial. The most important is pulmonary congestion with increased interstitial or intra-alveolar fluid, which activates juxtacapillary J receptors, stimulating a rapid and shallow pattern of breathing. Increased lung stiffness may enhance the work of breathing, leading to a perception of dyspnea. Central regulation of respiration may be disturbed in those with more severe heart failure, resulting in disordered sleep patterns and sleep apnea. Cheyne-Stokes respiration, or periodic breathing, is common in advanced heart failure, is usually associated with low-output states, and may be perceived by the patient (and the patient's family) as either severe dyspnea or transient cessation of breathing. Hypoxia, which is uncommon in heart failure unless there is accompanying pulmonary disease, suggests the presence of pulmonary edema. Dyspnea is a relatively sensitive symptom of heart failure when patients maintain or attempt a moderate level of activity. However, in patients who are inactive, dyspnea may not be prominent, and the diagnosis of heart failure is often delayed or overlooked. In addition, dyspnea may become less prominent with the onset of RV failure and tricuspid regurgitation, which may lead to lower pulmonary venous pressures. Dyspnea, moreover, is also a common symptom of patients with pulmonary disease (Chapter 83), obesity, or anemia and of sedentary individuals.

Orthopnea and Paroxysmal Nocturnal Dyspnea

Orthopnea is dyspnea that is positional, occurring in the recumbent or semirecumbent position. It occurs as a result of the increase in venous return from the extremities and splanchnic circulation to the central circulation with changes in posture, with resultant increases in pulmonary venous pressures and pulmonary capillary hydrostatic pressure. Nocturnal cough may be a manifestation of this process and is an under-recognized symptom of heart failure. Orthopnea is a relatively specific symptom of heart failure, although it may occur in patients with pulmonary disease who breathe more effectively in an upright posture and in individuals with significant abdominal obesity or ascites. Most patients with mild or moderate heart failure do not experience orthopnea if they are treated adequately.

Paroxysmal nocturnal dyspnea is an attack of acute, severe shortness of breath that awakens the patient from sleep, usually 1 to 3 hours after the patient retires. Symptoms usually resolve over 10 to 30 minutes after the patient arises, often gasping for fresh air from an open window. Paroxysmal nocturnal dyspnea results from increased venous return and mobilization of interstitial fluid from the extremities and elsewhere, with accumulation of alveolar edema. Paroxysmal nocturnal dyspnea almost always represents heart failure, but it is a relatively uncommon finding.

Acute Pulmonary Edema

Pulmonary edema results from transudation of fluid into the alveolar spaces due to acute rises in capillary hydrostatic pressures caused by an acute depression of cardiac function or an acute rise in intravascular volume. The initial symptoms may be cough or progressive dyspnea. Because alveolar edema may precipitate bronchospasm, wheezing is common. If the edema is not treated, the patient may begin coughing up pink (or blood-tinged), frothy fluid and become cyanotic and acidotic.

Exercise Intolerance

Activity or exercise intolerance is, together with dyspnea, the most characteristic symptom of chronic heart failure. Intuitively, it might be assumed that exercise would be limited by shortness of breath because of rising pulmonary venous pressures and pulmonary congestion. Although this mechanism may contribute, it is only one of many operating. Blood flow to exercising muscles is impaired as a result of reduced cardiac output reserve and impaired peripheral vasodilation; oxygen delivery is limited, and early fatigue ensues. Heart failure is associated with additional abnormalities of skeletal muscle itself, including biochemical changes and alterations in fiber types, which increase muscle fatigue and impair muscle function. Finally, heart failure may affect adversely respiratory muscle function and ventilatory control.

Fatigue

Fatigue is a common, if nonspecific, complaint of patients with heart failure. Perhaps the most common origin of this complaint is muscle fatigue. Fatigue also may be a nonspecific response to the systemic manifestations of heart failure, such as chronic increases in catecholamines and circulating levels of cytokines, sleep disorders, and anxiety.

Edema and Fluid Retention (Ascites, Pleural Effusion, Pericardial Effusion)

Elevated right atrial pressures increase the capillary hydrostatic pressures in the systemic circulation, with resultant transudation. The location of edema fluid is determined by position (e.g., dependent) and by the accompanying pathology. Most commonly, edema accumulates in the extremities and resolves at night, when the legs are not dependent. Edema may occur only in the feet and ankles, but if it is more severe, it may accumulate in the thighs, scrotum, and abdominal wall. Edema is more likely and more severe in patients with accompanying venous disease, in those who have had veins harvested for coronary bypass surgery, and in patients taking calcium channel blockers, which themselves cause edema. Fluid retention associated with thiazolidinediones (Chapter 237) and nonsteroidal anti-inflammatory drugs may precipitate heart failure or mimic it.

Fluid also may accumulate in the peritoneal cavity and in the pleural or pericardial spaces. Ascites occurs as a result of elevated pressures in the hepatic, portal, and systemic veins draining the peritoneum. Ascites is unusual in heart failure and almost always is associated with peripheral edema. Most commonly, there is severe tricuspid regurgitation, with potential damage to the liver. Otherwise, significant primary liver disease should be suspected as an exacerbating factor or cause of ascites. Pleural effusions are fairly common in chronic heart failure, especially when they are accompanied by left-sided and right-sided manifestations. The effusions result from an increase in transudation of fluid into the pleural space and from impaired lymphatic drainage caused by elevated systemic venous pressures. Pericardial effusions are far less frequent but may occur.

Abdominal and Gastrointestinal Symptoms

Passive congestion of the liver may lead to right upper quadrant pain and tenderness and mild jaundice. Usually only mild elevations of transaminase levels and modest increases in bilirubin levels are observed. With severe, acute rises in central venous pressures, especially if associated with systemic hypotension, a severe congestive and ischemic hepatopathy may occur, with striking elevations in liver function markers and hypoglycemia. Recovery is usually rapid and complete if the hemodynamic abnormalities are corrected.

Bowel wall edema may lead to early satiety (a common symptom in heart failure), nausea, diffuse abdominal discomfort, malabsorption, and a rare

form of protein-losing enteropathy. The potential role of heart failure in producing these nonspecific gastrointestinal symptoms is often overlooked, leading to extensive diagnostic testing or unnecessary discontinuation of medications.

Sleep Disorders and Central Nervous System Manifestations

Periods of nocturnal oxygen desaturation to less than 80 to 85% are relatively common in patients with heart failure; they coincide with episodes of apnea (Chapter 100) and often are preceded or followed by episodes of hyperventilation. These are similar to, and may represent truncated forms of, Cheyne-Stokes respiration. These episodes reflect altered central nervous system ventilatory control and have been associated with diminished heart rate variability. Supplemental oxygen appears to reverse some of the ventilatory disorders, and the apneic spells respond to nasal positive-pressure ventilation. In some patients, these interventions have a striking beneficial effect on fatigue and other symptoms of heart failure.

Aside from the common complaint of fatigue, which originates in part in the central nervous system, brain function is not affected in most patients with heart failure. In advanced heart failure, cerebral hypoperfusion can cause impairment of memory, irritability, limited attention span, and altered mentation.

Cardiac Cachexia

In chronic, severe heart failure, unintentional chronic weight loss may occur, leading to a syndrome of cardiac cachexia. The mechanisms underlying this syndrome are unclear, but it may result from many factors, including increased levels of pro-inflammatory cytokines (e.g., TNF), elevated metabolic rates, loss of appetite, and malabsorption. Cardiac cachexia carries a poor prognosis.

PHYSICAL EXAMINATION

The physical findings associated with heart failure generally reflect elevated ventricular filling pressures and, to a lesser extent, reduced cardiac output. In chronic heart failure, many of these findings are absent, often obscuring the correct diagnosis.

Appearance and Vital Signs

Compensated patients may be comfortable, but patients with more severe symptoms are often restless, dyspneic, and pale or diaphoretic. Although the heart rate is usually at the high end of the normal range or higher (>80 beats per minute), it may be lower in patients with chronic, stable heart failure. Premature beats and arrhythmias are common. Pulsus alternans (alternating amplitude of successive beats) is a sign of advanced heart failure (or of a large pericardial effusion). The blood pressure may be normal or high, but in advanced low-output heart failure, it is usually on the low end of normal or lower.

Jugular Veins and Neck Examination

Examination of the jugular veins is one of the most useful aspects of the evaluation of patients with heart failure. The jugular venous pressure should be quantified in centimeters of water (normal = 8 cm H_2O) (see Figs. 50-2 and 50-3 in Chapter 50), estimating the level of pulsations above the sternal angle (and arbitrarily adding 5 cm H_2O in any posture). The presence of abdominal-jugular reflux should be assessed by putting pressure on the right upper quadrant of the abdomen for 30 seconds and avoiding an induced Valsalva maneuver; a positive finding is a rise in the jugular pressure of at least 1 cm. Either an elevated jugular venous pressure or an abnormal abdominal-jugular reflux has been reported in 80% of patients with advanced heart failure. No other simple sign is nearly as sensitive.

An additional important finding in the neck is evidence of tricuspid regurgitation—a large "cv" wave, usually associated with a high jugular venous pressure. This finding is confirmed by hepatic pulsations, which can be detected during the abdominal-jugular reflux determination. The carotid pulses should be evaluated for evidence of aortic stenosis, and thyroid abnormalities should be sought.

Pulmonary Examination

Although dyspnea is the most common symptom of patients with heart failure, the pulmonary examination is usually unremarkable. Rales, representing alveolar fluid, are a hallmark of heart failure; when they are present in patients without accompanying pulmonary disease, they are highly specific for the diagnosis. In chronic heart failure, they are often absent, however, even in patients known to have pulmonary capillary wedge pressures greater than 20 mm Hg (normal, <12 mm Hg). LV failure cannot be excluded by the absence of rales. Pleural effusions, which tend to lateralize on the right side because of the greater surface area of the lungs, are not uncommon, but large effusions are relatively rare in chronic heart failure.

Cardiac Examination

The cardiac examination is a crucial part of the evaluation of the patient with heart failure, but it is more useful for identification of associated cardiac abnormalities than for assessment of the severity of the heart failure (Chapter 50). Assessment of the point of maximal impulse may provide information concerning the size of the heart (enlarged if displaced below the fifth intercostal space or lateral to the midclavicular line) and its function (if sustained beyond one third of systole or palpable over two interspaces). Additional precordial pulsations may indicate an LV aneurysm. A parasternal lift is valuable evidence of pulmonary hypertension.

The first heart sound (S_1) may be diminished in amplitude when LV function is poor, and the pulmonic component of the second heart sound (P_2) may be accentuated when pulmonary hypertension is present. An apical third heart sound (S_3) is a strong indicator of significant LV systolic dysfunction, but it is present only in a minority of patients with low EFs and elevated LV filling pressures. A fourth heart sound (S_4) is not a specific indicator of heart failure, but it is usually present in patients with diastolic dysfunction. An S_3 at the lower left or right sternal border or below the xiphoid indicates RV dysfunction. Murmurs may indicate the presence of significant valvular disease as the cause of heart failure, but mitral and tricuspid regurgitation also are common secondary manifestations of severe ventricular dilation and dysfunction.

Examination of the Abdomen and Extremities

The size, pulsatility, and tenderness of the liver should be evaluated as evidence of passive congestion and tricuspid regurgitation. Ascites and edema should be sought and quantified.

Characterization: Essential and Contingent Tests

Essential Tests

Chest Radiography

Although the standard posteroanterior and lateral chest radiographs provide limited information about chamber size, the presence of overall cardiomegaly (a cardiothoracic ratio of >0.50, especially if >0.60) is a strong indicator of heart failure or another cause of cardiomegaly (especially valvular insufficiency) (see Fig. 53-4 in Chapter 53). However, almost 50% of patients with heart failure do not have this high a cardiothoracic ratio.

Most patients with acute heart failure, but only a minority of those with chronic heart failure, have clear evidence of pulmonary venous hypertension (upper lobe redistribution, enlarged pulmonary veins), interstitial edema (haziness of the central vascular shadows or increased central interstitial lung markings), or pulmonary edema (perihilar or patchy peripheral infiltrates). The absence of these findings reflects the subjectivity of interpretation and the increased capacity of the lymphatics to remove interstitial and alveolar fluid in chronic heart failure. This absence of radiographic findings is consistent with the absence of rales in most patients with chronic heart failure despite markedly elevated pulmonary venous pressures. Pleural effusions are important adjunctive evidence of heart failure. Characteristically, these are more common and larger on the right than on the left side, reflecting the greater pleural surface area of the right lung.

Electrocardiography

The major importance of the electrocardiogram is to evaluate cardiac rhythm, identify prior MI, and detect evidence of LV hypertrophy (Chapter 54). Prior MI suggests that the cause is ischemic cardiomyopathy with systolic dysfunction. LV hypertrophy is a nonspecific finding but may point toward LV diastolic dysfunction if the EF is not depressed.

Echocardiography

Noninvasive cardiac imaging is a crucial part of the diagnosis and evaluation of heart failure. The most useful procedure is transthoracic echocardiography (Chapter 55), which provides a quantitative assessment of LV function; in the presence of appropriate symptoms and signs, it can confirm the presence of heart failure resulting from systolic dysfunction or indicate whether the patient has heart failure with preserved systolic function. The

echocardiogram also provides a wealth of additional valuable information, including assessment of LV and RV size and regional wall motion (as an indicator of prior MI), evaluation of the heart valves, and diagnosis of LV hypertrophy. Particularly valuable are quantitative measurements of pulmonary artery and central venous pressures. The echocardiogram generally has replaced the chest radiograph in the diagnostic assessment of heart failure, and it can provide useful hemodynamic measurements without cardiac catheterization.

Measurements of Natriuretic Peptides

Serum levels of natriuretic peptides can be measured quickly and accurately, including point-of-care testing at the bedside. B-type natriuretic peptide (BNP) and amino (N)-terminal pro-BNP are relatively sensitive and specific markers for clinically confirmed heart failure These peptides have been found to be useful adjuncts in the diagnosis of patients presenting in the acute care setting with possible heart failure, particularly when the diagnosis remains uncertain.[1] However, levels of both BNP and N-terminal pro-BNP increase with age in the absence of clinical heart failure, especially in women, probably reflecting increased ventricular stiffness associated with aging and hypertension. BNP levels may also be increased slightly in patients with chronic obstructive pulmonary disease, in whom elevations may reflect diastolic dysfunction or RV dysfunction but nonetheless may lead to a false-positive clinical diagnosis of heart failure. Elevated natriuretic peptide measurements are associated with a worse prognosis and may be helpful in assessing the response to therapy. Randomized clinical trials that have assessed the clinical value of serial measurements in guiding therapy suggest a reduction in all-cause mortality compared with usual clinical practice.[2]

Contingent Tests

After the diagnosis of heart failure is made, the goal of additional testing is to identify potentially correctable or specifically treatable causes and to obtain further information that is necessary for future management.

Laboratory Testing

An extensive battery of laboratory tests is not required for most patients with heart failure. Routine testing should include a complete blood cell count (to detect anemia and systemic diseases with hematologic manifestations); measurement of renal function and electrolytes, including magnesium (to exclude renal failure and to provide a baseline for subsequent therapy); liver function tests (to exclude accompanying liver pathology and provide a baseline); and blood glucose and lipid testing (to diagnose diabetes and dyslipidemia, both of which should be managed aggressively in patients with heart failure).

A few additional tests may be indicated. Thyrotoxicosis, and to a lesser extent hypothyroidism, may cause heart failure and may be difficult to diagnose clinically, especially in older patients (Chapter 233). Many guidelines recommend thyroid function tests for all patients, or at least all elderly patients and those with atrial fibrillation. Hemochromatosis (Chapter 219) is a potentially treatable cause of heart failure; particularly if there is accompanying diabetes or hepatic disease, measurement of serum ferritin levels is indicated. Sarcoidosis (Chapter 95) is another potentially treatable cause, although it would be unusual not to have evidence of accompanying lung disease. Amyloidosis (Chapter 194) should be considered in patients with other manifestations, but treatment of the cardiac manifestations is rarely successful except with heart transplantation.

Assessment of Left Ventricular Function

Although heart failure is a syndrome with many pathogenic mechanisms, the most common are LV systolic dysfunction and LV diastolic dysfunction. In some patients, it is almost impossible to distinguish between these two forms of heart failure by clinical evaluation because both may present with the same symptoms and with only subtle differences on physical examination. However, it is important to distinguish between these two entities because they may require different diagnostic evaluations and different therapeutic approaches (Chapter 59). The most useful and practical test is the echocardiogram (Chapter 55); alternative approaches include radionuclide measurements of LVEF (Chapter 56) and left ventriculography if cardiac catheterization (Chapter 57) is being performed. All these tests allow the detection of significant systolic dysfunction; diastolic dysfunction sometimes can be documented (Chapter 55) but often is identified primarily as a process of exclusion in patients with preserved systolic function. Randomized trials have found no benefit, in terms of days alive and out of hospital or in a number of other relevant end points, among patients who were monitored with pulmonary artery catheterization compared with those who were not.[3]

DIAGNOSTIC EVALUATION

Assessment for Coronary Artery Disease

Coronary artery disease is the most common cause of heart failure in industrialized societies, particularly in men. Often it is known that a patient has coronary disease based on a prior history of MI or positive results on an angiogram or noninvasive test, but in some patients, MI can be silent. There are two reasons to identify the coexistence of heart failure and coronary disease: first, to treat symptoms that may be caused by ischemia and, second, to improve prognosis (Chapters 71, 72, and 73). A prudent approach is to divide patients with heart failure into three groups: (1) those with clinical evidence of ongoing ischemia (active angina or a possible ischemic equivalent), (2) those who have had a prior MI but do not currently have angina, and (3) those who may or may not have underlying coronary disease. The first group of patients may be evaluated most expeditiously by coronary angiography because they stand to benefit in terms of symptoms and probably have more extensive ischemia. In the second group are patients with heart failure and prior MI who by other criteria (age, absence of other major comorbid conditions) are good candidates for coronary revascularization; they generally should undergo noninvasive stress testing in conjunction with nuclear myocardial perfusion imaging or echocardiography to assess regional function and myocardial viability (Chapter 71). CT angiography is a useful screening test to evaluate coronary anatomy (Chapter 56), but it provides little physiologic information. These procedures identify individuals with extensive ischemic but viable myocardium, whose prognosis and symptoms also may be improved with revascularization. The third group, patients without either angina or prior MI, are much less likely to benefit from an evaluation for asymptomatic coronary disease.

Myocardial Biopsy

There is no rationale for routine myocardial biopsy in patients with heart failure, even in the subgroup without apparent coronary disease. Few entities that might be detected are amenable to specific therapy, and those that are (hemochromatosis, sarcoidosis) usually can be detected by their other manifestations or other procedures. A possible exception is acute fulminant myocarditis (Chapter 60), particularly eosinophilic and giant cell myocarditis, which may respond to immunosuppressive therapy. Another exception is in the patient being evaluated for cardiac transplantation (Chapter 82) because the presence of some entities may preclude this procedure.

Assessment of Exercise Capacity

Quantitative assessment of exercise capacity provides additional insight into prognosis beyond the clinical evaluation and measurements of cardiac function, particularly when a detailed history of activity tolerance cannot be obtained. Exercise testing with measurements of peak oxygen uptake by respiratory gas exchange has become a routine part of the evaluation for transplantation (Chapter 82) because it provides an indication of need for early intervention and an additional method for follow-up. In most patients, testing is not necessary, however. Emphasis should be placed on eliciting each patient's maximum tolerated activity and the minimum activity associated with symptoms; both can be monitored from visit to visit as a guide to management.

Assessment of Arrhythmias

Ventricular arrhythmias are extremely common in patients with chronic heart failure, with 50 to 80% of patients exhibiting nonsustained ventricular tachycardia during 24-hour monitoring. Because approximately 50% of cardiac deaths in these patients are sudden, these arrhythmias have been viewed with concern. In multivariate analyses, asymptomatic ventricular arrhythmias carry little independent prognostic significance when the severity of symptoms, EF, and presence of concurrent coronary disease are taken into account. Arrhythmias are no more predictive of sudden death than of total mortality. Ventricular arrhythmias associated with syncope or hemodynamic compromise must be taken seriously and require further evaluation and treatment (Chapter 65). Selected patients with advanced heart failure will benefit from implantable cardioverter defibrillators (Chapters 59 and 66).

Differential Diagnosis

Although it is not difficult to make the definitive diagnosis of heart failure in a patient who presents with the classic symptoms and signs, several

alternative diagnoses need to be considered in less clear-cut situations, such as in the patient with normal LV function and less definitive clinical evidence. The most common alternative diagnosis is pulmonary disease, for which pulmonary function testing is usually helpful (Chapter 85). If LV systolic function is normal, it may be difficult to make a conclusive determination of the relative role of diastolic heart failure compared with other concomitant conditions, such as severe obesity, chronic anemia, or other systemic illnesses; in some patients, a therapeutic trial of treatment for heart failure (Chapter 59) may be diagnostic.

Follow-Up Testing

After the diagnosis of heart failure is confirmed and the initial evaluation is complete, there is little need for further testing beyond the laboratory tests necessary to monitor therapy (primarily renal function and electrolytes). If the status of ventricular function is known, there are few indications for retesting. Exceptions are monitoring for transplantation and important changes in clinical status, such as marked deterioration in a patient previously known to have preserved LV function or the occurrence of new murmurs in conjunction with declining status.

HEART FAILURE: MANAGEMENT AND PROGNOSIS

JOHN J. V. MCMURRAY AND MARC A. PFEFFER

EVALUATION AND MANAGEMENT OF HEART FAILURE

Heart failure is an overarching term for a syndrome (i.e., a constellation of signs and symptoms) that encompasses a vast spectrum of cardiovascular disorders and is associated with a greatly heightened risk for death and nonfatal adverse cardiovascular events (Chapter 58). Treatment is initially directed toward prevention of cardiac injury (e.g., due to hypertension or myocardial infarction) or toward limiting structural progression if cardiac damage has already occurred (e.g., left ventricular remodeling with declining left ventricular ejection fraction) and delaying the development of symptomatic heart failure. Once symptoms develop, treatments are also directed at improving functional status as well as prognosis.

Approximately one in five adults will develop heart failure. In the United States, 5.8 million people have heart failure, and U.S. hospitals annually admit 1.1 million patients with a primary diagnosis of heart failure. The estimated cost of heart failure in the United States is about $39 billion per year. Randomized controlled clinical trials (RCTs) supply the framework for quantifying what different therapeutic approaches can offer. Even when they are definitive, RCTs only generate data about average risks and benefits of the tested therapeutic option in a selected cohort. Because an individual patient's responses can only be implied from the overall estimated group responses, RCTs cannot definitively direct the approach of every patient or answer the myriad questions that confront the practitioner regarding the specific circumstances of the patient. Another major limitation of RCTs is the relatively narrow time frame of observation, generally only months to several years, compared with epidemiologic experiences during decades. Despite these limitations, RCTs are the premier tool of evidence-based medicine, and the field of heart failure has fortunately been the focus of relatively high-quality RCTs that have provided robust evidence to improve clinical care and prognosis (Table 59-1). Indeed, the implementation of evidence from RCTs into clinical practice has resulted in impressive temporal improvements in survival after discharge from a first hospital admission for heart failure. Moreover, the age at which symptomatic heart failure first becomes evident has increased. Despite these tangible advances, heart failure continues to be a leading cause of morbidity and mortality in elderly people.

STAGES OF HEART FAILURE

The American Heart Association/American College of Cardiology Guidelines for the Evaluation and Management of Chronic Heart Failure in the Adult use a staging classification to underscore the evolution and progression of heart failure severity (Fig. 59-1). This classification emphasizes the use of different strategies and therapeutic options across the full spectrum of the syndrome, from prevention of heart failure to palliation of patients with end-stage disease.

Stage A: Individuals at Risk for Development of Heart Failure

Stage A designates patients at risk for development of heart failure based on concomitant cardiovascular diseases such as hypertension, coronary artery disease, and diabetes mellitus. Also included in stage A are individuals with prior exposure to cardiotoxic agents such as doxorubicin (Chapter 182) and those with a family history of a cardiomyopathy (Chapter 60). Although these predisposing factors do not by themselves technically constitute the syndrome of heart failure, the guidelines stress the importance of identifying individuals with modifiable factors because this represents an important opportunity to reduce the reservoir of patients at risk.

Population-based preventive approaches can reduce the incidence of heart failure. For example, public health programs targeting the eradication of the insect vector for *Trypanosoma cruzi* (Chapter 355) have reduced the incidence of Chagas' cardiomyopathy (Chapter 60) in endemic regions of South and Central America.

Other population-based approaches to reduce the incidence of heart failure require specific screening efforts to identify individuals with modifiable risk factors. The most important, although unfortunately nonmodifiable, risk factor for the development of heart failure is advanced age; the incidence of heart failure rises sharply per decade after the age of 45 years (Chapter 58). For each decade of age after 45 years, the incidence of heart failure doubles, and heart failure is the leading hospital diagnosis for patients older than 65 years in the United States.

Hypertension

Of the modifiable factors, hypertension (Chapter 67) undoubtedly contributes the greatest population-attributable risk for heart failure. In other words, even though the increased risk of heart failure in an individual with hypertension is modest, the high prevalence of hypertension in the general population means that at a population level, hypertension is the major cause of heart failure.

The contribution of hypertension to the risk of heart failure was a consistent finding from all major cardiovascular epidemiologic studies, and the earliest RCTs of antihypertensive therapy showed unambiguous reductions in the risk of heart failure. Of the components of blood pressure, elevated systolic pressure has a greater influence on the incidence of heart failure than does diastolic pressure. In fact, aging is associated with a progressive rise in systolic blood pressure and fall in diastolic pressure as the compliance of the arterial tree diminishes (Chapter 67). In community-based studies, isolated systolic hypertension and elevated pulse pressure have been the most predictive blood pressure measurements for development of heart failure. In the Systolic Hypertension in the Elderly Program, antihypertensive treatment with chlorthalidone followed by atenolol reduced the incidence of new heart failure by about 50%, a treatment effect size recently exceeded (relative risk reduction, 64%) with indapamide followed by perindopril in the Hypertension in Very Elderly Trial, probably the last placebo-controlled

antihypertensive trial. In general, the actual extent of blood pressure lowering achieved, not the agent used, is the most important factor in reducing overall rates of major cardiovascular events. However, the greatest reduction in risk of heart failure seems to be seen when initial therapy is based on a diuretic and angiotensin-converting enzyme (ACE) inhibitor. By comparison, treatment with α-blockers increases the risk of heart failure compared with other antihypertensive drugs. Most important, it is estimated that effective treatment of hypertension (Chapter 67) will substantially reduce the age-adjusted incidence of heart failure by approximately 60% in women and 50% in men.

Other Risk Factors

Treatment of atherosclerotic risk factors, such as hypercholesterolemia (Chapter 213), and promotion of measures that encourage healthier lifestyles, such as smoking cessation (Chapter 31), weight control (Chapter 227), and aerobic exercise (Chapter 15), should also reduce the number of individuals who progress from stage A to stage B (structural heart disease but without symptoms of heart failure). ACE inhibitors protect against the development of heart failure in patients with diabetes mellitus or with evidence of atherosclerosis. Although obesity is correlated with hypertension, lipid abnormalities, and glucose intolerance, an elevated body mass index is also an independent risk factor for the development of heart failure.

Stage B: Asymptomatic Structural or Functional Heart Disease

Stage B identifies asymptomatic (class I; Chapter 58) patients who have a structural or functional cardiac disorder (e.g., left ventricular hypertrophy, enlargement, or dysfunction and valvar abnormalities) but do not have the signs and symptoms, such as dyspnea and fatigue, of the heart failure syndrome. In addition to history, physical examination, and electrocardiography (Chapter 54), more extensive screening with echocardiography (Chapter 55) or other imaging modalities (Chapter 56) is often required to detect patients with asymptomatic cardiac structural abnormalities.

A patient who has an acute myocardial infarction not complicated by early heart failure is an obvious example of someone who transitions from stage A to stage B. Rapid pharmacologic or mechanical coronary reperfusion is one of the immediate goals of therapy, with the aim of limiting the extent of myocardial injury and reducing the risk for death and future development of heart failure (Chapters 72 and 73). Survivors of the acute phase of myocardial infarction, a well-studied stage B cohort, are at particularly high risk for the future development of heart failure, with an overall annual incidence of 2% per year—but higher in patients who are older, have a lower left ventricular ejection fraction (LVEF), do not routinely perform at least moderate exercise, or have concomitant hypertension or diabetes mellitus. For example, a clinically stable asymptomatic patient who has recovered from a myocardial infarction but who is older than 60 years with an LVEF of less than 50% and a history of diabetes and hypertension has an estimated 30% 5-year likelihood of experiencing death or heart failure; without diabetes or hypertension, the 5-year estimated rate becomes 12%. By comparison, a younger myocardial infarction survivor who has an LVEF over 50% and does not have hypertension or diabetes would be anticipated to have a 5-year rate for heart failure or death of only 3%. Data also suggest that an assessment of right ventricular function provides further independent incremental prediction for the risk of developing heart failure. With the continued improvements in care of patients with acute myocardial infarction (Chapters 72 and 73) and the use of implantable cardioverter-defibrillators (ICDs) after myocardial infarction in patients with reduced LVEF, this pool of stage B patients, who represent a reservoir for new-onset heart failure, has been expanding.

The impaired left ventricle, often due to a prior myocardial infarction, can undergo progressive chamber enlargement. This process, also termed *left ventricular remodeling*, describes the time-dependent and often insidious structural alterations of the impaired left ventricle, whereby the relationship of the left ventricular cavity volume increases out of proportion to mass, so the overall ventricular geometry becomes more distorted, usually more spherical. This distortion of left ventricular geometry often leads to mitral regurgitation. These structural changes produce regional and global increases in myocardial wall stress, which can promote further remodeling and contribute to the progressive deterioration of cardiac function and structure often associated with the later stages of symptomatic heart failure.

TREATMENT Rx

ACE Inhibitors and Angiotensin Receptor Blockers

Mechanistic studies confirm that ACE inhibitors inhibit progressive left ventricular enlargement by reducing wall stress during the entire cardiac cycle as well as by more direct inhibition of the intracellular signaling pathways involved in myocardial hypertrophy and interstitial fibrosis. This attenuation of ventricular remodeling by ACE inhibitors reduces the development of symptomatic heart failure and death in stage B asymptomatic patients with left ventricular dysfunction by about 20%.[1,2] In addition, deaths, often sudden and unexpected, attributed to cardiovascular causes, are reduced in stage B patients by ACE inhibitor therapy.

Several ACE inhibitors are effective as prophylactic therapy for high-risk stage B patients (see Fig. 59-1), and the target dose of each agent is established (Table 59-2). The angiotensin receptor blocker (ARB) valsartan (Table 59-3) is as effective as captopril in reducing risk for cardiovascular death and other nonfatal cardiovascular outcomes,[3] thereby providing an alternative pharmacologic class of agents. Importantly, in patients with left ventricular dysfunction or acute heart failure in the context of a myocardial infarction, the combination of an ACE inhibitor and ARB is not better than either alone, so combination therapy is not recommended in this setting.

β-Blockers

β-Adrenergic receptor blockers (β-blockers) have long been known to reduce death and recurrent myocardial infarction when they are administered during the acute phase of myocardial infarction in patients without pulmonary congestion (Chapter 73). However, carvedilol (Table 59-4) also improves survival, reduces subsequent nonfatal myocardial infarctions, and has a favorable trend for reduced hospitalizations for heart failure in patients with a recent myocardial infarction and reduced LVEF (≤40%) when it is added to an ACE inhibitor.[4] For stage B patients whose left ventricular dysfunction does not have an ischemic etiology, the evidence for β-blockers is less firm.

Treatment of Arrhythmias

Functional as well as structural problems may lead to the development of heart failure. For example, a persistently rapid ventricular rate in patients with atrial fibrillation can cause a rate-related (tachycardia-induced) cardiomyopathy (Chapter 64). Adequate pharmacologic control of the ventricular rate or interventions to restore sinus rhythm or to ablate re-entry pathways (Chapter 66) may reduce the risk for heart failure.

Other Therapies

Any treatments that control hypertension or reduce the risk of myocardial infarction will benefit stage B patients. Examples include statins, antiplatelet agents, and smoking cessation.

TABLE 59-2 PRACTICAL GUIDANCE ON THE USE OF ANGIOTENSIN-CONVERTING ENZYME INHIBITORS IN PATIENTS WITH HEART FAILURE DUE TO LEFT VENTRICULAR SYSTOLIC DYSFUNCTION

WHY?

Two major randomized trials (CONSENSUS I and SOLVD-T) and a meta-analysis of smaller trials have conclusively shown that angiotensin-converting enzyme (ACE) inhibitors increase survival, reduce hospital admissions, and improve NYHA class and quality of life in patients with *all* grades of symptomatic heart failure. Other major randomized trials in patients with systolic dysfunction after acute myocardial infarction (SAVE, AIRE, TRACE) have shown that ACE inhibitors increase survival. In patients with heart failure (ATLAS), the composite end point of death or hospital admission was reduced by higher doses of ACE inhibitor compared with lower doses. ACE inhibitors have also been shown to delay or to prevent the development of symptomatic heart failure in patients with *asymptomatic* left ventricular systolic dysfunction.

IN WHOM AND WHEN?

Indications:
- Potentially *all* patients with heart failure and a low ejection fraction
- First-line treatment (along with β-blockers) in patients with NYHA class II-IV heart failure; start as early as possible in course of disease. ACE inhibitors are also of benefit in patients with asymptomatic left ventricular systolic dysfunction (NYHA class I).

Contraindications:
- History of angioedema
- Known bilateral renal artery stenosis

Cautions/seek specialist advice:
- Significant hyperkalemia ($K^+ > 5.0$ mmol/L)
- Significant renal dysfunction (creatinine >221 μmol/L or >2.5 mg/dL)
- Symptomatic or severe asymptomatic hypotension (systolic blood pressure <90 mm Hg)

Drug interactions to look out for:
- K^+ supplements/K^+-sparing diuretics, e.g., amiloride and triamterene (beware combination preparations with furosemide)
- Aldosterone antagonists (spironolactone, eplerenone), angiotensin receptor blockers, NSAIDs*
- "Low-salt" substitutes with a high K^+ content

WHERE?

In the community for most patients
Exceptions—see *Cautions/seek specialist advice*

WHICH ACE INHIBITOR AND WHAT DOSE?

	Starting Dose	Target Dose
Captopril	6.25 mg thrice daily	50 mg thrice daily
Enalapril	2.5 mg twice daily	10-20 mg twice daily
Lisinopril	2.5-5.0 mg once daily	20-35 mg once daily
Ramipril	2.5 mg once daily	5 mg twice daily or 10 mg once daily
Trandolapril	0.5 mg once daily	4 mg once daily

HOW TO USE?

Start with a low dose (see above).
Double dose at not less than 2-week intervals.
Aim for target dose (see above) or, failing that, the highest tolerated dose.
Remember: some ACE inhibitor is better than no ACE inhibitor.
Monitor blood pressure and blood chemistry (urea/blood urea nitrogen, creatinine, K^+).
Check blood chemistry 1-2 weeks after initiation and 1-2 weeks after final dose titration.
When to stop up-titration, reduce dose, stop treatment—see Problem Solving.
A specialist heart failure nurse may assist with education of the patient, follow-up (in person or by telephone), biochemical monitoring, and dose up-titration.

ADVICE TO PATIENT

Explain expected benefits (see Why?).
Treatment is given to improve symptoms, to prevent worsening of heart failure leading to hospital admission, and to increase survival.
Symptoms improve within a few weeks to a few months of starting treatment.
Advise patients to report principal adverse effects, (i.e., dizziness/symptomatic hypotension, cough)—see Problem Solving.
Advise patients to avoid NSAIDs* not prescribed by a physician (self-purchased over-the-counter) and salt substitutes high in K^+—see Problem Solving.

PROBLEM SOLVING

Asymptomatic low blood pressure
- Does not usually require any change in therapy

Symptomatic hypotension
- If dizziness, lightheadedness, or confusion and a low blood pressure, reconsider need for nitrates, calcium-channel blockers,† and other vasodilators.
- If no signs or symptoms of congestion, consider reducing diuretic dose.
- If these measures do not solve problem, seek specialist advice.

Cough
- Cough is common in patients with heart failure, many of whom have smoking-related lung disease.
- Cough is also a symptom of pulmonary edema, which should be excluded when a new or worsening cough develops.
- ACE inhibitor–induced cough rarely requires treatment discontinuation.
- When a troublesome cough does develop (e.g., one stopping the patient from sleeping) and can be proved to be due to ACE inhibition (i.e., recurs after ACE inhibitor withdrawal and rechallenge), substitution of an angiotensin receptor blocker can be considered (see Table 59-3).

Worsening renal function
- Some rise in urea (blood urea nitrogen), creatinine, and potassium is to be expected after initiation of an ACE inhibitor; if an increase is small and asymptomatic, no action is necessary.
- An increase in creatinine of up to 50% above baseline, or ≤266 μmol/L (3 mg/dL), whichever is the smaller, is acceptable.
- An increase in potassium to ≤5.5 mmol/L is acceptable.
- If urea, creatinine, or potassium does rise excessively, consider stopping concomitant nephrotoxic drugs (e.g., NSAIDs*) and other potassium supplements or retaining agents (triamterene, amiloride, spironolactone-eplerenone‡) and, if no signs of congestion, reducing the dose of diuretic.
- If greater rises in creatinine or potassium than those outlined above persist despite adjustment of concomitant medications, the dose of the ACE inhibitor should be halved and blood chemistry rechecked within 1-2 weeks; if there is still an unsatisfactory response, specialist advice should be sought.
- If potassium rises to >5.5 mmol/L or creatinine increases by >100% or to above 310 μmol/L (3.5 mg/dL), the ACE inhibitor should be stopped and specialist advice sought.
- Blood chemistry should be monitored frequently and serially until potassium and creatinine have plateaued.

Note: It is very rarely necessary to stop an ACE inhibitor, and clinical deterioration is likely if treatment is withdrawn. Ideally, specialist advice should be sought before treatment discontinuation.
*Avoid nonsteroidal anti-inflammatory drugs (NSAIDs) unless essential.
†Calcium-channel blockers should be discontinued unless absolutely essential (e.g., for angina or hypertension).
‡The safety and efficacy of an ACE inhibitor used with an angiotensin receptor blocker and spironolactone (as well as β-blocker) are uncertain, and the use of all three inhibitors of the renin-angiotensin-aldosterone system together is not recommended.
Modified from McMurray J, Cohen-Solal A, Dietz R, et al. Practical recommendations for the use of ACE inhibitors, β-blockers, aldosterone antagonists and angiotensin receptor blockers in heart failure: putting guidelines into practice. *Eur J Heart Fail.* 2005;7:710-721.

Stages C and D: Symptomatic Heart Failure

The development of symptoms and signs of the heart failure syndrome defines the transition from patients in the asymptomatic "at-risk" stages (A and B) to those who fulfill the clinical diagnosis of symptomatic heart failure (Chapter 58). This transition to the symptomatic phase underscores the progressive nature of heart failure and heralds a marked decline in prognosis. In one study, for example, the 2-year mortality rate was 27% in symptomatic patients compared with 10% in asymptomatic patients despite similarly reduced LVEFs and comorbidities.

TABLE 59-3 PRACTICAL GUIDANCE ON THE USE OF ANGIOTENSIN RECEPTOR BLOCKERS IN PATIENTS WITH HEART FAILURE DUE TO LEFT VENTRICULAR SYSTOLIC DYSFUNCTION

WHY?

Added to standard therapy, including an angiotensin-converting enzyme (ACE) inhibitor, in patients with all grades of symptomatic heart failure, the angiotensin receptor blockers (ARBs) valsartan and candesartan have been shown, in two major randomized trials (Val-HeFT and CHARM), to reduce heart failure hospital admissions, to improve NYHA class, and to maintain quality of life. The two CHARM low-left ventricular ejection fraction trials (CHARM-Alternative and CHARM-Added) also showed that candesartan reduced all-cause mortality. In patients previously intolerant of an ACE inhibitor, candesartan has been shown to reduce the risk of the composite outcome of cardiovascular death or heart failure hospitalization, to reduce the risk of heart failure hospital admission, and to improve NYHA class. These findings in heart failure are supported by another randomized trial in patients with left ventricular systolic dysfunction, heart failure, or both complicating acute myocardial infarction (VALIANT) in which valsartan was as effective as the ACE inhibitor captopril in reducing mortality and cardiovascular morbidity.

IN WHOM AND WHEN?

Indications:
- Potentially *all* patients with heart failure
- First-line treatment (along with β-blockers) in patients with NYHA class II-IV heart failure intolerant of an ACE inhibitor
- Second-line treatment (after optimization of ACE inhibitor and β-blocker*) in patients with NYHA class II-IV heart failure

Contraindications:
- Known bilateral renal artery stenosis

Cautions/seek specialist advice:
- Significant hyperkalemia (K^+ > 5.0 mmol/L)
- Significant renal dysfunction (creatinine, >221 μmol/L or >2.5 mg/dL)
- Symptomatic or severe asymptomatic hypotension (systolic blood pressure < 90 mm Hg)

Drug interactions to look out for:
- K^+ supplements/K^+-sparing diuretics, e.g., amiloride and triamterene (beware combination preparations with furosemide)
- Aldosterone antagonists (spironolactone, eplerenone), ACE inhibitors, NSAIDs†
- "Low-salt" substitutes with a high K^+ content

WHERE?

In the community for most patients
Exceptions—see *Cautions/seek specialist advice*

WHICH ARB AND WHAT DOSE?

	Starting Dose	Target Dose
Candesartan	4 or 8 mg once daily	32 mg once daily
Valsartan	40 mg twice daily	160 mg twice daily
Losartan	50 mg once daily	150 mg daily

HOW TO USE?

Start with a low dose (see above).
Double dose at not less than 2-week intervals.
Aim for target dose (see above) or, failing that, the highest tolerated dose.
Remember: some ARB is better than no ARB.
Monitor blood pressure and blood chemistry (urea/blood urea nitrogen, creatinine, K^+).
Check blood chemistry 1-2 weeks after initiation and 1-2 weeks after final dose titration.
When to stop up-titration, reduce dose, stop treatment—see Problem Solving.
A specialist heart failure nurse may assist with education of the patient, follow-up (in person or by telephone), biochemical monitoring, and dose up-titration.

ADVICE TO PATIENT

Explain expected benefits (see Why?).
Treatment is given to improve symptoms, to prevent worsening of heart failure leading to hospital admission, and to increase survival.
Symptoms improve within a few weeks to a few months of starting treatment.
Advise patients to report principal adverse effect (i.e., report dizziness/symptomatic hypotension)—see Problem Solving.
Advise patients to avoid NSAIDs† not prescribed by a physician (self-purchased over-the-counter) and salt substitutes high in K^+—see Problem Solving.

PROBLEM SOLVING

Asymptomatic low blood pressure
- Does not usually require any change in therapy

Symptomatic hypotension
- If dizziness, lightheadedness, or confusion and a low blood pressure, reconsider need for nitrates, calcium-channel blockers,‡ and other vasodilators.
- If no signs or symptoms of congestion, consider reducing diuretic dose.
- If these measures do not solve problem, seek specialist advice.

Worsening renal function
- Some rise in urea (blood urea nitrogen), creatinine, and potassium is to be expected after initiation of an ARB; if the increase is small and asymptomatic, no action is necessary.
- An increase in creatinine of up to 50% above baseline, or ≤266 μmol/L (3 mg/dL), whichever is the smaller, is acceptable.
- An increase in potassium to ≤5.5 mmol/L is acceptable.
- If urea, creatinine, or potassium does rise excessively, consider stopping concomitant nephrotoxic drugs (e.g., NSAIDs†) and potassium supplements or retaining agents (triamterene, amiloride, spironolactone-eplerenone*) and, if no signs of congestion, reducing the dose of diuretic.
- If greater rises in creatinine or potassium than those outlined above persist despite adjustment of concomitant medications, the dose of the ARB should be halved and blood chemistry rechecked within 1-2 weeks; if there is still an unsatisfactory response, specialist advice should be sought.
- If potassium rises to >5.5 mmol/L or creatinine increases by >100% or to above 310 μmol/L (3.5 mg/dL), the ARB should be stopped and specialist advice sought.
- Blood chemistry should be monitored frequently and serially until potassium and creatinine have plateaued.

Note: It is very rarely necessary to stop an ARB, and clinical deterioration is likely if treatment is withdrawn. Ideally, specialist advice should be sought before treatment discontinuation.
*The safety and efficacy of an ARB used with an ACE inhibitor and spironolactone (as well as a β-blocker) are uncertain, and the use of all three inhibitors of the renin-angiotensin-aldosterone system together is not recommended.
†Avoid nonsteroidal anti-inflammatory drugs (NSAIDs) unless essential.
‡Calcium-channel blockers should be discontinued unless absolutely essential (e.g., for angina or hypertension).
Modified from McMurray J, Cohen-Solal A, Dietz R, et al. Practical recommendations for the use of ACE inhibitors, β-blockers, aldosterone antagonists and angiotensin receptor blockers in heart failure: putting guidelines into practice. *Eur J Heart Fail.* 2005;7:710-721.

TREATMENT Rx

The goals of treatment for patients with stage C and stage D heart failure are relief of symptoms, avoidance of hospital admission, and prevention of premature death. In general, the preventive measures that are of value during stages A and B should be sustained in patients with stages C and D heart failure.

Heart Failure with Reduced Left Ventricular Ejection Fraction

Pharmacologic Treatment

Drugs are the mainstay of the treatment of patients with symptomatic heart failure on the basis of the cumulative experiences from RCTs (see Table 59-1), particularly for patients with reduced LVEF. However, devices and surgery have an important and increasing role in patients with advanced symptomatic heart failure (stages C and D; see Fig. 59-1). Exercise clearly improves well-being and clinical outcomes (see Table 59-1), but the evidence base for other lifestyle interventions is less robust. The organization and delivery of care can also have a substantial impact on outcomes.

Diuretics

Mechanism of Action. Diuretics act by blocking sodium reabsorption at specific sites in the renal tubule, thereby enhancing urinary excretion of sodium and water.

Clinical Benefits. Although not proven to improve mortality and morbidity in large trials, diuretics are required in nearly all patients with symptomatic heart failure (stages C and D) to relieve dyspnea and the signs of sodium and water retention ("congestion"), that is, peripheral and pulmonary edema. No other treatment relieves symptoms and the signs of sodium and water overload as rapidly and effectively. Once a patient needs a diuretic, treatment is usually necessary for the rest of the patient's life, although the dose and type of diuretic may vary.

TABLE 59-4 PRACTICAL GUIDANCE ON THE USE OF β-BLOCKERS IN PATIENTS WITH HEART FAILURE DUE TO LEFT VENTRICULAR SYSTOLIC DYSFUNCTION

WHY?

Several major randomized controlled trials (i.e., USCP, CIBIS II, MERIT-HF, COPERNICUS) have shown, conclusively, that certain β-blockers increase survival, reduce hospital admissions, and improve NYHA class and quality of life when added to standard therapy (diuretics, digoxin, and angiotensin-converting enzyme [ACE] inhibitors) in patients with *stable* mild and moderate heart failure and in some patients with severe heart failure. In the SENIORS trial, which differed substantially in design from the aforementioned studies (older patients, some patients with preserved left ventricular systolic function, longer follow-up), nebivolol appeared to have a smaller treatment effect, although direct comparison is difficult. One other trial (BEST) did not show a reduction in all-cause mortality but did report a reduction in cardiovascular mortality and is otherwise broadly consistent with the aforementioned studies. The COMET trial showed that carvedilol was substantially more effective than a low dose of short-acting metoprolol tartrate* (long-acting metoprolol succinate was used in MERIT-HF).

IN WHOM AND WHEN?

Indications:
- Potentially *all* patients with *stable* mild and moderate heart failure; patients with severe heart failure should be referred for specialist advice
- First-line treatment (along with ACE inhibitors) in patients with *stable* NYHA class II-III heart failure; start as early as possible in course of disease

Contraindications:
- Asthma
- Second- or third-degree atrioventricular block

Cautions/seek specialist advice:
- Severe (NYHA class IV) heart failure
- Current or recent (<4 wk) exacerbation of heart failure (e.g., hospital admission with worsening heart failure, heart block, or heart rate <60/min)
- Persisting signs of congestion, hypotension/low blood pressure (systolic <90 mm Hg), raised jugular venous pressure, ascites, marked peripheral edema

Drug interactions to look out for:
- Verapamil, diltiazem (should be discontinued)†
- Digoxin, amiodarone

WHERE?

In the community in stable patients (NYHA class IV/severe heart failure patients should be referred for specialist advice)
Not in unstable patients hospitalized with worsening heart failure
Other exceptions—see *Cautions/seek specialist advice*

WHICH β-BLOCKER AND WHAT DOSE?

	Starting Dose	Target Dose
Bisoprolol	1.25 mg once daily	10 mg once daily
Carvedilol	3.125 mg twice daily	25-50 mg twice daily
Metoprolol CR/XL	12.5-25 mg once daily	200 mg once daily*
Nebivolol	1.25 mg once daily	10 mg once daily

HOW TO USE?

Start with a low dose (see above).
Double dose at not less than 2-week intervals.
Aim for target dose (see above) or, failing that, the highest tolerated dose.
Remember: some β-blocker is better than no β-blocker.
Monitor heart rate, blood pressure, and clinical status (symptoms, signs—especially signs of congestion, body weight).
Check blood chemistry 1-2 weeks after initiation and 1-2 weeks after final dose titration.
When to stop up-titration, reduce dose, stop treatment—see Problem Solving.
A specialist heart failure nurse may assist with education of the patient, follow-up (in person or by telephone), and dose up-titration.

ADVICE TO PATIENT

Explain expected benefits (see Why?).
Treatment is given to improve symptoms, to prevent worsening of heart failure leading to hospital admission, and to increase survival.
Symptomatic improvement may develop slowly after starting treatment, taking 3-6 months or longer.
Temporary symptomatic deterioration may occur during initiation or up-titration phase; in the long term, β-blockers improve well-being.
Advise patient to report deterioration (see Problem Solving) and that deterioration (tiredness, fatigue, breathlessness) can usually be easily managed by adjustment of other medication; patients should be advised not to stop β-blocker therapy without consulting the physician.
To detect and to treat deterioration early, patients should be encouraged to weigh themselves daily (after waking, before dressing, after voiding, before eating) and to increase their diuretic dose should their weight increase, persistently (>2 days), by >1.5-2.0 kg.‡

PROBLEM SOLVING

Worsening symptoms or signs (e.g., increasing dyspnea, fatigue, edema, weight gain)
- If increasing congestion, increase dose of diuretic or halve dose of β-blocker (if increasing diuretic does not work).
- If marked fatigue (or bradycardia—see below), halve dose of β-blocker (rarely necessary); review patient in 1-2 weeks; if not improved, seek specialist advice.
- If serious deterioration, halve dose of β-blocker or stop this treatment (rarely necessary); seek specialist advice.

Low heart rate
- If <50 beats/min and worsening symptoms, halve dose of β-blocker or, if severe deterioration, stop β-blocker (rarely necessary).
- Review need for other heart rate–slowing drugs (e.g., digoxin, amiodarone, diltiazem, or verapamil†).
- Arrange electrocardiogram to exclude heart block.
- Seek specialist advice.

Asymptomatic low blood pressure
- Does not usually require any change in therapy

Symptomatic hypotension
- If dizziness, lightheadedness, or confusion and a low blood pressure, reconsider need for nitrates, calcium-channel blockers,† and other vasodilators.
- If no signs or symptoms of congestion, consider reducing diuretic dose or ACE inhibitor.
- If these measures do not solve problem, seek specialist advice.

Note: β-Blockers should not be stopped suddenly unless absolutely necessary (there is a risk for a "rebound" increase in myocardial ischemia or infarction and arrhythmias). Ideally, specialist advice should be sought before treatment discontinuation.

*Metoprolol tartrate should not be used in preference to an evidence-based β-blocker in heart failure.

†Calcium-channel blockers should be discontinued unless absolutely necessary, and diltiazem and verapamil are generally contraindicated in heart failure.

‡This is generally good advice for all patients with heart failure.

Modified from McMurray J, Cohen-Solal A, Dietz R, et al. Practical recommendations for the use of ACE inhibitors, β-blockers, aldosterone antagonists and angiotensin receptor blockers in heart failure: putting guidelines into practice. *Eur J Heart Fail.* 2005;7:710-721.

Practical Use. The key principle is to prescribe the minimum dose of diuretic needed to maintain an edema-free state ("dry weight"). Excessive use can lead to electrolyte imbalances, such as hyponatremia, hypokalemia (and risk of digitalis toxicity), hyperuricemia (and risk of gout), and uremia. The risk of renal dysfunction is increased by concomitant use of nonsteroidal anti-inflammatory drugs (NSAIDs). Diuretic-induced hypovolemia may also cause symptomatic hypotension and prerenal azotemia. Restriction of dietary sodium intake may help reduce but does not eliminate the requirement for diuretics. Diuretic dosing should be flexible, with temporary increases for evidence of fluid retention (e.g., increasing symptoms, weight gain, edema) and decreases for evidence of hypovolemia (e.g., as a consequence of increased electrolyte loss due to gastroenteritis, decreased fluid intake, or both).

In some patients with milder symptoms of heart failure and preserved renal function (stage C), a thiazide diuretic such as chlorthalidone may suffice. In more advanced heart failure (stage D) or in patients with concomitant renal dysfunction, a loop diuretic such as furosemide is often needed. Loop diuretics cause a rapid onset of an intense but relatively short-lived diuresis compared with the longer-lasting but gentler effect of a thiazide diuretic. The timing of administration of a loop diuretic, which need not be taken first thing every morning, can be adjusted according to the patient's social activities. The dose may be postponed or even temporarily omitted if the patient has to travel or has another activity that might be compromised by the prompt action of the diuretic. In severe heart failure (stage D), the effects of long-term administration of a loop diuretic may be diminished by increased sodium reabsorption at the distal tubule. This problem can be offset by use of the combination of a loop diuretic and a thiazide or thiazide-like diuretic (e.g., hydrochlorothiazide or metolazone), which act in synergy with a loop diuretic by blocking sodium reabsorption in different segments of the nephron. This combination requires more frequent monitoring of electrolytes and renal function for diuretic-induced hyponatremia, abnormalities of the serum potassium level, and prerenal azotemia.

A period of intravenous loop diuretic, given either as bolus injections or by continuous infusion, may be required in patients who become resistant to the action of oral diuretics. Why this resistance develops is uncertain, but factors thought to be important include impaired absorption of oral diuretics due to gut edema, hypotension, reduced renal blood flow, and adaptive changes in the nephron.

In patients with advanced heart failure (stage D), an aldosterone antagonist, such as spironolactone, which increases excretion of sodium but not of potassium, usually should be added. Patients receiving a combination of diuretics require careful monitoring of blood chemistry and clinical status. The use of an aldosterone antagonist (or, rarely, a potassium-sparing diuretic) along with an ACE inhibitor or ARB (treatment with all three is not recommended) requires particular care and surveillance for hyperkalemia.

Although they are highly effective in relieving symptoms and signs, diuretics alone are not sufficient for treatment of heart failure. In cases of severe resistant volume overload, mechanical removal of fluid by ultrafiltration may be considered. The addition of other treatments will better maintain clinical stability, slow structural progression, and reduce the risk of hospital admission and premature death.

ACE Inhibitors

Mechanism of Action. These drugs act by inhibiting the enzyme that converts the inactive decapeptide angiotensin I to the active octapeptide angiotensin II (and that also breaks down bradykinin). In patients with heart failure, excessive angiotensin II is thought to exert myriad harmful actions mediated through stimulation of the angiotensin II type 1 receptor subtype (AT_1R), including vasoconstriction (which increases ventricular afterload), excessive growth of myocytes and the extracellular matrix (contributing to maladaptive left ventricular remodeling), activation of the sympathetic nervous system, prothrombotic actions, and augmentation of the release of arginine vasopressin and the retention of sodium (both directly and through stimulation of aldosterone secretion).

ACE inhibitors also reduce the breakdown of bradykinin (as ACE is identical to kininase II), and the resultant accumulation of bradykinin is directly or indirectly responsible for two of the specific adverse effects of ACE inhibitors, cough and angioedema. Bradykinin may, however, also have beneficial effects (vasodilation, inhibition of adverse cardiovascular remodeling, and antithrombotic actions), although the importance of these bradykinin-mediated actions to the clinical benefits of ACE inhibition is uncertain.

Clinical Benefits. Clinical trials have shown that treatment with an ACE inhibitor, when it is used alone or added to diuretics and digoxin, decreases left ventricular size, improves systolic function, reduces symptoms and hospital admissions, and prolongs survival (see Table 59-1).[5-8] These agents also reduce the risk for development of myocardial infarction, diabetes, and atrial fibrillation. Consequently, treatment with an ACE inhibitor is recommended for all patients with systolic dysfunction, irrespective of symptoms or etiology. ACE inhibitors are not a substitute for a diuretic but mitigate diuretic-induced hypokalemia.

Practical Use. ACE inhibitors should be introduced as early as possible in a patient's treatment. The only contraindications are current symptomatic hypotension and bilateral renal artery stenosis (Chapter 127); the latter is often associated with a prompt and marked increase in serum levels of blood urea nitrogen and creatinine when renal perfusion is reduced precipitously by inhibiting the production and actions of angiotensin. Treatment should be started in a low dose (see Table 59-2), with the dose gradually increased toward a target dose proven of benefit in a clinical trial. The patient should be evaluated for symptomatic hypotension, uremia, and hyperkalemia after each dose increment; these adverse effects are uncommon and can usually be resolved by reduction in the dose of diuretic (if the patient is edema free) or concomitant hypotensive or nephrotoxic medications (e.g., nitrates, calcium-channel blockers, or NSAIDs). A dry, nonproductive cough occurs in approximately 15% of patients treated with an ACE inhibitor, and if it is troublesome, substitution of an ARB is recommended. In the rare cases of angioedema (Chapter 260), the ACE inhibitor should be stopped and not used again; an ARB can be cautiously substituted.

Angiotensin Receptor Blockers

Mechanism of Action. Instead of inhibiting the production of angiotensin II through ACE, ARBs block the binding of angiotensin II to the AT_1R. This pharmacologically distinct mechanism of action may be important because angiotensin II is also believed to be produced by other enzymes, such as chymase. ARBs do not inhibit kininase II or the breakdown of bradykinin, so they do not cause cough and cause less angioedema than do ACE inhibitors.

Clinical Benefits. When they are used as the sole agent in heart failure, ARBs produce benefits similar to those of ACE inhibitors and can be substituted for them in patients who have cough or angioedema with ACE inhibitors.[7,8] When they are used in clinically effective doses, other adverse effects such as hypotension, renal dysfunction, and hyperkalemia are encountered as frequently as with an ACE inhibitor. As with an ACE inhibitor, the specific agents, dosing regimens, and target doses that were of demonstrable benefit in clinical trials are recommended (see Table 59-1).

In the broader population of patients with symptomatic (stage C or stage D, functional class II to class IV) heart failure that can be treated with an ACE inhibitor, an ARB *in combination with* an ACE inhibitor (and β-blocker) further improves LVEF, relieves symptoms, reduces the risk of hospital admission for worsening heart failure, and can also reduce the risk for cardiovascular death (see Table 59-3).[9,10] Consequently, the addition of an ARB to both an ACE inhibitor and a β-blocker may be considered in any patient with persisting symptoms (stages C and D). There is, however, also strong evidence that addition of an aldosterone antagonist to an ACE inhibitor is of benefit in patients with advanced (classes III to IV) heart failure (see later), but the efficacy and safety of the four-drug combination of an ACE inhibitor, β-blocker, ARB, and aldosterone antagonist are uncertain. Consequently, either an ARB or an aldosterone antagonist, but not both, should be added to an ACE inhibitor and a β-blocker in such patients.

The approach to initiation, titration, and monitoring of an ARB is similar to that of an ACE inhibitor (see Table 59-3). The adverse effects, with the exception of cough and angioedema, are similar. Use of multiple inhibitors of the renin-angiotensin-aldosterone system requires even more diligent monitoring, especially in patients at higher risk for uremia, hypotension, or hyperkalemia (i.e., patients 75 years of age and older or with a systolic blood pressure below 100 mm Hg, diabetes, or renal impairment) because combined treatment with an ACE inhibitor and an ARB significantly increases the risks of worsening renal function, hyperkalemia, and symptomatic hypotension.

As with ACE inhibitors, β-blockers, and aldosterone antagonists, treatment with ARBs should be indefinite unless there is intolerance.

β-*Blockers*

Mechanism of Action. Heart failure is characterized by excessive activation of the sympathetic nervous system, which causes vasoconstriction and sodium retention, thereby increasing cardiac preload and afterload and often inducing myocardial ischemia or arrhythmias. In addition, norepinephrine can cause hypertrophy of myocytes and augment their apoptosis. β-Blockers counteract many of these harmful effects of the hyperactivity of the sympathetic nervous system.

Clinical Benefits. The long-term addition of a β-blocker to an ACE inhibitor (and diuretic and digoxin) further improves left ventricular function and symptoms, reduces hospital admissions, and strikingly improves survival.[11-13] Consequently, a β-blocker is recommended for all patients with symptomatic systolic dysfunction, irrespective of etiology and severity, and the combination of a β-blocker with an ACE inhibitor is now the cornerstone of the treatment of symptomatic heart failure (see Fig. 59-1).

Practical Use. The major contraindications to use of a β-blocker in heart failure are asthma (although it is important to note that the dyspnea caused by pulmonary congestion can be confused with reactive airway disease) and second- or third-degree atrioventricular block. Initiation of treatment during an episode of acute decompensated heart failure should also generally be avoided. In addition, caution is advised in patients with a heart rate below 60 beats per minute or a systolic blood pressure below 90 mm Hg. It is recommended that a β-blocker shown to produce benefits in a randomized trial be used (see Table 59-1).

Like ACE inhibitors, β-blockers should be introduced as early as possible in a patient's treatment, started in a low dose (see Table 59-4), and increased gradually toward a target dose used in a clinical trial (the "start low–go slow" approach). The patient should be checked for symptomatic hypotension and excessive bradycardia after each dose increment, but both of these side effects are uncommon, and hypotension can often be resolved by reduction in the dose of other nonessential blood pressure–lowering medications (e.g., nitrates and calcium-channel blockers). Bradycardia is more likely in patients who are also taking digoxin or amiodarone, and the simultaneous use of these agents should be reviewed if excessive bradycardia occurs. On occasion, symptomatic worsening and fluid retention (e.g., weight gain or edema) may occur after initiation of a β-blocker or during dose up-titration; these side effects usually can be resolved by a temporary increase in the diuretic dose without necessitating discontinuation of the β-blocker.

Treatment with a β-blocker should be given for life, although the dose may need to be decreased (or, rarely, treatment discontinued) during episodes of acute decompensation if the patient shows signs of circulatory underperfusion or refractory congestion.

Aldosterone Antagonists

Mechanism of Action. Aldosterone, which is the second effector hormone in the renin-angiotensin-aldosterone cascade, has detrimental vascular, renal, autonomic, and cardiac actions when it is produced in excess in patients with heart failure. Excessive aldosterone promotes sodium retention and hypokalemia, and it is believed to contribute to myocardial fibrosis, all of which predispose to arrhythmias. Aldosterone antagonists block these undesirable actions and act as potassium-sparing diuretics.

Clinical Benefits. The aldosterone antagonist spironolactone (Table 59-5) improves symptoms, reduces hospital admissions, and increases survival when it is added to an ACE inhibitor (and diuretics and digoxin) in patients with a reduced LVEF and severely symptomatic heart failure.[11] Eplerenone, another aldosterone antagonist, reduces mortality and morbidity when it is added to both an ACE inhibitor and β-blocker in patients with a reduced LVEF and heart failure or diabetes after a recent myocardial infarction (see Table 59-5)[12] and when added to an ACE inhibitor/ARB and β-blockers in class II heart failure.[13] Consequently, an aldosterone antagonist should be considered in patients who remain in severe heart failure (class III or IV) despite treatment with a diuretic, ACE inhibitor (or ARB), and β-blocker. When begun, it should be given indefinitely. The combination of an ACE inhibitor, an ARB, and an aldosterone antagonist has not been adequately evaluated and is not recommended.

Treatment with an aldosterone antagonist should be initiated with a low dose (see Table 59-5) with careful monitoring of serum electrolytes and renal function. Hyperkalemia and uremia are the adverse effects of greatest concern (as with ACE inhibitors and ARBs), and an aldosterone antagonist should not be given to patients with a serum potassium concentration of more than 5.0 mmol/L, serum creatinine concentration above 2.5 mg/dL (>221 μmol/L) or other evidence of markedly impaired renal function. The importance of selection of patients and dose is underscored by reports of a worrisome incidence of serious hyperkalemia in community practice settings. Spironolactone can have antiandrogenic effects, especially painful gynecomastia, in men; because eplerenone has less of an action on the androgen receptor, it is a reasonable substitute in patients who experience this adverse effect.

Digoxin

Mechanism of Action. Digitalis glycosides inhibit the cell membrane Na^+,K^+-ATPase pump, thereby increasing intracellular calcium and myocardial contractility. In addition, digoxin is thought to enhance parasympathetic and reduce sympathetic nervous activity as well as to inhibit renin release.

TABLE 59-5 PRACTICAL GUIDANCE ON THE USE OF SPIRONOLACTONE IN PATIENTS WITH HEART FAILURE DUE TO LEFT VENTRICULAR SYSTOLIC DYSFUNCTION

WHY?

The RALES study showed that low-dose spironolactone increased survival, reduced hospital admissions, and improved NYHA class when added to standard therapy (diuretic, digoxin, angiotensin-converting enzyme [ACE] inhibitor, and, in a minority of cases, β-blocker) in patients with severe (NYHA class III or IV) heart failure. In patients with left ventricular systolic dysfunction and heart failure (or diabetes) complicating *acute* myocardial infarction (EPHESUS) and in patients with NYHA class II symptoms on an ACE inhibitor/ARB and β-blocker (EMPHASIS-HF), another aldosterone antagonist, eplerenone, increased survival and reduced hospital admissions for cardiac causes.

IN WHOM AND WHEN?

Indications:
- Potentially all patients with symptomatic heart failure (class II-IV NYHA)
- Second-line therapy (after ACE inhibitors and β-blockers*) in patients with NYHA class II-IV heart failure

Cautions/seek specialist advice:
- Significant hyperkalemia ($K^+ > 5.0$ mmol/L)†
- Significant renal dysfunction (creatinine > 221 μmol/L or 2.5 mg/dL)†

Drug interactions to look out for:
- K^+ supplements/K^+-sparing diuretics (e.g., amiloride and triamterene; beware combination preparations with furosemide)
- ACE inhibitors, angiotensin receptor blockers, NSAIDs‡
- "Low-salt" substitutes with a high K^+ content

WHERE?

In the community or in the hospital
Exceptions—see *Cautions/seek specialist advice*

WHICH DOSE?†

	Starting Dose	Target Dose
Spironolactone	25 mg once daily or on alternate days	25-50 mg once daily
Eplerenone	25 mg once daily	50 mg once daily

HOW TO USE?

Start with a low dose (see above).
Check blood chemistry at 1, 4, 8, and 12 weeks; 6, 9, and 12 months; every 6 months thereafter.
If K^+ rises above 5.5 mmol/L or creatinine rises to ≥221 μmol/L (2.5 mg/dL), reduce dose to 25 mg on alternate days and monitor blood chemistry closely.
If K^+ rises to ≥6.0 mmol/L or creatinine to ≥310 μmol/L (3.5 mg/dL), stop spironolactone immediately and seek specialist advice.
A specialist heart failure nurse may assist with education of the patient, follow-up (in person or by telephone), biochemical monitoring, and dose up-titration.

ADVICE TO PATIENT

Explain expected benefits (see Why?).
Treatment is given to improve symptoms, to prevent worsening of heart failure leading to hospital admission, and to increase survival.
Symptom improvement occurs within a few weeks to a few months of starting treatment.
Avoid NSAIDs‡ not prescribed by a physician (self-purchased over-the-counter) and salt substitutes high in K^+.
If diarrhea or vomiting occurs, patients should stop spironolactone and contact the physician.

PROBLEM SOLVING

Worsening renal function/hyperkalemia
- See How to Use?

Major concern is hyperkalemia (>6.0 mmol/L); although this was uncommon in RALES, it has been seen more commonly in clinical practice.
- Conversely, a high-normal potassium level may be desirable in patients with heart failure, especially if they are taking digoxin.
- It is important to avoid other K^+-retaining drugs (e.g., K^+-sparing diuretics such as amiloride and triamterene) and nephrotoxic agents (e.g., NSAIDs‡).
- The risk for hyperkalemia and renal dysfunction when an aldosterone antagonist is given to patients already taking an ACE inhibitor and angiotensin receptor blocker is higher than when an aldosterone antagonist is added to just an ACE inhibitor or angiotensin receptor blocker given singly; close and careful monitoring is mandatory.*
- Some "low-salt" substitutes have a high K^+ content.
- Male patients treated with spironolactone may develop breast discomfort or gynecomastia (these problems are significantly less common with eplerenone).

*The safety and efficacy of spironolactone used with an ACE inhibitor *and* an angiotensin receptor blocker (as well as a β-blocker) are uncertain, and the use of all three inhibitors of the renin-angiotensin-aldosterone system together is not recommended.
†It is extremely important to adhere to these cautions and doses in light of recent evidence of serious hyperkalemia with spironolactone in usual clinical practice in Ontario.
‡Avoid nonsteroidal anti-inflammatory drugs (NSAIDs) unless essential.
Modified from McMurray J, Cohen-Solal A, Dietz R, et al. Practical recommendations for the use of ACE inhibitors, β-blockers, aldosterone antagonists and angiotensin receptor blockers in heart failure: putting guidelines into practice. *Eur J Heart Fail.* 2005;7:710-721.

Clinical Benefits. Only one large RCT has examined the effects of starting (as opposed to withdrawing) digoxin on mortality and morbidity in patients with heart failure in sinus rhythm. In that trial, digoxin did not reduce mortality but did decrease the risk for admission to hospital for worsening heart failure when it was added to a diuretic and an ACE inhibitor.[14] In patients in sinus rhythm, addition of digoxin is recommended only for those whose heart failure remains symptomatic despite standard three-drug treatment with a diuretic, ACE inhibitor, and β-blocker plus an ARB or aldosterone antagonist. In patients with atrial fibrillation, digoxin may be used at an earlier stage if a β-blocker fails to control the ventricular rate (ideally less than 70 beats per minute at rest and less than 100 beats per minute during exercise; Chapter 64). Digoxin can also be used to control the ventricular rate when β-blocker treatment is being initiated or up-titrated.

If the effect of digoxin is needed urgently, loading with 10 to 15 μg/kg *lean* body weight, given in three divided doses 6 hours apart, may be used. The maintenance dose should be one third of the loading dose. Smaller maintenance doses (e.g., one fourth of the loading dose and not more than 62.5 μg/day) should be used in elderly patients and in patients with reduced renal function as well as in patients with a low body mass. Monitoring of the serum digoxin concentration is recommended because of the narrow therapeutic window. A steady state is reached 7 to 10 days after treatment is started; blood should be collected at least 6 hours (and ideally 8 to 24 hours) after the last dose. The currently recommended therapeutic range is 0.5 to 1.0 ng/mL.

Digoxin can cause anorexia, nausea, arrhythmias, confusion, and visual disturbances, especially if the serum concentration is above 2.0 ng/mL. Hypokalemia increases susceptibility to the adverse effects. The dose of digoxin should be reduced in elderly patients and patients with renal dysfunction. Certain drugs increase serum digoxin concentration, including amiodarone.

Hydralazine and Isosorbide Dinitrate

Mechanism of Action. Hydralazine is a powerful direct-acting arterial vasodilator. Its mechanism of action is not understood, although it may inhibit enzymatic production of superoxide, which neutralizes nitric oxide and may induce nitrate tolerance. Nitrates dilate both veins and arteries, thereby reducing preload and afterload by stimulating the nitric oxide pathway and increasing cyclic guanosine monophosphate in vascular smooth muscle. Neither drug on its own nor any other direct-acting vasodilator has been demonstrated to be beneficial in heart failure.

Clinical Benefits. Although this combination has been known for some time to improve systolic function and probably to reduce death in classes II to IV heart failure compared with placebo, head-to-head comparison showed that an ACE inhibitor is superior for improving survival. Nevertheless, on the basis of subgroup analyses suggesting that African Americans responded better to hydralazine and isosorbide dinitrate, a subsequent RCT showed that the addition of hydralazine and isosorbide dinitrate in African Americans, most of whom were receiving an ACE inhibitor and β-blocker and many of whom were taking spironolactone, further reduced mortality and hospital admissions for heart failure and improved quality of life.[15]

A fixed combination of 37.5 mg of hydralazine and 20 mg of isosorbide dinitrate was used in the trial; one tablet was given and if tolerated, a second was given 12 hours later. One tablet was then prescribed three times daily for 3 to 5 days, at which point the dose was increased to the target maintenance of two tablets three times daily, that is, a daily dose of 225 mg hydralazine and 120 mg isosorbide dinitrate. Because of the limited inclusion criteria of this RCT, however, it is uncertain whether this combination of vasodilators is an effective addition in other populations of patients.

Practical Use. Other than for African Americans, the main indication for hydralazine and isosorbide dinitrate is in patients with intolerance to an ACE inhibitor and an ARB. Hydralazine and isosorbide dinitrate should be used as additional treatment in African Americans and considered for other patients who remain symptomatic with other proven therapies. The main dose-limiting adverse effects are headache and dizziness. A rare adverse effect of higher doses of hydralazine, especially in slow acetylators, is a systemic lupus erythematosus–like syndrome (Chapter 274).

Omega-3 Polyunsaturated Fatty Acids (n-3 PUFA)

A trial of 1 g of n-3 PUFA (850 to 852 mg eicosapentaenoic acid and docosahexaenoic acid as ethyl esters in the average ratio of 1 : 1.2) per day led to a small reduction in cardiovascular morbidity and mortality in patients with heart failure. However, in light of negative trials in post-MI patients and for the prevention of AF, the role of these agents remains uncertain.

Other Pharmacologic Issues

Ivabradine, a specific inhibitor of the sinus node (at 7.5 mg twice daily), reduces mean heart rate from 75 to 64 beats per minute and reduced subsequent hospital admission in patients with chronic heart failure by about 25%. However, this agent has not reduced mortality, and the risks of symptomatic bradycardia and other side effects offset much of its benefits. Some therapies that are of proven value for cardiovascular conditions that underlie or are associated with heart failure are of uncertain benefit (antiplatelet treatment, Chapter 37) or do not improve outcomes (statins, Chapter 213) in patients with persistent, symptomatic heart failure. Warfarin is indicated in patients with atrial fibrillation, provided there is no contraindication to its use (Chapter 64). Warfarin may also be used in patients with evidence of intracardiac thrombus (e.g., detected during echocardiographic examination) or systemic thromboembolism. The many interactions of warfarin with other drugs, including some statins and amiodarone (Chapter 37), must always be considered when warfarin or another drug in a patient taking warfarin is initiated. Heparin prophylaxis (Chapter 37) against deep venous thrombosis is indicated when patients with heart failure are bed bound, such as during hospital admission.

Vaccination against influenza and pneumococcal infection is advised (Chapter 17) in all patients with heart failure because infection can lead to clinical deterioration.

The aforementioned treatments are the only pharmacologic therapies shown to be of benefit in patients with heart failure and a reduced LVEF. Other treatments have been tested in randomized trials and shown to have a neutral (e.g., amlodipine) or uncertain (e.g., bosentan and etanercept) effect on mortality and morbidity or to increase mortality (e.g., milrinone, flosequinan, vesnarinone, and moxonidine).

Drugs to Use with Caution in Heart Failure

Patients with heart failure, especially if it is severe, often have renal and hepatic dysfunction, so any drug excreted predominantly by the kidneys or metabolized by the liver may accumulate (Chapter 28). Similarly, because of their extensive comorbidity, patients with heart failure are inevitably treated with multiple drugs, thereby increasing the risk of drug interactions.

Drugs that should be avoided, if possible, in heart failure include thiazolidinediones (because of the risk of fluid retention), most antiarrhythmic drugs (including dronedarone, although amiodarone and dofetilide may be used), most calcium-channel blockers (with the exception of amlodipine), corticosteroids, NSAIDs, cyclooxygenase 2 inhibitors, many antipsychotics (e.g., clozapine), and antihistamines. Metformin (because of the risk of lactic acidosis) should be used with caution. Some salt substitutes contain substantial amounts of potassium and must be used cautiously. Other dietary constituents (e.g., grapefruit and cranberry juice) and supplements such as St. John's wort can interact with drugs taken by patients with heart failure, especially warfarin and digoxin.

Organization of Care

Several studies have shown that organized, nurse-led, multidisciplinary care can improve outcomes in patients with heart failure, particularly by reducing recurrent hospital admissions. The most successful approach seems to involve education of the patients, their families, and caregivers about heart failure and its treatment (including flexible diuretic dosing and reinforcing the importance of adherence), recognizing (and acting on) early deterioration (dyspnea, sudden weight gain, edema), and optimizing proven pharmacologic treatments.[16] A home-based rather than clinic-based approach may be best, although trials are needed to compare these types of interventions directly. Even telephone follow-up is of value. New technology enabling noninvasive home telemonitoring of physiologic measures (e.g., heart rate and rhythm, blood pressure, temperature, respiratory rate, weight, and estimated body water content) and implanted devices, which collect similar data and may be interrogated remotely, are also being tested as aids to monitoring and management. Despite the usefulness of B-type natriuretic peptide (BNP) in the diagnosis of heart failure and as a prognostic measure, treatment guided by BNP levels has not been shown in randomized trials to be any better than standard, evidence-based care.

Education

Education of the patient, family, and caregivers is invaluable (Table 59-6). Self-detection of early signs and symptoms of deterioration provides for earlier intervention. Counseling on the proper use of therapies, with an emphasis on adherence, is critical.

Useful patient-oriented material is available from several reliable sources the Heart Failure Society of America (*www.abouthf.org/education_modules.htm*), American Heart Association (*www.americanheart.org/presenter.jhtml?identifier=1486*), National Heart, Lung, and Blood Institute (*www.nhlbi.nih.gov/health/dci/Diseases/Hf/HF_WhatIs.html*), the Heart Failure Association of the European Society of Cardiology (*www.heartfailurematters.org/EN/Pages/index.aspx*), and other organizations.

Medication Use Counseling. When appropriate, a patient should be taught how to adjust the dose of diuretic within individualized limits. The dose should be increased (or a supplementary diuretic added) if there is evidence of fluid retention (symptoms of congestion) and decreased if there is evidence of hypovolemia (e.g., increased thirst associated with weight loss or postural dizziness, especially during hot weather or an illness causing decreased fluid intake or sodium and water loss). If hypovolemia is more marked, the doses of other medications also will have to be reduced.

The expected effects, beneficial and adverse, of other drugs should also be explained in detail (e.g., possible association of cough with ACE inhibitor). It is useful to inform patients that improvement with many drugs is gradual and may become fully apparent only after several weeks or even months of

TABLE 59-6 TOPICS THAT SHOULD BE DISCUSSED WITH A PATIENT WITH HEART FAILURE AND WITH HIS OR HER FAMILY AND CAREGIVERS

- General advice
  - Explain what heart failure is and why symptoms occur
    - Causes of heart failure
    - How to recognize symptoms
    - What to do if symptoms occur
    - Self-weighing (to identify fluid retention)
  - Rationale for treatments
  - Importance of adhering to pharmacologic and nonpharmacologic (e.g., dietary) treatments
  - Smoking advice
  - Prognosis
- Drug counseling
  - Rationale (i.e., benefits of individual drugs)
  - Dose and time of administration
  - Potential adverse effects (and what, if any, action to take)
  - What to do in case of missed or skipped doses
  - Self-management (e.g., flexible diuretic dosing)
- Rest and exercise
  - Rest
  - Exercise and activities related to work
  - Daily physical activity
  - Sexual activity
  - Rehabilitation
- Vaccinations and immunizations
- Travel
- Driving
- Dietary and social habits
  - Control sodium intake when necessary (e.g., some patients with severe heart failure)
  - Avoid excessive fluids in severe heart failure
  - Avoid excessive alcohol intake

Modified from Swedberg K, Cleland J, Dargie H, et al, for the Task Force for the Diagnosis and Treatment of Chronic Heart Failure of the European Society of Cardiology. Guidelines for the diagnosis and treatment of chronic heart failure: executive summary (update 2005). *Eur Heart J*. 2005;26:1115-1140.

treatment. It is also important to explain the need for gradual titration with ACE inhibitors, ARBs, and β-blocking drugs to a desired dose level, which again may take weeks or even months to achieve. Patients should be advised not to use NSAIDs without consultation and to be cautious about using herbal or other nonproprietary preparations (Chapter 38).

Adherence. Education and counseling of the patient, caregiver, and family promote adherence, which is associated with better outcomes. Drug adherence can also be helped by certain pharmacy aids, such as dose allocation (dosette) boxes.

Exercise. Tailored, structured, supervised aerobic exercise is safe and improves functional capacity and quality of life in patients with heart failure (see Table 59-1).[17] An appropriate exercise prescription may also reduce hospitalizations and mortality in patients with heart failure.

Diet, Nutrition, Alcohol. Most guidelines advocate avoidance of foods containing relatively high salt content in the belief that doing so may reduce the need for diuretic therapy. This recommendation is based on clinical experience, which suggests that excess sodium intake can be a precipitant of clinical decompensation. Some salt substitutes have a high potassium content, which can lead to hyperkalemia.

Restriction of fluid intake is indicated only during episodes of decompensation associated with peripheral edema or hyponatremia. In these situations, daily intake should be restricted to 1.5 to 2.0 L to help facilitate reduction in extracellular fluid volume and to avoid hyponatremia.

Reducing excessive weight will reduce the work of the heart and may lower blood pressure (Chapter 67). Conversely, malnutrition is common in severe heart failure, and the development of cardiac cachexia is an ominous sign. Reduced food intake is sometimes caused by nausea (e.g., related to digoxin use or hepatosplenic congestion) or abdominal bloating (e.g., due to ascites). In these cases, small frequent meals and high-protein and high-calorie liquids may be helpful. In severe decompensated heart failure, eating may be difficult because of dyspnea.

Moderate alcohol intake is not thought to be harmful in heart failure, although excessive intake can cause cardiomyopathy and atrial arrhythmias in susceptible individuals. In patients with suspected alcoholic cardiomyopathy, abstinence from alcohol may improve cardiac function.

Smoking. Smoking causes peripheral vasoconstriction, which is detrimental in heart failure. Nicotine replacement therapy (Chapter 31) is believed to be safe in heart failure. The safety of bupropion in heart failure is uncertain, especially as it is known to increase blood pressure.

Sexual Activity. Sexual activity need not be restricted in patients with compensated heart failure, although dyspnea may be limiting. In men with erectile dysfunction (Chapter 242), treatment with a cyclic guanine monophosphate phosphodiesterase type 5 inhibitor can be useful, but these drugs must not be taken within 24 hours of prior nitrate use, and nitrates must not be restarted for at least 24 hours afterward.

Driving. Patients with heart failure can continue to drive, provided their condition does not induce undue dyspnea, fatigue, or other incapacitating symptoms. Patients with recent syncope, cardiac surgery, percutaneous coronary intervention, or device placement may be restricted from driving, at least temporarily, according to local regulations. Patients holding an occupational or commercial license may also be subject to additional restrictions.

Traveling. Short flights are unlikely to cause problems for a patient with compensated heart failure. Cabin pressure is generally maintained to provide an oxygen level no lower than equivalent to 6000 feet above sea level, which should be well tolerated in patients without severe pulmonary disease or pulmonary hypertension. Longer journeys may cause limb edema and dehydration, thereby predisposing to venous thrombosis. Adjustment of the dose of diuretics and other treatments should be discussed with the patient wishing to travel to a warm climate or a country where the risk of gastroenteritis is high. It is also advisable for heart failure patients to carry a list of medications and contact information for their health care provider.

Comorbidity

Comorbid conditions, which are common and important in patients with heart failure, may be due to the underlying cardiovascular disease that caused or contributed to heart failure (e.g., hypertension, coronary artery disease, diabetes mellitus), may arise as a complication of heart failure (e.g., arrhythmias), or can result from an adverse effect of treatment given for heart failure (e.g., gout). The exact causes of other comorbidities in heart failure, such as diabetes (Chapters 236 and 237), depression (Chapter 404), sleep apnea (Chapter 100), renal dysfunction (Chapter 132), and anemia (Chapter 161), are complex and uncertain. These and other comorbid conditions, such as chronic obstructive pulmonary disease and asthma, are important because they are a major determinant of prognosis and may limit the use of certain treatments for heart failure (e.g., renal dysfunction limiting use of ACE inhibitors or asthma limiting β-blockers) and because treatment of comorbidities may affect the stability of heart failure (e.g., NSAIDs needed for rheumatic conditions can cause salt and water retention and renal dysfunction). Both prevention (e.g., diabetes mellitus) and treatment (e.g., anemia) of comorbidities are being evaluated as a potential new therapeutic goal in heart failure.

Angina. β-Blockers are of benefit in both angina (Chapter 71) and heart failure. Ivabradine, which is an inhibitor of the I_f current in the sinus node, reduces heart rate, is an effective antianginal agent at 2.5 to 7.5 mg twice daily, and is safe in patients with left ventricular systolic dysfunction. Nitrates relieve angina but on their own are not of proven value in chronic heart failure. Calcium-channel blockers should generally be avoided in heart failure because they have a negative inotropic action and cause peripheral edema; only amlodipine has been shown to have no adverse effect on survival. Trimetazidine, ranolazine, and nicorandil are antianginal drugs that are available in certain countries; their safety in patients with heart failure is uncertain. Percutaneous and surgical (Chapter 74) revascularization is also of value in relieving angina in selected patients with heart failure (see below).

Atrial Fibrillation. Atrial fibrillation (Chapter 64) may be the cause of or a consequence of heart failure in a patient presenting with atrial fibrillation and a rapid ventricular rate, and the distinction can be difficult, especially because prolonged atrial fibrillation may lead to a rate-related cardiomyopathy. Thyrotoxicosis (Chapter 233) and mitral valve disease (Chapter 75), especially stenosis, must be excluded. Alcohol abuse should also be considered. β-Blockers and digoxin are given to control the ventricular rate. The patient should be supervised closely after the initiation of these treatments because underlying sinus node dysfunction may raise the risk of bradycardia. Unless the patient presents emergently with symptoms or signs of heart failure, myocardial ischemia, or hypertension, there is little or no evidence to support a strategy of restoring sinus rhythm rather than controlling the ventricular rate in most patients with heart failure (Chapter 64).[18] Atrioventricular node ablation and pacing may be required to control ventricular rate (Chapter 66). The use of catheter ablation to cure atrial fibrillation in patients with heart failure is promising but is not currently recommended routinely (Chapter 66). There is a strong indication for thromboembolism prophylaxis with warfarin in patients with heart failure and atrial fibrillation (Chapter 64).

Asthma and Reversible Airways Obstruction. Asthma is a contraindication for use of a β-blocker, but most patients with chronic obstructive pulmonary disease (Chapter 88) can tolerate a β-blocker. Pulmonary congestion can mimic chronic obstructive pulmonary disease. Systemic administration of a corticosteroid to treat reversible airways obstruction may cause sodium and water retention and exacerbate heart failure, whereas inhalation therapy is better tolerated.

Diabetes Mellitus. Diabetes mellitus is discussed in detail elsewhere (Chapters 236 and 237). The prevalence and incidence of diabetes mellitus are high in heart failure, and the risk for development of type 2 diabetes may be

reduced by ACE inhibitors and ARBs. β-Blocker treatment is not contraindicated and is of benefit in patients with diabetes and heart failure. Thiazolidinediones cause sodium and water retention, may lead to decompensation, and are not recommended in patients with or at risk of heart failure. Metformin may cause lactic acidosis and is not recommended in patients with severe heart failure.

Abnormal Thyroid Function. Both thyrotoxicosis and hypothyroidism can cause heart failure (and thyrotoxicosis can cause atrial fibrillation, which may precipitate heart failure). Amiodarone can also induce both hypothyroidism and hyperthyroidism, the latter being particularly difficult to diagnose. The risk of thyroid dysfunction may be less with the related antiarrhythmic agent dronedarone, but dronedarone increases mortality in severe heart failure and should be avoided in patients with stage C or D heart failure or recently decompensated heart failure.

Gout. Hyperuricemia and gout (Chapter 281) are common in heart failure and can be caused or aggravated by diuretic treatment. Allopurinol may prevent gout, and acute attacks are better treated with colchicine, oral steroids, or intra-articular steroids rather than by an NSAID.

Renal Dysfunction. Most patients with heart failure have a reduced glomerular filtration rate. ACE inhibitors, ARBs, and aldosterone antagonists often cause a further small reduction in glomerular filtration rate and rise in serum blood urea nitrogen and creatinine levels, which, if limited, should not lead to discontinuation of treatment. Marked increases in blood urea nitrogen and creatinine, however, should prompt consideration of underlying renal artery stenosis (Chapter 127). Renal dysfunction may also be caused by sodium and water depletion, leading to relative hypovolemia (e.g., due to excessive diuresis, diarrhea, and vomiting) or hypotension. Nephrotoxic agents such as NSAIDs are also a common cause of renal dysfunction in heart failure.

Prostatic Obstruction. For prostatic disease (Chapter 131), a 5α-reductase inhibitor may be preferable to an α-adrenoceptor antagonist, which can cause hypotension and salt and water retention. Prostatic obstruction should also be considered in male patients with deteriorating renal function.

Anemia. A normocytic, normochromic anemia (Chapter 161) is also common in heart failure, in part because of the high prevalence of renal dysfunction. Malnutrition and blood loss may also contribute. Intravenous iron treatment with 200 mg of ferric carboxymaltose improves quality of life and reduces symptoms in patients with class II or III heart failure and iron deficiency without adverse effects.[19]

Depression. Depression (Chapter 404) is common in patients with heart failure, perhaps partly owing to disturbance of the hypothalamic-pituitary axis and other neurochemical pathways but also as a result of social isolation and the adjustment to chronic disease. Depression is associated with worse functional status, reduced adherence to treatment, and poor clinical outcomes. Both psychosocial interventions and pharmacologic treatment are helpful. Selective serotonin reuptake inhibitors are believed to be the best tolerated pharmacologic agents, whereas tricyclic antidepressants should be avoided because of their anticholinergic actions and potential to cause arrhythmias.

Cancer. Many anticancer drugs, particularly anthracyclines, cyclophosphamide, and trastuzumab (Herceptin), can cause myocardial damage and heart failure, as can mediastinal radiotherapy. Pericardial constriction can be a result of previous radiotherapy, and malignant pericardial involvement can cause effusion and tamponade (Chapter 77).

Devices and Surgery

Implantable Cardioverter-Defibrillators

About half of patients with heart failure die suddenly, mainly as the result of a ventricular arrhythmia. The relative risk of sudden death, as opposed to death from progressive heart failure, is greatest in patients with milder heart failure. In patients with more advanced heart failure, progressive pump failure deaths are relatively more common. Antiarrhythmic drugs have not been shown to improve survival in heart failure, but ICDs (Chapter 66) reduce the risk of death in selected patients after myocardial infarction (Chapter 73) and improve survival in patients with class II or III heart failure and systolic dysfunction who were otherwise treated with optimal medical therapy.[20,21] All patients with class II or class III heart failure, irrespective of etiology, and an LVEF of 35% or less should be considered for an ICD provided they have no other conditions greatly limiting life expectancy (i.e., have an anticipated survival of at least a year) or quality of life.

Cardiac Resynchronization Therapy

About 30% of patients with heart failure have substantial prolongation of the QRS duration on the surface electrocardiogram, which is a marker of abnormal electrical activation of the left ventricle causing dyssynchronous contraction, less efficient ventricular emptying, and, often, mitral regurgitation. Atrioventricular coupling may also be abnormal, as reflected by a prolonged PR interval, as may interventricular synchrony. Cardiac resynchronization therapy (CRT) with atrial-biventricular or multisite pacing optimizes atrioventricular timing and improves synchronization of cardiac contraction. In selected patients with marked systolic dysfunction (LVEF ≤ 35%), severe symptoms (functional class III or IV), and a wide QRS (120 milliseconds or more, usually manifest with left bundle branch block morphology), CRT improves pump function, reduces mitral regurgitation, relieves symptoms, and significantly prolongs exercise capacity. CRT reduces the composite of death or hospital admission in such patients (see Table 59-1) by more than 35%,[21] and in one trial, it also reduced the risk of death from any cause by 36%.[21] Many other outcome measures, including quality of life, were also improved. The combination of CRT plus an ICD also reduces all-cause mortality by 25% in patients with an LVEF <30%, a QRS >120 milliseconds, and functional class II or III heart failure.[22] In patients with New York Heart Association (NYHA) class I and II symptoms, an LVEF of 30% or less, and a QRS duration of 130 milliseconds or more, CRT (plus an ICD) improved ventricular function and reduced the risk of worsening heart failure, compared with an ICD alone (see Table 59-1); these effects were most pronounced in individuals with a QRS 150 milliseconds or more. CRT did not reduce the risk of death in this population with a relatively low mortality.[23]

The current debate focuses on whether additional patients will benefit from CRT. CRT appears to be beneficial in patients in sinus rhythm, class I or II symptoms, LVEF of 30% or less, a left bundle branch block morphology, and a QRS duration of at least 130 milliseconds. The combination of a CRT plus an ICD improves ventricular function and reduces the risk of worsening heart failure compared with an ICD alone (see Table 59-1), especially in patients with a QRS ≥150 milliseconds.[23] CRT has not been shown to help patients with echocardiographic dyssynchrony but a narrow QRS (<120 milliseconds).

Whether patients with right bundle branch block and atrial fibrillation are helped by CRT is still uncertain. There is no consensus yet about whether (or in whom) CRT alone or a CRT with implantable cardioverter-defibrillator capabilities should be used.

Surgery

With the exception of cardiac transplantation and ventricular assist devices, there are no generally accepted criteria for surgical intervention. Use of operative procedures is variable among centers and greatly dependent on local experience and expertise. Expert imaging and detailed hemodynamic and functional assessments are usually required when any patient with heart failure is considered for surgery, and close liaison between the relevant experts in these fields is essential. The collective expertise in surgical centers is often used to make highly individualized decisions about whether to operate and what procedures will be attempted. "Established" operative treatments for patients with heart failure include coronary artery bypass grafting, surgery for mitral valve incompetence, left ventricular remodeling surgery (including aneurysmectomy), implantation of ventricular assist devices, and heart transplantation. "Experimental" approaches include ventricular constraint devices and intramyocardial cell transplantation.

A recent trial showed no benefit (in symptoms or rates of death or hospitalization for cardiac causes) of surgical ventricular reconstruction. Cardiomyoplasty and partial left ventriculectomy are other recently developed operations for heart failure now thought to be without benefit.

Percutaneous Coronary Intervention or Coronary Artery Bypass Grafting. Percutaneous coronary intervention or coronary artery bypass grafting (Chapter 74), as appropriate, is indicated for relief of angina. The extent of ischemia and residual myocardial viability can be determined by noninvasive assessments such as dobutamine echocardiography (Chapter 55), magnetic resonance imaging (Chapter 56), and positron emission tomographic scanning (Chapter 56) in patients with impaired LVEF. In patients with coronary artery disease and an ejection fraction ≤35%, coronary artery bypass surgery plus optimal medical therapy can significantly reduce cardiovascular mortality but not overall mortality compared with optimal medical therapy alone.[24] As a result, the role of surgery in such patients should be individualized.

Cardiac Transplantation. Cardiac transplantation (Chapter 82) remains the most accepted surgical intervention in end-stage heart failure. Selection criteria usually focus on patients with refractory heart failure, that is, those with severe symptoms and functional limitations (peak oxygen consumption of less than 10 mL/kg/min), as well as a particularly worrisome clinical course and prognosis attributed to their cardiac condition. These patients are often dependent on intravenous inotropic agents and mechanical support.

Left Ventricular Assist Devices. Given the scarcity of organ donors, left ventricular assist devices are used as a "bridge to transplantation" or even as a permanent, definitive, procedure ("destination therapy") for some patients with advanced heart failure. A pulsatile volume-displacement left ventricular assist device can provide a short but significant prolongation of survival in patients who have end-stage heart failure and are ineligible for transplantation (see Table 59-1), but the rates of bleeding, infective and thrombotic complications, and mechanical dysfunction necessitating repeat surgery were high with this older device. In patients with end-stage heart failure ineligible for transplantation, a new continuous-flow device is significantly better than this older device in terms of 2-year survival without repeat device surgery or disabling stroke (46% versus 11%).[25]

A recent trial showed no benefit (in symptoms or rates of death or hospitalization for cardiac causes) of surgical ventricular reconstruction. Cardiomyoplasty and partial left ventriculectomy are other recently developed operations for heart failure now thought to be without benefit.

Heart Failure with Preserved Left Ventricular Ejection Fraction (Diastolic Dysfunction)

Although all patients with symptomatic heart failure share a constellation of signs and symptoms, impaired physical capacity, and reduced quality of life, some have a preserved LVEF (generally above 40 or 50%) and many are thought to have diastolic dysfunction (Chapter 58). Diastolic heart failure often has a cause different from that of systolic heart failure and a better survival rate (Chapters 52, 58, and 60), but sometimes it is an early manifestation of what will evolve into heart failure with a reduced LVEF. The distinction is important, however, because most of the RCTs that generated the evidence for treatment of heart failure included only patients with reduced LVEFs (see Table 59-1). Treatment of the underlying cardiovascular and other disorders that contribute to symptomatic stage C and stage D of heart failure with preserved LVEF, such as hypertension, myocardial ischemia, and diabetes, is critical and is as for stages A and B (see earlier). In patients with atrial fibrillation, control of the ventricular rate with a β-blocker or a rate-limiting calcium-channel blocker (or restoration of sinus rhythm) is particularly important (Chapter 64). Diuretics are used empirically to treat sodium and water retention, according to the same principles as in heart failure with reduced LVEF. In one trial of patients with an LVEF higher than 40% (mean, 54%), treatment with the ARB candesartan decreased the risk of hospital admission for heart failure but did not improve survival or the composite outcome of cardiovascular death or hospital admission for worsening heart failure. In a more recent study of patients with an LVEF of 45% or higher (mean, 60%), the ARB irbesartan had no beneficial effect, raising the possibility that the benefit of candesartan in the earlier trial was largely in patients with borderline systolic dysfunction (i.e., LVEF of 40-50%).[26] Smaller studies in patients in sinus rhythm have shown that the calcium-channel blocker verapamil or the nonselective β-adrenergic blocker propranolol can improve symptoms and exercise capacity in patients with heart failure and preserved LVEF, possibly by reducing heart rate and thereby increasing the duration of diastolic left ventricular filling as well as by directly enhancing myocardial relaxation. There are, however, no current RCTs in which these drugs decisively reduced mortality or morbidity in patients with heart failure and preserved LVEF, so treatment currently is aimed to relieve symptoms.

Heart Failure Due to Valvular Heart Disease

Heart failure also can arise as a result of regurgitant and stenotic valve disease (Chapter 75). It can sometimes be difficult to determine whether mitral regurgitation is primary or secondary in a patient with heart failure and left ventricular dilation, although a prior history of known valve disease or rheumatic fever may suggest a primary valve problem. The objective of treatment of primary valve disease is the prevention of heart failure by surgical repair or replacement of the diseased valve or valves (Chapter 75). The development of overt heart failure is an ominous sign, sometimes requiring emergent valve replacement (e.g., aortic stenosis) but sometimes indicating that valve replacement may not be possible (e.g., because of severe pulmonary hypertension).

Aortic Stenosis

Evaluation of the aortic valve (Chapter 75) can be difficult in patients with poor left ventricular systolic function. Such patients may have insufficient cardiac output to generate a high gradient across even a severely stenotic valve. Conversely, a calcified and degenerate but nonstenotic aortic valve may appear stenosed simply because it does not open normally in patients with very low cardiac output. A calculated valve area provides a better assessment of the severity of aortic stenosis in these patients. Stress echocardiography (Chapter 55) may help assess the potential for ventricular recovery after relief of aortic stenosis. Consideration should be given as to whether concomitant myocardial ischemia from coronary artery disease may also be contributing to a reversible depression of systolic function. Transcatheter valve replacement is a promising new technique for patients who have aortic stenosis but are at very high risk for open valve replacement.

Mitral Regurgitation

Mitral regurgitation can be a primary cause or a secondary manifestation in a patient with heart failure and left ventricular dilation (Chapter 75). Surgery sometimes will result in clinical improvement, but some patients with advanced left ventricular dysfunction will not achieve substantial benefit (e.g., mitral valve surgery in a patient with long-standing severe mitral regurgitation). Valve repair or annuloplasty may, however, be beneficial in carefully selected patients with secondary mitral regurgitation caused by or exacerbated by left ventricular dilation. Valve repair is generally preferable to valve replacement.

Heart Failure Due to Nonischemic Dilated Cardiomyopathy

Patients with heart failure and normal coronary arteries should be evaluated for possible reversible causes. Untreated hypertension is now an unusual cause of dilated cardiomyopathy in the United States, but hypertension was once a leading cause in the United States and remains a major consideration in many parts of the world. Infiltrative cardiomyopathies (e.g., hemochromatosis, amyloid, sarcoid) and arteritides sometimes have specific recommended therapies (Chapters 60, 95, 194, and 219). Chagas' disease (Chapter 355) must be considered in patients from endemic areas. Alcohol and other toxins (e.g., chemotherapeutic agents) are other recognized causes of dilated cardiomyopathy. Dilated cardiomyopathy can also develop in the peripartum period. Most cases of nonischemic dilated cardiomyopathy are usually labeled idiopathic (i.e., no specific etiology can be determined), although many may have a genetic origin, especially if there is a positive family history. Irrespective of etiology, patients with nonischemic dilated cardiomyopathy should be treated in the same way as patients whose dilated, poorly contracting left ventricle is a result of coronary artery disease.

Heart Failure Due to Hypertrophic Cardiomyopathy

Heart failure can arise in patients with hypertrophic cardiomyopathy because of predominant diastolic dysfunction, associated mitral incompetence, or the development of systolic dysfunction. The management of hypertrophic cardiomyopathy and its complications is often very different from the management of dilated cardiomyopathy (Chapter 60), thereby underscoring the value of echocardiography in the evaluation of the patient with heart failure.

Acute Decompensated Heart Failure and Pulmonary Edema

Patients presenting with acute heart failure include those who develop heart failure de novo as a consequence of another cardiac event, usually a myocardial infarction, and those who present for the first time with decompensation of previously asymptomatic and often unrecognized cardiac dysfunction (patients previously in stage B, a transition with profound prognostic implications). However, because of frequent recurrences, most episodes of acute decompensation occur in patients with established, chronic heart failure that has worsened as a result of the unavoidable natural progression of the syndrome, with an intercurrent cardiac (e.g., arrhythmia) or noncardiac (e.g., pneumonia) event, or as a consequence of an avoidable reason, such as nonadherence with treatment or use of an agent that can alter renal function. Although it is not always identified, searching for a reversible precipitant is an important aspect of the initial therapy plan (Table 59-7).

Most patients with acute heart failure require admission to the hospital, especially if pulmonary edema is present. In contrast to chronic heart failure, data from RCTs generally are not available to guide effective therapy for patients with acute decompensated heart failure. The principal goals of management of this heterogeneous group of patients are to relieve symptoms, the most important of which is extreme dyspnea, and to maintain or restore vital organ perfusion. An intravenous bolus or infusion of a loop diuretic (e.g., furosemide, 50 to 100 mg intravenous bolus twice daily, or 10 mg per hour continuous intravenous infusion, titrated according to the symptom response,[27] the reduction in edema, and renal function) and, in hypoxemic patients, oxygen are the key first-line treatments. An intravenous opiate may also be given to relieve anxiety and distress. Noninvasive ventilation using a tight-fitting mask to provide positive-pressure ventilation reduces respiratory distress and metabolic disturbances more rapidly than does standard oxygen therapy but has not reduced short-term mortality.[28] Intravenous infusion of a nitrate (e.g., continuous intravenous infusion of 20 to 200 μg/mm of nitroglycerin, titrated according to the symptomatic response and hemodynamic measurements, particularly arterial blood pressure) is also valuable in patients with a systolic blood pressure of 100 mm Hg or higher (Fig. 59-2). Intravenous nesiritide (human BNP as a 2.0 μg/kg intravenous bolus followed by a continuous intravenous infusion of 0.01 to 0.03 μg/kg/mm titrated according to the symptomatic response and hemodynamic measurements, particularly arterial blood pressure) can reduce the pulmonary capillary wedge pressure more promptly than intravenous nitroglycerin, but the effect of this short-term

[1] Causal arrhythmia (e.g., ventricular tachycardia). It can be difficult to determine whether atrial fibrillation is a primary cause of acute pulmonary edema or secondary to it. An ECG is an essential investigation.

[2] Acute mechanical problems include ventricular septal rupture and mitral valve papillary muscle rupture. Mechanical support (e.g., an intra-aortic balloon pump) and urgent surgery should be considered. An echocardiogram should be performed as soon as possible, especially in a patient without a prior diagnosis of heart failure/other relevant heart disease (e.g., prior myocardial infarction or valve disease).

[3] Dose of diuretic depends on prior diuretic use and renal function—a lower dose may suffice if preserved renal function and no prior diuretic use.

[4] Oxygen causes an increase in systemic vascular resistance and a reduction in heart rate and cardiac output and should only be administered to patients with hypoxemia.

[5] Consider if patient agitated/distressed/in pain; may cause respiratory depression and dose should be reduced in very elderly.

[6] An intravenous infusion of dobutamine may be started at a dose of 2.5 µg/kg/min, doubling every 15 minutes according to response and tolerability (dose titration usually limited by excessive tachycardia, arrhythmias, or ischemia). A dose above 20 µg/kg/min is rarely needed.

[7] E.g., an intra-aortic balloon pump

[8] Improvement in symptoms and peripheral perfusion and adequate urine output—patient should be monitored closely, and usually a response will occur within 30 minutes. Bladder catheterization may help in monitoring urine output.

[9] Continuous positive airways pressure (CPAP) is valuable in severe pulmonary edema, especially if associated with hypoxemia. Endotracheal intubation and invasive mechanical ventilation should be considered in patients with persisting hypoxemia and physical ventilatory exhaustion.

[10] An intravenous infusion of nitroglycerin (NTG) should be started at a dose of 10 µg/min and doubled every 10 minutes according to response and tolerability (usually dose up-titration is limited by hypotension). A dose of more than 100 µg/min is rarely needed.

FIGURE 59-2. Approach to the patient with acute pulmonary edema. ECG = electrocardiogram.

therapy on other clinical outcomes is controversial. In volume-overloaded patients with severe heart failure unresponsive to diuretics, ultrafiltration is an option at specialized centers.

In patients with marked hypotension or other evidence of organ hypoperfusion, an inotropic agent such as dobutamine (continuous intravenous infusion of 2.5 to 25 µg/kg/mm, titrated according to hemodynamic and heart rate response and induction of arrhythmias or myocardial ischemia) or a phosphodiesterase inhibitor (e.g., milrinone) should be considered, although neither treatment has ever been shown to reduce in-hospital deaths. In some countries, the calcium sensitizer levosimendan is also available for use in these patients. In general, potent inotropic agents should be used in a cardiac-monitored setting at the lowest clinically effective dose and for the shortest duration possible (Chapter 107). Although there are limited data supporting a benefit, low-dose dopamine (intravenous infusion of 2.5 µg/kg/mm) may be administered in an attempt to improve renal function. Patients with severe hyponatremia may benefit from the arginine vasopressin antagonist tolvaptan (15 to 60 mg orally once daily).

In more critically ill patients, mechanical support (e.g., with an intra-aortic balloon pump) may also be considered (Chapter 107). The aim of treatment is to support the patient's circulation and vital organ function until either the patient's heart recovers or a definitive operative procedure can be performed (e.g., transplantation or permanent implantation of a ventricular-assist device).

In patients admitted to the hospital, discharge planning and subsequent management to reduce the risk of readmission are important. Ideally, an effective oral diuretic regimen should have been identified, and fluid-volume and biochemical stability should have been achieved. This optimization of volume status and development of a stable oral regimen before discharge is thought to reduce the risk of early readmission. Treatment with an ACE inhibitor, β-blocker, and ARB or aldosterone antagonist, as appropriate, should also be started and titrated in the stabilized patient before discharge. Outpatient follow-up should be arranged to ensure that any of those treatments that have not been started before discharge are initiated after discharge and that the dose of each drug is increased, as tolerated, to the appropriate target.

Outpatient Follow-Up

The key to successful follow-up is the careful tracking of clinical symptoms and the patient's weight, which often involves interviewing not only the patient but also family members, who may be more aware of changes in status than the patient (see Organization of Care, earlier). Continuity of care and seamless transitions from the inpatient to the outpatient setting are crucial aspects of optimal management. Patients with advanced heart failure and patients requiring frequent hospitalization require special handling. Programs that provide telephone-based tracking of daily weights and symptoms can detect deterioration in time to intervene before the need for hospitalization. Although these programs may be costly, several evaluations have found them to be cost-effective. Because the management of these patients requires considerable experience and expertise, specialized heart failure programs and clinics have been developed and may provide additional benefit compared with traditional care.

PROGNOSIS

The prognosis of patients with heart failure is poor despite advances in therapy. Of patients who survive the acute onset of heart failure, only 35% of men and 50% of women are alive after 5 years. Although it is difficult to predict prognosis in individual patients, patients with symptoms at rest (class IV) have a 30 to 50% annual mortality rate, patients who are symptomatic with mild activity (class III) have mortality rates of 10 to 20% annually, and patients with symptoms only with moderate activity (class II) have a 5 to 10% annual mortality rate. Mortality rates are higher in older patients, men, and patients with a reduced LVEF or underlying coronary heart disease.

END-OF-LIFE CONSIDERATIONS

Although predicting the trajectory of illness in patients with advanced heart failure is notoriously difficult, it is often apparent when a patient has progressed to end-stage heart failure, commonly associated with concomitant renal failure. In these circumstances, the expertise of the palliative care team may be especially helpful (Chapter 3). Useful websites providing information on palliative care relevant to heart failure are available (*www.goldstandardsframework.nhs.uk/* and *www.palliativecarescotland.org.uk/assets/files/AR%2031%20March%202009.pdf*). Medications such as parenteral opiates (with an antiemetic) and benzodiazepines may be particularly helpful in relieving dyspnea, anxiety, and pain that arises from ascites, hepatic congestion, lower limb edema, and pressure points. At this stage in the patient's illness, it may be appropriate to discuss withdrawal of conventional treatment, deactivation of an ICD to avoid undesired and unpleasant electrical discharges, and a do-not-resuscitate order if the patient and others involved in the patient's care agree that "comfort care" is appropriate. Hospice care may be chosen by some at this point.

FUTURE DIRECTIONS

The discovery of primitive pluripotent stem cells that have the potential to differentiate into contractile tissue has generated considerable optimism about their transplantation into patients with impaired systolic function. Stimulation of the small population of resident stem cells in adult myocardium may also be possible.

DISEASES OF THE MYOCARDIUM AND ENDOCARDIUM

WILLIAM MCKENNA AND PERRY ELLIOTT

MYOCARDIAL DISEASE

A substantial minority of cases of heart failure result from familial (genetic) or nonfamilial (acquired) disorders, which can be confined to the heart or be multisystem disorders. The term *cardiomyopathy* refers to myocardial disorders in which the heart muscle is structurally and functionally abnormal in the absence of coronary artery disease (Chapter 73), hypertension (Chapter 67), valvular disease (Chapter 75), or congenital heart disease (Chapter 69) sufficient to cause the observed myocardial abnormality. Cardiomyopathies are classified according to ventricular morphology and pathophysiology into four major types: dilated cardiomyopathy, hypertrophic cardiomyopathy, restrictive cardiomyopathy, and arrhythmogenic right ventricular cardiomyopathy (ARVC) (Table 60-1; Fig. 60-1). Diseases that do not fit into these groups (such as endocardial fibroelastosis and left ventricular noncompaction) are termed *unclassified cardiomyopathies*. Mixed phenotypes can exist; for example, patients with hypertrophic and dilated cardiomyopathies frequently have a restrictive left ventricular physiology or develop ventricular dilation.

Hypertrophic Cardiomyopathy

DEFINITION AND EPIDEMIOLOGY

Hypertrophic cardiomyopathy is defined as unexplained left ventricular hypertrophy in the absence of abnormal loading conditions (valve disease, hypertension, congenital heart defects) sufficient to explain the degree of hypertrophy. The disease occurs in all racial groups, with a prevalence of between 0.2 and 0.5%.

PATHOBIOLOGY

Hypertrophic cardiomyopathy is usually familial with autosomal dominant inheritance. Mutations in sarcomeric contractile protein genes (Table 60-2) account for approximately 50 to 60% of cases. More than 400 different

TABLE 60-1 PROFILES OF MYOCARDIAL DISEASE

	HYPERTROPHIC	DILATED	RESTRICTIVE	ARVC
Causes	Genetic (see Table 60-2)	Myocarditis (see Table 60-4) Metabolic/endocrine Genetic (see Table 60-2)	Infiltrative or storage diseases (see Table 60-8) Endomyocardial (e.g., Löffler's, carcinoid) Genetic (see Table 60-2)	Genetic (see Table 60-2)
Ejection fraction	Increased	Reduced	25-50%	Normal until end stage 30% regional LV disease
Left ventricular	Usually decreased	Increased	Normal	Normal until end stage
End-diastolic dimension Left ventricular wall thickness	Increased	Normal	Normal or mildly increased	Right ventricle dilated Normal
Atrial size	Increased	Increased	Increased; may be massive	Left atrium normal; right dilated in severe disease
Valvular disease	Mitral regurgitation (SAM)	Mitral (functional); tricuspid regurgitation in late stages	Mitral and tricuspid regurgitation, rarely severe	Tricuspid regurgitation in severe disease
Common symptoms	Dyspnea; chest pain, syncope Late: orthopnea, PND	Dyspnea, fatigue Late: orthopnea, PND	Dyspnea Late: orthopnea, PND, right heart failure	Palpitations, syncope Late: right heart failure
Arrhythmia	Atrial fibrillation, ventricular tachycardia; conduction block in PRKAG2, mitochondrial; Fabry's disease	Ventricular tachyarrhythmias; heart block in Chagas' disease, giant cell myocarditis, laminopathies	Atrial fibrillation; conduction block in sarcoid, amyloidosis, desminopathy	Ventricular ectopy and tachycardia

ARVC = arrhythmogenic right ventricular cardiomyopathy; LV = left ventricular; SAM = systolic anterior motion of mitral valve; PND = paroxysmal nocturnal dyspnea.

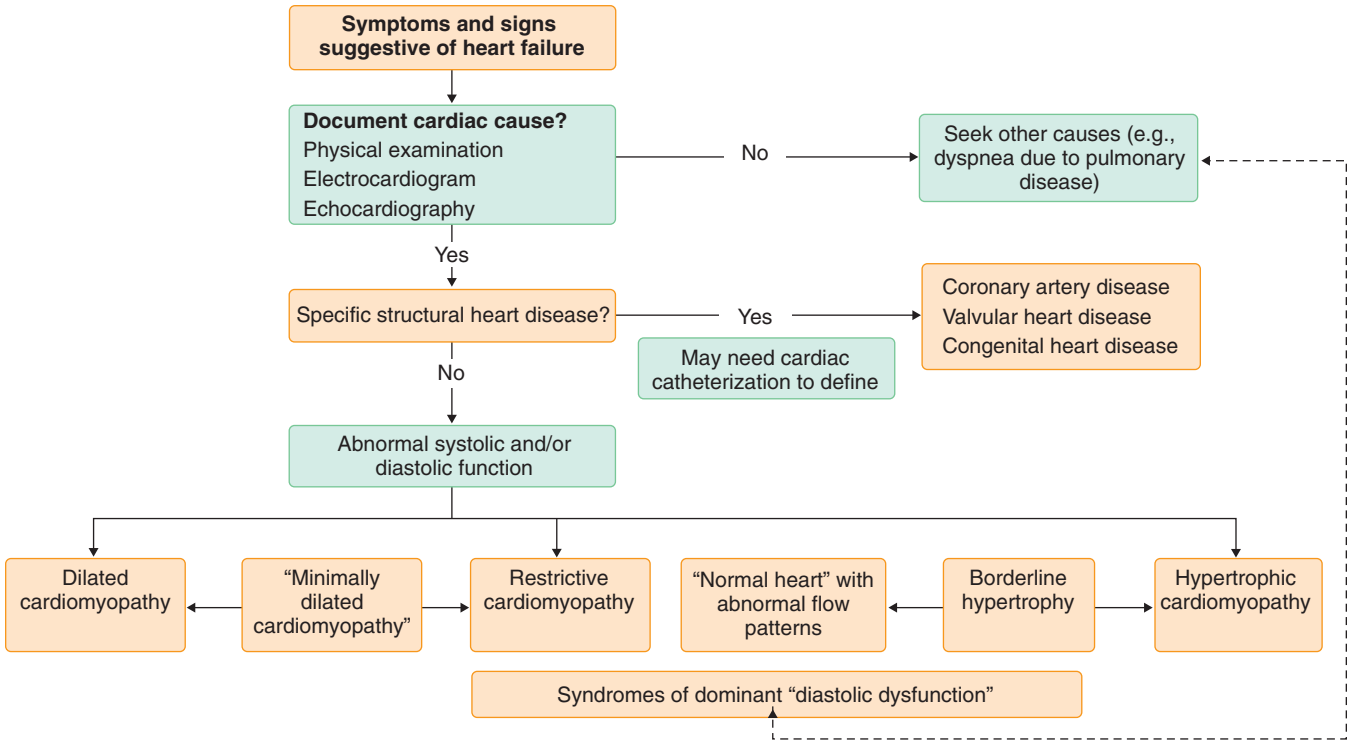

FIGURE 60-1. Initial approach to classification of cardiomyopathy. The evaluation of symptoms or signs consistent with heart failure first includes confirmation that they can be attributed to a cardiac cause. Although this conclusion is often apparent from routine physical examination and electrocardiography, echocardiography serves to confirm cardiac disease and provides clues to the presence of other cardiac diseases, such as focal abnormalities, suggesting primary valve disease or congenital heart disease. Having excluded these conditions, cardiomyopathy is generally considered to be dilated, restrictive, or hypertrophic, as shown in Table 60-1. Patients with apparently normal cardiac structure and contraction are occasionally found to demonstrate abnormal intracardiac flow patterns consistent with diastolic dysfunction but should also be evaluated carefully for other causes of their symptoms. Most patients with so-called diastolic dysfunction also demonstrate at least borderline criteria for left ventricular hypertrophy, frequently in the setting of chronic hypertension and diabetes. A moderately decreased ejection fraction without marked dilation or a pattern of restrictive cardiomyopathy is sometimes referred to as *minimally dilated cardiomyopathy*, which may represent either a distinct entity or a transition between acute and chronic disease.

mutations have been identified, with marked variation in disease penetrance and clinical expression. A similar clinical phenotype is seen in association with other uncommon genetic disorders, including Noonan's syndrome (Chapter 69), Friedreich's ataxia (Chapter 429), neurofibromatosis (Chapter 426), hereditary spherocytosis (Chapter 164), respiratory chain disorders, glycogen storage diseases (Chapter 214), and lysosomal storage disorders (Chapter 215) (see Table 60-2).

PATHOLOGY

In the common form of autosomal dominant hypertrophic cardiomyopathy, myocardial hypertrophy usually affects the interventricular septum more than other regions of the left ventricle. Other patterns, including concentric, mid-ventricular (sometimes associated with a left ventricular apical diverticulum), and apical also occur. Coexistent right ventricular hypertrophy is

present in up to 17% of cases. The papillary muscles are often displaced anteriorly, thereby contributing to systolic anterior motion of the anterior mitral valve leaflet in 25% of patients and of the posterior leaflets in 10% of cases in the resting state. Often, the mitral valve is structurally abnormal, with elongation of the anterior leaflet and occasional direct insertion of the papillary muscle into the anterior leaflet. The histologic hallmark of hypertrophic cardiomyopathy is a triad of myocyte hypertrophy, myocyte disarray, and interstitial fibrosis. Myocyte disarray refers to architectural disorganization of the myocardium, with adjacent myocytes aligned obliquely or perpendicular to each other in association with increased interstitial collagen. The myofibrillar architecture within the myocyte is also disorganized. Although myocyte disarray occurs in aortic stenosis, long-standing hypertension, and some forms of congenital heart disease, the presence of extensive disarray (more than 10% of ventricular septal myocytes) is thought to be a highly specific marker for hypertrophic cardiomyopathy. Small intramural coronary arteries are often dysplastic and narrowed owing to wall thickening by smooth muscle cell hyperplasia.

PATHOPHYSIOLOGY

Abnormal ventricular geometry, wall thickening, myocyte hypertrophy, myocyte and myofibrillar disarray, and myocardial fibrosis all contribute to impairment of left ventricular diastolic function. The net result is elevation of left ventricular end-diastolic pressures, symptoms of heart failure, and reduced exercise tolerance. Global measures of left ventricular systolic function are often normal, but regional myocardial dysfunction and progressive systolic impairment are relatively common.

Approximately 25% of patients have left ventricular outflow tract obstruction at rest caused by contact between the anterior leaflet of the mitral valve and the interventricular septum during ventricular systole. Many patients without outflow obstruction at rest develop it during physiologic and pharmacologic interventions that reduce left ventricular end-diastolic volume or increase left ventricular contractility (e.g., amyl nitrate inhalation, Valsalva maneuver, and administration of intravenous inotropic agents).

CLINICAL MANIFESTATIONS

Most patients are asymptomatic or have only mild or intermittent symptoms. Symptomatic progression is usually slow, age related, and associated with a gradual deterioration in left ventricular function over decades. Fewer than 5% of patients may have rapid, symptomatic deterioration. Symptoms can develop at any age, even many years after the appearance of electrocardiographic (ECG) or echocardiographic manifestations of left ventricular hypertrophy. Occasionally, sudden death may be the initial presentation. However, most individuals with hypertrophic cardiomyopathy have few if any symptoms, and the diagnosis is often made as a result of family screening or the incidental detection of a heart murmur or an abnormal ECG.

Approximately 20 to 30% of adults develop chest pain (Chapters 50 and 71), which may occur on exertion, at rest, or nocturnally. Postprandial angina associated with mild exertion is typical. Mild to moderate dyspnea on exertion is relatively common, and some patients develop paroxysmal nocturnal dyspnea that may be caused by transient myocardial ischemia or arrhythmia. Approximately 20% of patients experience syncope (Chapters 50 and 62), and a similar proportion complain of presyncope. Palpitations (Chapter 62) are frequent and are usually attributable to supraventricular or ventricular ectopy or to forceful cardiac contraction. Sustained palpitations are usually caused by supraventricular tachyarrhythmias, but initial presentation with a symptomatic arrhythmia is uncommon. Patients with distal or apical hypertrophy have fewer symptoms, better exercise capacity, no arrhythmias, and good prognosis. Occasionally, however, patients with distal or apical hypertrophy may have severe refractory chest pain or may present with troublesome supraventricular arrhythmias.

DIAGNOSIS

A three- to four-generation family history, which should be obtained in all patients with a new diagnosis of cardiomyopathy, helps to determine the probability of familial disease and its mode of inheritance. The initial diagnostic evaluation includes a family history focusing on premature cardiac disease or death, a comprehensive medical history focusing on cardiovascular symptoms, a careful physical examination, a 12-lead ECG, and a two-dimensional echocardiogram.

The general evaluation may provide diagnostic clues in patients whose hypertrophic cardiomyopathy is associated with syndromes or metabolic disorders. For example, Noonan's syndrome (Chapter 69) is characterized by short stature, developmental delay, cutaneous abnormalities (café au lait spots), hypertelorism, ptosis, low-set posteriorly rotated ears, and a webbed neck. These features are shared with the less common LEOPARD syndrome. Angiokeratomas, anhidrosis, Raynaud's-like symptoms with neuropathy, cornea verticillata, retinal vascular dilation, tinnitus, diarrhea, and proteinuria are typical features of Fabry's disease (Chapter 215).

Clinical examination of the cardiovascular system is often normal. In the presence of left ventricular outflow tract obstruction, the arterial pulse has a rapid upstroke and downstroke (sometimes with a bisferiens character), the apex beat is sustained or double (reflecting a palpable atrial impulse followed by left ventricular contraction), and auscultation will demonstrate a systolic ejection murmur that is heard loudest at the left sternal edge and that radiates to the right upper sternal edge and apex (Chapter 50). Most patients with left ventricular outflow tract obstruction also have the murmur of mitral regurgitation, which results from failure of the mitral valve leaflets to coapt owing to the systolic anterior motion of the mitral valve. Physiologic and pharmacologic maneuvers that decrease afterload or venous return (e.g., standing, Valsalva maneuver, inhalation of amyl nitrite) or increase contractility (e.g., a post-extrasystole beat) will increase the intensity of the murmur, whereas interventions that increase afterload and venous return (e.g., squatting or handgrip) will reduce it (see Table 50-2 in Chapter 50). In contrast, physical signs in most patients who do not have left ventricular outflow tract obstruction are subtle and are limited to features that reflect the hyperdynamic contraction (rapid upstroke pulse) and poorly compliant right (prominent a wave in jugular venous pressure) and left (S_4 gallop, double-apex beat) ventricles (Chapter 50).

Diagnostic Testing

More than 90% of patients have abnormal ECG findings, but no changes are disease specific. The most common abnormalities are increased QRS voltage consistent with left ventricular hypertrophy, left axis deviation (15 to 20%), abnormal Q waves (25 to 30%, most commonly in inferolateral leads), and ST segment or T wave changes (>50%). An isolated increase in the QRS voltage without ST segment changes or T wave inversion is rare in hypertrophic cardiomyopathy. The presence of predominantly distal or apical thickening is associated with giant negative T wave inversion on the ECG tracing.

Two-dimensional echocardiography (Chapter 55) is the mainstay of diagnostic imaging, but magnetic resonance imaging (Chapter 56) and computed tomography (Chapter 56) provide alternatives if the echocardiogram is of poor quality. In most patients, the hypertrophy is asymmetrical and involves the anterior and posterior intraventricular septum (Fig. 60-2). The hypertrophy, however, may be more generalized and involve the free wall of the left ventricle, or it may be localized and confined to areas other than the septum, such as the lateral or posterior wall of the left ventricle. The echocardiogram can measure left ventricular outflow tract obstruction, both at rest and after provocative maneuvers. Patients with an outflow tract gradient of 30 mm Hg or more typically have systolic anterior motion of the mitral valve, with contact of either the anterior or (less commonly) the posterior mitral leaflet with the intraventricular septum during systole, in association with a posteriorly directed jet of mitral regurgitation, the severity of which is proportionate to the severity of the obstruction. Most patients with hypertrophic cardiomyopathy have left atrial enlargement as well as echocardiographic evidence of diastolic dysfunction.

When available, cardiopulmonary exercise testing with metabolic gas exchange measurements provides an accurate and reproducible assessment of exercise capacity, which can be followed serially. Cardiac catheterization is rarely required for diagnosis or management, but it may be indicated when measurement of intracardiac pressures is required to guide therapeutic decisions (e.g., in patients with severe mitral regurgitation) and for the exclusion of coexistent coronary artery disease in patients with chest pain.

Diagnostic Criteria

A wall thickness of more than 2 standard deviations above the mean, corrected for age, gender, and height, is generally accepted as diagnostic. In adults, this value is typically 1.5 cm or greater in men and 1.3 cm or greater in women. In the presence of other causes of left ventricular hypertrophy such as long-standing systemic hypertension or aortic stenosis, the diagnosis of hypertrophic cardiomyopathy may be problematic. However, secondary hypertrophy from other causes rarely exceeds 1.8 cm. Hypertrophy in the

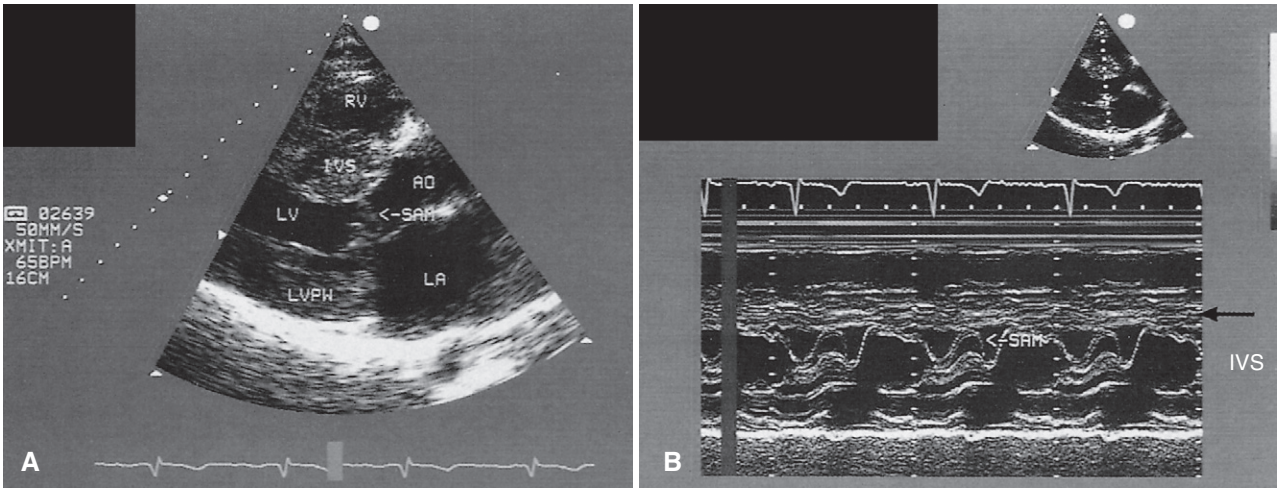

FIGURE 60-2. Hypertrophic obstructive cardiomyopathy. A, The two-dimensional long-axis parasternal view shows the chambers of the heart. The left ventricle posterior wall (LVPW) is thickened, and the most striking abnormality is the hypertrophy of the interventricular septum (IVS). Another characteristic feature is a Venturi effect: as blood leaves the left ventricle (LV), it sucks the anterior leaflet of the mitral valve forward, a phenomenon called *systolic anterior motion* (SAM). **B,** This phenomenon is more clearly shown in the parasternal long-axis M-mode echocardiogram. The massive thickening of the septum is also obvious in the M-mode image (IVS). AO = aorta; LA = left atrium; RV = right ventricle. (From Forbes CD, Jackson WF. *Color Atlas and Text of Clinical Medicine,* 3rd ed. London: Mosby; 2003.)

TABLE 60-3 DIAGNOSTIC CRITERIA FOR HYPERTROPHIC CARDIOMYOPATHY IN FIRST-DEGREE RELATIVES OF AFFECTED PATIENTS*

MAJOR CRITERIA	MINOR CRITERIA
ECHOCARDIOGRAPHY	
Left ventricular wall thickness ≥13 mm in the anterior septum or posterior wall or ≥15 mm in the posterior septum or free wall	Left ventricular wall thickness of 12 mm in the anterior septum or posterior wall or of 14 mm in the posterior septum or free wall
Severe SAM of the mitral valve (septal-leaflet contact)	Moderate SAM of the mitral valve (no mitral leaflet-septal contact)
	Redundant mitral valve leaflets
ELECTROCARDIOGRAPHY	
Left ventricular hypertrophy with repolarization changes (Romhilt and Estes)	Complete bundle branch block or (minor) interventricular conduction defects (in left ventricular leads)
T wave inversion in leads I and aVL (≥3 mm with QRS-T wave axis difference ≥30 degrees), V_3-V_6 (≥3 mm) or II and III and aVF (≥5 mm)	Minor repolarization changes in left ventricular leads Deep S wave in lead V_2 (>25 mm)
Abnormal Q waves (>40 msec or >25% R wave) in at least two leads from II, III, aVF (in absence of left anterior hemiblock), and V_1-V_4; or I, aVL, V_5-V_6	Unexplained chest pain, dyspnea, or syncope

*The diagnosis of hypertrophic cardiomyopathy in first-degree relatives of patients with the disease is based on the presence of one major criterion or two minor echocardiographic criteria or one minor echocardiographic and two minor electrocardiographic criteria.
aVF = augmented voltage unipolar left foot lead; aVL = augmented voltage unipolar left arm lead; SAM = systolic anterior motion.
Adapted from McKenna WJ, Spirito P, Desnos M, et al. Experience in clinical genetics in hypertrophic cardiomyopathy. *Heart.* 1997;77:130-132.

highly trained athlete is usually less than 1.6 cm in males and 1.4 cm in females, and typically occurs in association with an increased left ventricular end-diastolic dimension and stroke volume. An ECG tracing showing Q waves or inferolateral repolarization changes in an athlete favors the diagnosis of hypertrophic cardiomyopathy.

Given the 50% probability of disease in a first-degree relative of a patient with hypertrophic cardiomyopathy, modified diagnostic criteria (Table 60-3) consider the high probability that their otherwise unexplained ECG and echocardiographic findings reflect incomplete disease expression, with the corresponding risks for complications and for passing the gene to their children.

TREATMENT Rx

Clinical management is based mainly on symptoms (Fig. 60-3). Exceptions include specific therapies for lysosomal storage diseases, such as Pompe's (Chapter 214) and Fabry's disease (Chapter 215), and for Friedreich's ataxia (Chapter 429). The treatment of the remaining patients with hypertrophic cardiomyopathy focuses on the counseling of family members, the management of symptoms, and the prevention of disease-related complications.

Family Evaluation

All patients with hypertrophic cardiomyopathy should be counseled on the implications of the diagnosis for their families. Careful pedigree analysis can reassure relatives who are not at risk for inheriting the disease. For those who are at risk, current guidelines recommend screening with a 12-lead ECG and echocardiogram at intervals of 12 to 18 months, usually starting at the age of 12 years (unless there is a "malignant" family history of premature sudden death, the child is symptomatic or a competitive athlete, or there is a clinical suspicion of left ventricular hypertrophy) until full growth and maturation are achieved (usually by the age of 18 to 21 years). Thereafter, if there are no signs of disease expression, screening approximately every 5 years is advised because the onset of left ventricular hypertrophy may be delayed until well into adulthood in some families. Modified diagnostic criteria (see Table 60-3) consider the high probability that otherwise unexplained ECG and echocardiographic findings in first-degree relatives reflect incomplete disease expression.

When available, genetic testing can identify a disease-causing mutation in an index case and thereby provide presymptomatic diagnosis of family members. Whenever genetic testing is considered, individuals should be informed about the purpose of the test, the most probable mode of inheritance, and the potential hazards and limitations of genetic testing.

Symptom Management

Medical Therapy

Therapeutic options in patients *without* left ventricular outflow gradients are limited predominantly to pharmacologic therapy. β-Blockade may improve chest pain and dyspnea. The dose (starting at a dose equivalent to propranolol, 120 mg/day) should be titrated to achieve a target heart rate of 50 to 70 beats per minute at rest and 130 to 140 beats per minute at peak exercise. Calcium antagonists such as verapamil (starting at a dose of 120 mg/day) and diltiazem (starting at a dose of 180 mg/day) are useful alternatives, particularly in patients with refractory chest pain, but high doses (e.g., verapamil >480 mg/day, diltiazem >360 mg/day) may be required. In patients with paroxysmal nocturnal dyspnea and no evidence of ventricular outflow obstruction, a transient mechanism such as myocardial ischemia or arrhythmia may be the cause, although investigations usually fail to identify the precise cause. Such patients, as well as those with chronically raised pulmonary pressures, may require diuretics (e.g., furosemide, 20 to 40 mg orally as needed, followed by 20 mg/day if required). The dose and duration of diuretic therapy should be minimized because injudicious use of these drugs can be dangerous, particularly in patients with severe diastolic impairment or labile obstruction.

In patients with symptoms caused by left ventricular outflow tract obstruction, the main aim of treatment is to reduce the outflow tract gradient. Options include negative inotropic drugs, surgery, atrioventricular sequential pacing,

and percutaneous alcohol ablation of the interventricular septum. Approximately 60 to 70% of patients improve with β-blockers, although high doses (equivalent to propranolol at 480 mg/day) are frequently required, and side effects are often limiting. When β-blockade alone is ineffective, disopyramide, titrated to the maximal tolerated dose (usually between 400 and 600 mg/day), may be effective in up to two thirds of patients, but side effects related to the anticholinergic effects (e.g., dry eyes and mouth) limit its use. Disopyramide should be given concomitantly with a small to medium dose of a β-blocker (e.g., propranolol, 120 to 240 mg/day), which will slow the heart rate and also blunt rapid atrioventricular nodal conduction should supraventricular arrhythmias develop. In patients who have left ventricular outflow tract obstruction and are taking a β-blocker and disopyramide, other antiarrhythmic drugs that alter repolarization (e.g., sotalol or amiodarone) must be avoided because of the potential proarrhythmic effect. In patients with outflow tract gradients, verapamil can be effective, but caution is required in patients with severe obstruction or elevated pulmonary pressures.

Interventional Therapy

Surgery should be considered for significant outflow obstruction (gradient >50 mm Hg) in patients who have symptoms refractory to medical therapy. The most commonly performed surgical procedure, ventricular septal myectomy, either abolishes or substantially reduces the gradient in 95% of cases, reduces mitral regurgitation, and improves exercise capacity and symptoms. Surgery should be performed in an experienced center, where mortality rates should be less than 1% for isolated myomectomy. The main complications (atrioventricular block, ventricular septal defects) are rare. In some patients, concomitant mitral valve repair or replacement may be required.

In experienced centers, the selective injection of alcohol into a septal perforator branch of the left anterior descending coronary artery to create a localized septal scar yields outcomes similar to surgery. The main nonfatal complication is atrioventricular block requiring a pacemaker in 5 to 20% of patients.

Dual-chamber pacing using a short-programmed atrial ventricular delay to produce maximal pre-excitation while maintaining effective atrial transport can reduce the outflow gradient by 30 to 50% but provides little objective improvement in exercise capacity in most patients.

Supraventricular Arrhythmia

Atrial fibrillation in hypertrophic cardiomyopathy is associated with a high risk for systemic embolization, so anticoagulation (international normalized ratio in the range of 2.0 to 3.0) should be considered in all patients with sustained or paroxysmal atrial fibrillation (Chapter 64). Treatment with low-dose amiodarone, 1000 to 1400 mg/week, is effective in maintaining sinus rhythm and in controlling the ventricular response during breakthrough episodes. The addition of a low-dose β-blocker, verapamil, or diltiazem may be required for rate control. Serious side effects on low-dose amiodarone are uncommon. β-blockers, particularly those with class III action (e.g., sotalol), are less effective alternatives. In general, the principles of managing atrial fibrillation in patients with hypertrophic cardiomyopathy are similar to those in other conditions (Chapter 64), with the provision that the threshold to use anticoagulation should be low because of the significant embolic risk.

Prevention of Sudden Death

The overall risk for sudden death in children and adults with hypertrophic cardiomyopathy is approximately 1% per year, but a minority of individuals have a much greater risk for ventricular arrhythmia and sudden death. The most powerful predictor of sudden cardiac death in hypertrophic cardiomyopathy is a history of previous cardiac arrest. In patients without such a history, the most useful markers of risk are a family history of premature (<40 years of age) sudden cardiac death; unexplained syncope (unrelated to neurocardiogenic mechanisms); a flat or hypotensive blood pressure response to upright exercise; nonsustained ventricular tachycardia on ambulatory electrocardiographic monitoring or during exercise; and severe left ventricular hypertrophy on echocardiography (defined as a maximal left ventricular wall thickness of 30 mm or more). Patients with two or more of these markers have an annual mortality rate of 3 to 6% and should receive an implantable cardioverter-defibrillator (ICD) (Chapter 66). All patients with hypertrophic cardiomyopathy should be advised to avoid competitive sports and intense physical exertion. Patients without any risk factors do not warrant an ICD. For patients with one risk factor, decisions regarding an ICD should be individualized based on the patient's age and severity of disease.

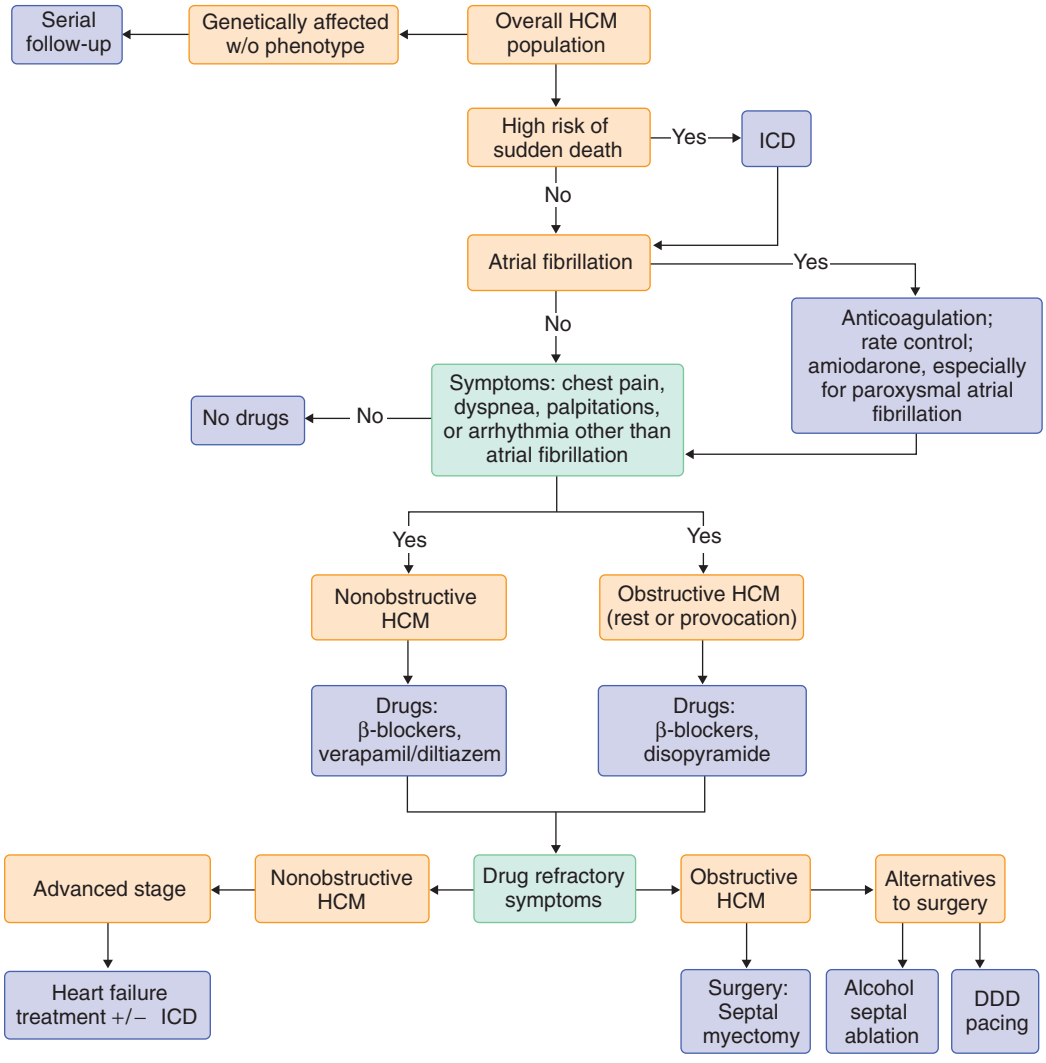

FIGURE 60-3. Approach to the management of hypertrophic cardiomyopathy (HCM). ICD = implantable cardioverter-defibrillator. (Adapted from Maron BJ, McKenna WJ, Danielson GK, et al. American College of Cardiology/European Society of Cardiology clinical expert consensus document on hypertrophic cardiomyopathy. *J Am Coll Cardiol.* 2003;42:1687-1713.)

PROGNOSIS

Most patients with hypertrophic cardiomyopathy follow a stable and benign course with a low risk for adverse events and a survival similar to that of age- and gender-matched normal populations, but many experience progressive symptoms caused by atrial arrhythmia and gradual deterioration in left ventricular systolic and diastolic function. About 1% of affected individuals die suddenly each year. The annual incidence of stroke varies from 0.56 to 0.8%/year, rising to 1.9% in patients older than 60 years, and 23% of strokes are fatal. The development of severe systolic heart failure is associated with a poor prognosis, with an overall mortality rate of up to 11% per year. The incidence of infective endocarditis is 1.4 per 1000 person-years overall but 3.8 per 1000 person-years in patients with obstruction.

Myocarditis

DEFINITION AND EPIDEMIOLOGY

Myocarditis, which is an inflammatory process involving the myocardium, can be caused by infections, immune-mediated damage, or toxins (Table 60-4). The incidence and prevalence of myocarditis are difficult to estimate because the clinical presentation varies from asymptomatic ECG abnormalities to hemodynamic collapse and sudden death. Population estimates of the prevalence of myocarditis range from 1 in 100,000 to 1 in 10,000, whereas postmortem studies report myocarditis in up to 12% of young victims of sudden cardiac death.

Worldwide, the most common infective myocarditis is Chagas' disease, caused by *Trypanosoma cruzi*, a protozoan organism endemic in rural areas of South and Central America (Chapter 355). In the Western world, viral myocarditis is the most common cause of inflammatory heart disease. Human immunodeficiency virus (HIV) infection (Chapter 392) is associated with lymphocytic monocarditis and is a strong predictor of poor prognosis. Smallpox vaccination (Chapter 17) causes myopericarditis, with a reported incidence of 7.8 cases per 100,000 vaccine administrations. Other rare myocarditises include giant cell myocarditis, myocarditis complicating autoimmune disorders such as systemic lupus erythematosus (Chapter 274), and cocaine abuse (Chapter 33).

PATHOBIOLOGY

Myocarditis is defined histologically by the presence of myocyte injury, with degeneration or necrosis, and an inflammatory infiltrate not due to ischemia. Four patterns are recognized: *active myocarditis,* with myocyte degeneration or necrosis and definite cellular infiltrate with or without fibrosis; *borderline myocarditis,* with a definite cellular infiltrate without evidence of myocardial cellular injury; *persistent myocarditis,* with continued active myocarditis on repeat biopsy; and *resolving or resolved myocarditis,* characterized by a diminished or absent infiltrate with evidence of connective tissue healing on repeat biopsy. Despite their widespread use, these criteria have low specificity and sensitivity, with a diagnostic yield as low as 10 to 20% in some series. Therefore, newer virology techniques used in conjunction with conventional light microscopy include nested polymerase chain reaction (PCR) or reverse transcription PCR on RNA and DNA extracted from endomyocardial biopsy specimens, as well as immunohistochemical staining for subtypes of infiltrating lymphocytes and abnormal expression of cellular adhesion molecules on interstitial or endothelial cells.

Viral Myocarditis

Most data on the pathology of viral myocarditis come from murine models. Initially, there is direct invasion of the myocardium by cardiotropic viruses, which enter the cardiomyocyte through receptor-mediated endocytosis. The viral genome, which translated intracellularly to produce viral protein or is incorporated into the host cell genome, may contribute to myocyte dysfunction by cleaving dystrophin. In the second phase, activation of the host immune system, including recruitment of natural killer cells and macrophages, increases the expression of proinflammatory cytokines such as interleukin-1 and tumor necrosis factor. Activation of $CD4^+$ T lymphocytes promotes clonal expansion of B lymphocytes, thereby resulting in further myocardial cell damage, inflammation, and the production of circulating anti-heart antibodies directed against contractile, structural, and mitochondrial proteins. This autoimmune response may result in long-term ventricular remodeling owing to direct effects on myocardial structural components or alterations in the extracellular matrix.

TABLE 60-4 CAUSES OF MYOCARDITIS

INFECTION
Viral
Coxsackievirus, human immunodeficiency virus, echovirus, adenovirus, influenza, measles, mumps, parvovirus, poliovirus, rubella, varicella-zoster virus, herpes simplex virus, cytomegalovirus, hepatitis C virus, rabies virus, respiratory syncytial virus, vaccine virus, dengue virus, yellow fever virus
Protozoal
Trypanosoma cruzi, Toxoplasma gondii
Bacterial
Brucella, Corynebacterium diphtheriae, Salmonella, Haemophilus influenzae, Mycoplasma pneumoniae, Neisseria meningitidis (meningococcus), *Streptococcus pneumoniae, Staphylococcus, Mycobacterium, Neisseria gonorrhoeae* (gonococcus), *Vibrio cholerae*
Spirochetal
Treponema pallidum, Borrelia, Leptospira
Fungal
Aspergillus, Candida, Cryptococcus, Actinomyces, Blastomyces, Histoplasma, Coccidioides
Rickettsial
Coxiella burnetii, Rickettsia rickettsii, Rickettsia tsutsugamushi
Parasitic
Trichinella spiralis, Echinococcus granulosus, Taenia solium
IMMUNE-MEDIATED DISORDERS
Alloantigens
Heart transplant rejection
Autoantigens
Churg-Strauss syndrome, celiac disease, Whipple's disease, giant cell myocarditis, Kawasaki disease, systemic lupus erythematosus, systemic sclerosis, sarcoidosis, scleroderma, polymyositis, thrombocytopenic purpura
Allergens (Drugs)
Penicillin, sulfonamides, tetracycline, methyldopa, streptomycin, tricyclic antidepressants, thiazide diuretics, dobutamine, indomethacin
TOXIC CAUSES
Drugs
Anthracyclines, catecholamines, amphetamines, cocaine, cyclophosphamide, 5-fluorouracil, Herceptin, interferon, interleukin-2
Physical Agents
Electric shock, radiation, hyperpyrexia
Heavy Metals
Copper, iron, lead
Others
Arsenic, snake bite, scorpion bite, wasp and spider stings, phosphorus, carbon monoxide
GENETIC DISORDERS
Inherited cardiomyopathies with immune-mediated pathogenesis (dilated and right ventricular cardiomyopathy)

CLINICAL MANIFESTATIONS

Some patients report prodromal symptoms of viremia, including fever, myalgia, coryzal symptoms, or gastroenteritis, but many individuals with myocarditis are asymptomatic and manifest only transient ECG abnormalities such as nonspecific ST segment and T wave abnormalities, pathologic Q waves, and low QRS voltages. Less common ECG presentations include acute myocardial infarction (Chapter 73), atrioventricular block (Chapter 64), and ventricular arrhythmias (Chapter 65). Patients with impairment of left ventricular function may present with symptoms and signs of fulminant cardiogenic shock (Chapter 107) with acute cardiovascular collapse. In some cases, sudden cardiac death is the first presentation.

DIAGNOSIS

The diagnosis of myocarditis requires a high index of suspicion because it may mimic other common conditions. On echocardiography, evidence of impaired left ventricular systolic performance, often without significant left

ventricular dilatation, is typical. Regional wall motion abnormalities are common, and left (or right) ventricular thrombus may be present. Evidence of left ventricular diastolic impairment and pericardial effusions is common. Cardiac magnetic resonance imaging can detect myocardial inflammation and myocyte injury, with pericellular and cellular edema.

Routine blood tests such as full blood count and erythrocyte sedimentation rate are usually unhelpful, but serum markers of myocardial injury such as troponin T and I may be elevated. Creatine kinase and its cardiac isoform CK-MB are less sensitive and specific than troponin and are not useful as screening tests. Increased levels of autoantibodies against myocardial proteins (such as myosin and the adenine nucleotide translocator protein) correlate with progressive worsening of ventricular function.

Cardiac catheterization with right ventricular endomyocardial biopsy remains the gold standard diagnostic test for myocarditis. However, it is generally reserved for patients with heart failure refractory to standard management, features suggestive of systemic disease (e.g., connective tissue disease [Chapter 268], amyloidosis [Chapter 193], hemochromatosis [Chapter 219], sarcoidosis [Chapter 95]), or suspicion of giant cell myocarditis because of new-onset heart failure associated with tachyarrhythmias or conduction disease.

Specific Causes

Viral myocarditis may be suspected from the clinical picture of recent febrile illness, often with prominent myalgias, followed by angina-like chest pain, dyspnea, or arrhythmias. Elevated troponin levels support the diagnosis, and increasing viral titers (to coxsackievirus, echovirus, adenovirus, or influenza virus) confirm recent infection. Clinical cardiomyopathy occurs in 10 to 40% of patients infected with HIV, owing to the HIV itself or to coinfection with cytomegalovirus.

Giant cell myocarditis, which accounts for 10 to 20% of biopsy-positive cases of myocarditis, presents with the rapid onset of chest pain, fever, and hemodynamic compromise, often with ventricular tachycardia or atrioventricular block. When ventricular tachyarrhythmias are a major feature of myocarditis, particularly in a young person, endomyocardial biopsy is generally recommended to determine whether giant cell myocarditis is present, even though the diagnosis is statistically unlikely.

Toxoplasmosis (Chapter 357) *myocarditis*, owing to intermittent rupture of cysts in the myocardium, can cause atypical chest pain, arrhythmias, pericarditis, and symptomatic heart failure. Diagnosis is made from antibody titers. Lyme carditis (Chapter 329) classically presents with conduction system abnormalities resulting from infection with *Borrelia burgdorferi*, which is diagnosed serologically.

Immune-mediated myocarditis can be associated with polymyositis (Chapter 277) or systemic lupus erythematosus (Chapter 274), although pericarditis and coronary artery vasculitis are more common. Hypersensitivity reactions, especially to drugs (Chapter 262), can cause myocarditis that is often associated with peripheral eosinophilia and can be confirmed by endomyocardial biopsy.

TREATMENT

Rx

The first-line treatment of myocarditis is supportive with afterload reduction and diuresis (Chapter 59). Patients with fulminant acute myocarditis may require inotropic support, mechanical assist devices, or extracorporeal membrane oxygenation (Chapter 107). Following initial stabilization, patients with symptoms and signs of heart failure should receive angiotensin-converting enzyme inhibitors, diuretics, β-blockers, and anticoagulants in accordance with standard guidelines (Chapter 59). Patients with intractable and deteriorating heart failure may require cardiac transplantation (Chapter 82).

The role of immunosuppression is uncertain. In one randomized, placebo-controlled trial of 111 adults with biopsy-proven myocarditis, there was no difference in mortality or improvement in left ventricular function in patients treated with prednisolone plus either cyclosporine or azathioprine.■ Conversely, in a randomized trial of patients who had major histocompatibility complex expression on endomyocardial biopsy samples and who were randomized to prednisolone (1 mg/kg/day tapering to a maintenance dose of 0.2 mg/kg/day for a total of 90 days) and azathioprine (1 mg/kg/day for a total of 100 days) versus placebo, left ventricular ejection fraction improved in the immunosuppressed group, but no difference was observed in mortality or rates of transplantation or rehospitalization over a 2-year follow-up period.■ At present, immunosuppression is generally reserved for patients with giant cell myocarditis, in whom there is some benefit,■ although the optimal regimen is yet to be determined. Intravenous immunoglobulin therapy is not helpful.■

PROGNOSIS

Patients with acute myocarditis with mild heart failure or symptoms suggestive of myocardial ischemia or infarction typically improve within weeks without sequelae. An acute presentation of myocarditis with advanced heart failure (ejection fraction <35%) may resolve but can lead to chronic left ventricular dysfunction (dilated cardiomyopathy) or progress to death or cardiac transplantation. Patients who present with acute fulminant myocarditis, however, have an excellent prognosis, with survival rates of more than 90%. Giant cell myocarditis is usually fatal without heart transplantation.

Dilated Cardiomyopathy

DEFINITION AND EPIDEMIOLOGY

Dilated cardiomyopathy is a heart muscle disorder defined by dilation and impaired systolic function of the left or both ventricles, in the absence of coronary artery disease, valvular abnormalities, or pericardial disease. In adults, prevalence estimates range from 14 to 36 per 100,000. In children, dilated cardiomyopathy is the most common cardiomyopathy, accounting for up to 58% of cases. Overall, males and females are approximately equally affected, except for dilated cardiomyopathy associated with neuromuscular disorders or inborn errors of metabolism, for which there is male predominance, because some of these conditions have an X-linked inheritance.

PATHOBIOLOGY

A number of conditions are associated with dilated cardiomyopathy, including neuromuscular disorders, inborn errors of metabolism, and malformation syndromes. In most patients, no identifiable cause is found, and the disease is termed *idiopathic dilated cardiomyopathy*.

Genetic Dilated Cardiomyopathy

Between 20 and 50% of individuals with dilated cardiomyopathy have evidence of familial disease (see Table 60-2). Autosomal dominant inheritance, which accounts for 68% of familial cases, has two major forms: isolated dilated cardiomyopathy and dilated cardiomyopathy associated with conduction system disease. The latter patients may also have an associated skeletal myopathy. Genes implicated in isolated dilated cardiomyopathy include cytoskeletal and sarcomeric protein genes. Mutations in the lamin A/C gene, which encodes a nuclear envelope protein, cause atrial arrhythmia and progressive atrioventricular conduction disease, which precede the development of dilated cardiomyopathy by several years.

X-linked inheritance accounts for between 2 and 5% of familial cases of dilated cardiomyopathy Neuromuscular disorders account for 26% of cases, 90% of which are Duchenne, Becker's, and Emery-Driefuss muscular dystrophies (Chapter 429). Isolated X-linked dilated cardiomyopathy, also caused by mutations in the dystrophin gene, is characterized by raised serum creatine kinase muscle isoforms but does not result in clinical signs or symptoms of skeletal muscular dystrophy.

Acquired Dilated Cardiomyopathy

Common acquired causes of dilated cardiomyopathy include infectious myocarditis, chemotherapy (Chapter 182), radiotherapy (Chapter 19), alcohol (Chapter 32), cocaine (Chapter 33), nutritional deficiencies (Chapter 222), iron overload (Chapter 219), inflammatory and autoimmune disorders (Chapters 274 and 278), endocrinopathies (Chapter 233), and pregnancy (Chapter 247). Tachycardia-mediated cardiomyopathy (tachycardiomyopathy) is rare and usually reverses once the tachycardia is controlled.

CLINICAL MANIFESTATIONS

The symptoms and signs associated with dilated cardiomyopathy depend on the age of the patient and the degree of left ventricular dysfunction. Although the first presentation may be with sudden death or a thromboembolic event, most patients present with symptoms of high pulmonary venous pressure or low cardiac output (Chapter 58), which can be acute, sometimes precipitated by intercurrent illness or arrhythmia, or chronic. Increasingly, dilated cardiomyopathy is diagnosed incidentally in asymptomatic individuals during family screening.

Adults initially present with reduced exercise tolerance and dyspnea on exertion. With worsening left ventricular function, patients may develop dyspnea at rest, orthopnea, paroxysmal nocturnal dyspnea, peripheral edema, and ascites. Symptoms related to mesenteric ischemia, such as abdominal pain after meals, nausea, vomiting, and anorexia, may dominate, especially in

children. Arrhythmia symptoms, such as palpitations, presyncope, and syncope, can occur at any age.

In advanced disease, features of low cardiac output include sinus tachycardia, weak peripheral pulses, and hypotension. The jugular venous pressure may be elevated, and the apical impulse is displaced. Peripheral edema, hepatomegaly, and ascites are common in patients with heart failure. Auscultation of the chest typically reveals basal crackles. Auscultation of the heart may reveal the presence of a third (and sometimes also a fourth) heart sound. In patients with functional mitral regurgitation, a pansystolic murmur may be heard at the apex and radiate to the axilla, but frequently no murmurs are heard, even in the presence of mitral incompetence, especially if cardiac output is very low.

DIAGNOSIS

The ECG may be normal but more typically shows sinus tachycardia, nonspecific ST segment and T wave changes (most commonly in the inferior and lateral leads), atrial enlargement, and voltage criteria for ventricular hypertrophy. Atrioventricular block raises the possibility of mutations in the lamin A/C gene. Supraventricular and ventricular arrhythmias are common. The chest radiograph is usually abnormal, with an increased cardiothoracic ratio (greater than 0.5) reflecting left ventricular and left atrial dilation. Patients with pulmonary edema have increased pulmonary vascular markings and pleural effusion.

On echocardiography, the presence of ventricular end-diastolic dimensions greater than 2 standard deviations above body surface area–corrected means (or greater than 112% of predicted dimension) and fractional shortening less than 25% are sufficient to make the diagnosis. Other common features include functional mitral and tricuspid regurgitation and abnormalities of diastolic left ventricular function. Cardiac magnetic resonance imaging may show areas of myocardial fibrosis.

Other recommended tests (Table 60-5) include a complete blood count and tests of renal, thyroid, and hepatic function. Levels of serum creatine kinase should be measured in all patients with dilated cardiomyopathy because this may provide important clues to the etiology. Other cardiac biomarkers, such as troponin I and troponin T, can be elevated. Plasma B-type natriuretic peptide levels predict survival, hospitalization rates, and listing for cardiac transplantation. Symptom-limited exercise testing, combined with respiratory gas analysis, is a useful technique to assess functional limitation and disease progression in patients with stable dilated cardiomyopathy.

Cardiac catheterization is rarely needed except perhaps to exclude severe coronary artery disease or to provide more precise information about possible valvular heart disease. Endomyocardial biopsy may be diagnostic for myocarditis and for some metabolic or mitochondrial disorders but is rarely advised. Hemodynamic assessment of left ventricular end-diastolic and pulmonary artery pressures may be necessary before transplantation.

TABLE 60-5 LABORATORY EVALUATION OF CARDIOMYOPATHY

CLINICAL EVALUATION
History and physical examination to identify cardiac and noncardiac disorders*
Assessment of ability to perform routine and desired activities*
Assessment of volume status*
LABORATORY EVALUATION
Electrocardiogram*
Chest radiograph*
Two-dimensional and Doppler echocardiogram*
Chemistry
Serum sodium,* potassium,* glucose, creatinine,* blood urea nitrogen,* calcium,* magnesium*
Albumin,* total protein,* liver function tests,* serum iron, ferritin
Urinalysis
Creatine kinase
Thyroid-stimulating hormone*
Hematology
Hemoglobin/hematocrit*
White blood cell count with differential,* including eosinophils
Erythrocyte sedimentation rate
INITIAL EVALUATION IN SELECTED PATIENTS ONLY
Titers for suspected infection
Acute viral (coxsackievirus, echovirus, influenza virus)
Human immunodeficiency virus, Epstein-Barr virus
Lyme disease, toxoplasmosis
Chagas' disease
Catheterization with coronary angiography in patients with angina who are candidates for intervention*
Serologic studies for active rheumatologic disease
Endomyocardial biopsy

*Level I recommendations from Hunt SA, Abraham WT, Chin MH, et al. ACC/AHA 2005 Guideline Update for the Diagnosis and Management of Chronic Heart Failure in the Adult. *Circulation.* 2005;112:e154-e235.

TREATMENT Rx

Supportive therapy includes sodium and fluid restriction, avoidance of alcohol and other toxins, and use of established heart failure medications (Chapter 59). Although older recommendations emphasized rest and avoidance of exercise, this advice should be limited to patients with myocarditis or peripartum cardiomyopathy; for other patients, a submaximal exercise regimen is desirable to sustain mobility, to avoid deconditioning, and to maintain physical and psychological health. Patients with atrial fibrillation or with echocardiographic evidence of a left atrial or left ventricular mural thrombosis should be anticoagulated to an international normalized ratio of 2.0 to 3.0. An ICD is preferred over medication for ventricular arrhythmias, and some patients require management for advanced heart failure (Chapter 59) with biventricular pacing, inotropic medications, ventricular assist devices, and cardiac transplantation (Chapter 82).

Family Screening

Familial evaluation of first-degree relatives by history and physical examination and with 12-lead ECG and two-dimensional echocardiographic studies is warranted at the time of diagnosis and serially thereafter. Precise algorithms to guide the interval of evaluation remain to be determined; because disease progression is usually slow, evaluation about every 5 years until age 50 years appears appropriate. The detection of early disease in a family member offers an opportunity to initiate treatment, usually with an angiotensin-converting enzyme inhibitor or β-blocker, but the efficacy of such therapy remains to be proved.

PROGNOSIS

The prognosis of idiopathic and genetically determined dilated cardiomyopathy is related to the severity of disease at the time of presentation and the response to treatment. Most patients improve with treatment, but 5-year survival is less than 50% in patients who present with severe disease (e.g., ejection fraction <25%, left ventricular end-diastolic dimension >65 mm, peak oxygen consumption <12 mL/kg/minute).

Specific Causes of Dilated Cardiomyopathy

Alcoholic Cardiomyopathy

In the United States, excess alcohol consumption (Chapter 32) contributes to more than 10% of cases of heart failure. Alcohol and its metabolite, acetaldehyde, are cardiotoxins. Myocardial depression is initially reversible but, if alcohol consumption is sustained, can lead to myocyte vacuolization, mitochondrial abnormalities, and myocardial fibrosis. Even in chronic stages, however, the heart failure represents a sum of both reversible and irreversible myocardial dysfunction. The amount of alcohol necessary to produce symptomatic cardiomyopathy in susceptible individuals is not known but has been estimated to be six drinks (~4 oz of pure ethanol) a day for 5 to 10 years. Frequent binging without heavy daily consumption may also be sufficient. Alcoholic cardiomyopathy can develop in patients without social evidence of an alcohol problem. Abstinence leads to improvement in at least 50% of patients with severe symptoms, some of whom normalize their left ventricular ejection fractions. Patients with other causes of heart failure also should limit alcohol consumption.

Chemotherapy

Anthracycline (doxorubicin, daunorubicin, epirubicin) cardiotoxicity (Chapter 182) causes characteristic histologic changes on endomyocardial biopsy with overt heart failure in 5 to 10% of patients who receive doses greater than or equal to 450 mg/m^2 of body surface area. Patients who have received anthracyclines in the prepubertal period without apparent cardiotoxicity may develop cardiac failure in young adulthood. The risk is higher in patients who have lower baseline ejection fractions, concomitant radiation therapy, or higher doses of anthracycline. *Cyclophosphamide* and

ifosfamide can cause acute severe heart failure and malignant ventricular arrhythmias. Some *tyrosine kinase inhibitors* (e.g., sunitinib) cause a reduction in systolic function, especially in the presence of coronary artery disease, but there is good response to withdrawal and conventional medical therapy (Chapter 190). *5-Fluorouracil* can cause coronary artery spasm and depressed left ventricular contractility. Up to 11% of patients who receive *trastuzumab* (Chapter 204), a recombinant monoclonal antibody that binds to human epidermal growth factor type 2, develop dilated cardiomyopathy, which is reversible after withdrawal and conventional drug treatment. The risk for cardiotoxicity increases with previous anthracycline and radiation treatment. *Interferon-α* may be associated with hypotension and arrhythmias in up to 10% of patients, and *interleukin-2* rarely has been associated with cardiotoxicity.

Metabolic and Endocrine Disease

Excess catecholamines, as in *pheochromocytoma* (Chapter 235), may injure the heart by compromising the coronary microcirculation or by direct toxic effects on myocytes. *Cocaine* (Chapter 33) increases synaptic concentrations of catecholamines by inhibiting reuptake at nerve terminals; the result may be an acute coronary syndrome or chronic cardiomyopathy.

Thiamine deficiency from poor nutrition or alcoholism (Chapter 225) can cause beriberi heart disease, with vasodilation and high cardiac output followed by low output. *Calcium deficiency* resulting from hypoparathyroidism, gastrointestinal abnormalities, or chelation directly compromises myocardial contractility.

Hypophosphatemia (Chapter 121), which may occur in alcoholism, during recovery from malnutrition, and in hyperalimentation, also reduces myocardial contractility. Patients with *magnesium depletion* owing to impaired absorption or increased renal excretion (Chapter 121) also may present with left ventricular dysfunction.

Hypothyroidism (Chapter 233) depresses contractility and conduction and may cause pericardial effusions, whereas *hyperthyroidism* increases cardiac output, can worsen underlying heart failure, and may rarely be the sole cause of heart failure.

The presenting sign of *diabetes* (Chapter 236) can be cardiomyopathy, especially with diastolic dysfunction, independent of epicardial coronary atherosclerosis, for which it is a major risk factor.

Obesity (Chapter 227) can cause cardiomyopathy with increased ventricular mass and decreased contractility, which improve after weight loss, or it can aggravate underlying heart failure from other causes.

Peripartum Cardiomyopathy

Peripartum cardiomyopathy appears in the last month of pregnancy or in the first 5 months after delivery in the absence of preexisting cardiac disease (Chapter 247). The incidence is between 1 in 3000 and 1 in 15,000 deliveries, with increased risk in older mothers or in the setting of twins, malnutrition, tocolytic therapy, toxemia, or hypertension. Lymphocytic myocarditis, found in 30 to 50% of biopsy specimens, suggests an immune component, perhaps cross-reactivity between uterine and cardiac myocyte proteins or an enhanced susceptibility to viral myocarditis. More recently, it has been suggested that enhanced oxidative stress triggers activation of cathepsin D, a ubiquitous lysosomal enzyme, which cleaves serum prolactin in its antiangiogenic and proapoptotic 16-kD form. The latter appears to promote endothelial inflammation and impair cardiomyocyte metabolism and contraction. Presentation is usually with orthopnea and dyspnea on minimal exertion, most often within the first weeks after delivery when the excess volume of pregnancy would normally be mobilized. Preexisting cardiac disease must be excluded. Diuretics facilitate postpartum diuresis, and angiotensin-converting enzyme inhibitors improve symptoms (Chapter 59). In a small randomized trial, oral bromocriptine (2.5 mg twice daily for 2 weeks, then daily for 6 weeks) significantly improved recovery of left ventricular function and may reduce deaths.■ The prognosis is improvement to normal or near-normal ejection fraction during the next 6 months in more than 50% of patients. About 4% require heart transplantation, and about 9% die suddenly or from complications of heart transplantation.

Overlap with Restrictive Cardiomyopathy

Diseases causing primarily restrictive cardiomyopathies can occasionally overlap to cause a picture consistent with dilated cardiomyopathy. For example, *hemochromatosis* (Chapter 219) and *sarcoidosis* (Chapter 95) should be considered when evaluating any patient with a cardiomyopathy, although these conditions are more often considered with the restrictive diseases. *Amyloidosis* (Chapter 194) is less commonly confused with dilated than with hypertrophic cardiomyopathy but should be considered in a patient with a thick-walled ventricle with moderately depressed contractile function.

Arrhythmogenic Right Ventricular Cardiomyopathy

DEFINITION AND EPIDEMIOLOGY

ARVC (Chapter 65) is a genetically determined heart muscle disorder characterized histologically by loss of cardiomyocytes with replacement by fibrous or fibrofatty tissue in the right ventricular myocardium; clinically by ventricular arrhythmias, heart failure, and sudden death; and histologically by cardiomyocyte loss and replacement. It is associated with arrhythmia, heart failure, and premature sudden death. The disease is seen in patients of European, African, and Asian descent, with an estimated prevalence between 1 in 1000 and 1 in 5000 adults.

PATHOBIOLOGY

ARVC is inherited as an autosomal dominant disease, with incomplete penetrance, although recessive forms with cutaneous manifestations are recognized (see Table 60-2). Most cases are caused by heterozygous mutations in genes encoding components of the desmosome and adherens junction of cardiomyocytes. The most common occur in plakophilin-2, desmocollin-2, desmoplakin, and desmoglein-2. Homozygous mutations in plakoglobin are responsible for the rare autosomal recessive form, Naxos disease. Recently, a mutation in the transmembrane cytoplasmic protein 43 (TNEM43) has been described. Two other nondesmosomal genes, the cardiac ryanodine receptor and transforming growth factor-β3 (TGF-β3), have been linked with ARVC but are probably not important in most patients.

Pathology

The main pathologic feature is progressive loss of right ventricular myocardium, which is replaced by adipose and fibrous tissue. These changes begin in the inflow, outflow, and apical regions of the right ventricle. Aneurysm formation in these areas is typical. Progressive myocardial involvement may lead to global right ventricular dilation. Severe right ventricular disease is often associated with fibrofatty substitution of the left ventricular myocardium, with the posterolateral wall preferentially affected.

Mutations in desmosomal protein genes may increase the susceptibility of the myocardium to the damaging effects of mechanical stress, thereby predisposing to cardiomyocyte detachment, death, and eventual replacement with fibrofatty tissue. The acute phase of myocardial injury may be accompanied by inflammation. The predilection for the right ventricle has been explained by its thin wall and greater distensibility. As desmosomal proteins interact with many other proteins, including components of the cellular cytoskeleton and intermediate filaments, it is possible that ventricular dysfunction occurs as the result of reduced cytoskeletal integrity and impaired force transduction. Some desmosomal proteins, in particular plakoglobin, are also important signaling molecules that regulate the transcription of many other genes. Finally, a reduction in the number and size of gap junctions may result in a electrical coupling defect, thereby increasing the propensity to arrhythmia without significant morphologic changes.

CLINICAL MANIFESTATIONS

By convention, the natural history of ARVC is divided into four phases, but it is not inevitable that patients will progress through all phases. In the early phase, patients are usually asymptomatic, but resuscitated cardiac arrest and sudden death may be the initial manifestations, particularly in adolescents and young adults. The overt arrhythmic phase usually begins in adolescents and young adults, when patients note palpitations or syncope. Symptomatic sustained arrhythmias are usually accompanied by morphologic and functional abnormalities of the right ventricle. The third phase, characterized by diffuse right ventricular disease, occurs in the middle and later decades; patients may present with right-sided heart failure despite relatively preserved left ventricular function. In the advanced stage, left ventricular involvement and biventricular heart failure are seen.

DIAGNOSIS

Clinical evaluation includes inquiry for symptoms of arrhythmia (syncope, presyncope, sustained palpitation); a family history of premature cardiac symptoms or sudden death; 12-lead, 24-hour, and maximal exercise ECG testing; and two-dimensional echocardiography with specific right ventricular views. Contrast echocardiography may be required to obtain better

endocardial definition of the right ventricular myocardium and apex of the left ventricle. Magnetic resonance imaging may provide accurate assessment of ventricular volumes as well as noninvasive characterization of fibrous tissue and fat.

Ventricular arrhythmias with a left bundle branch block morphology, consistent with a right ventricular origin, are characteristic. However, the ECG and arrhythmic manifestations are not specific to ARVC and overlap with many other disease states, so standard criteria are recommended for diagnosis (Table 60-6). Because these criteria are highly specific but lack sensitivity for detecting early disease, more sensitive criteria are recommended for first-degree relatives of known cases (Table 60-7). The diagnosis of ARVC in a proband also raises the possibility of mutation analysis in the family to identify those at risk and in need of serial evaluation as well as those who need no specific follow-up.

Differential Diagnosis

The differential diagnosis includes other inherited cardiomyopathies, the inherited arrhythmia syndromes (long QT syndrome, Brugada's syndrome, and catecholaminergic polymorphic ventricular tachycardia; Chapter 65), and causes of right ventricular dilation such as intracardiac or extracardiac shunts (Chapter 69). The differentiation from so-called benign right ventricular outflow tract tachycardia may be problematic, although in the latter the 12-lead ECG and right ventricular imaging studies are typically normal, and no familial disease is present. Some patients with desmosomal protein

TABLE 60-6 REVISED TASK FORCE CRITERIA FOR ARRHYTHMOGENIC RIGHT VENTRICULAR CARDIOMYOPATHY IN PROBANDS*

Criteria	
MAJOR	**MINOR**
I. GLOBAL OR REGIONAL DYSFUNCTION AND STRUCTURAL ALTERATIONS*	
By two-dimensional echo: • Regional RV akinesia, dyskinesia, or aneurysm • *and* 1 of the following (end diastole): PLAX RVOT ≥32 mm (corrected for body size [PLAX/BSA] ≥19 mm/m^2) PSAX RVOT ≥36 mm (corrected for body size [PLAX/BSA] ≥21 mm/m^2) *or* fractional area change ≤33%	**By two-dimensional echo:** • Regional RV akinesia or dyskinesia • *and* 1 of the following (end diastole): PLAX RVOT ≥29 to <32 mm (corrected for body size [PLAX/BSA] ≥16 to <19 mm/m^2) PSAX RVOT ≥32 to <36 mm (corrected for body size [PSAX/BSA] ≥18 to <21 mm/m^2) *or* fractional area change >33% to ≤40%
By MRI: • Regional RV akinesia or dyskinesia or dyssynchronous RV contraction • *and* 1 of the following: RV end-diastolic volume indexed to BSA ≥110 mL/m^2 (male) or ≥100 mL/m^2 (female) *or* RV ejection fraction ≤40%	**By MRI:** • Regional RV akinesia or dyskinesia or dyssynchronous RV contraction • *and* 1 of the following: RV end-diastolic volume indexed to BSA ≥100 to <110 mL/m^2 (male) or ≥90 to <100 mL/m^2 (female) *or* RV ejection fraction >40% to ≤45%
By RV angiography: • Regional RV akinesia, dyskinesia, or aneurysm	
II. TISSUE CHARACTERIZATION OF WALL	
• Residual myocytes <60% by morphometric analysis (or <50% if estimated), with fibrous replacement of the RV free wall myocardium in ≥1 sample, with or without fatty replacement of tissue on endomyocardial biopsy	• Residual myocytes 60% to 75% by morphometric analysis (or 50% to 65% if estimated), with fibrous replacement of the RV free wall myocardium in ≥1 sample, with or without fatty replacement of tissue on endomyocardial biopsy
III. REPOLARIZATION ABNORMALITIES	
• Inverted T waves in right precordial leads (V_1,V_2, and V_3) or beyond in individuals >14 years of age (in the absence of complete right bundle-branch block QRS ≥120 msec)	• Inverted T waves in leads V_1 and V_2 in individuals >14 years of age (in the absence of complete right bundle branch block) or in V_4, V_5, or V_6 • Inverted T waves in leads V_1, V_2, V_3, and V_4 in individuals >14 years
IV. DEPOLARIZATION/CONDUCTION ABNORMALITIES	
• Epsilon wave (reproducible low-amplitude signals between end of QRS complex to onset of the T wave) in the right precordial leads (V_1 to V_3)	• Late potentials by SAECG in ≥1 of 3 parameters in the absence of a QRS duration ≥110 msec on the standard ECG • Filtered QRS duration (fQRS) ≥114 msec • Duration of terminal QRS <40 μV (low-amplitude signal duration) ≥38 msec • Root-mean-square voltage of terminal 40 msec ≤20 μV • Terminal activation duration of QRS ≥55 msec measured to the end of the QRS, including R′, in V_1, V_2, or V_3, in the absence of complete right bundle-branch block
V. ARRHYTHMIAS	
• Nonsustained or sustained ventricular tachycardia of left bundle branch morphology with superior axis (negative or indeterminate QRS in leads II, III, and aVF and positive in lead aVL)	• Nonsustained or sustained ventricular tachycardia of RV outflow configuration, left bundle branch block morphology with inferior axis (positive QRS in leads II, III, and aVF and negative in lead aVL) or of unknown axis • >500 ventricular extrasystoles per 24 hours (Holter)
VI. FAMILY HISTORY	
• ARVC confirmed in a first-degree relative who meets current Task Force criteria • ARVC confirmed pathologically at autopsy or surgery in a first-degree relative • Identification of a pathogenic mutation† categorized as associated or probably associated with ARVC in the patient under evaluation	• History of ARVC in a first-degree relative in whom it is not possible or practical to determine whether the family member meets current Task Force criteria • Premature sudden death (<35 years of age) due to suspected ARVC in a first-degree relative

*Hypokinesis is not included in this or subsequent definitions of right ventricular (RV) regional wall motion abnormalities for the proposed modified criteria.

†A pathogenic mutation is a DNA alteration associated with ARVC that alters or is expected to alter the encoded protein, is unobserved or rare in a large non-ARVC control population, and either alters or is predicted to alter the structure or function of the protein or has demonstrated linkage to the disease phenotype in a conclusive pedigree.

ARVC = arrhythmogenic right ventricular cardiomyopathy; aVF = augmented voltage unipolar left foot lead; aVL = augmented voltage unipolar left arm lead; BSA = body surface area; PLAX = parasternal long-axis view; PSAX = parasternal short-axis view; RVOT = right ventricular outflow tract.

Diagnostic terminology for original criteria: this diagnosis is fulfilled by the presence of 2 major, 1 major plus 2 minor, or 4 minor criteria from different groups.

Diagnostic terminology for revised criteria: definite diagnosis: 2 major, 1 major and 2 minor, or 4 minor criteria from different categories; borderline: 1 major and 1 minor or 3 minor criteria from different categories; possible: 1 major or 2 minor criteria from different categories.

From Marcus FI, McKenna WJ, Sherrill D, et al. Diagnosis of arrhythmogenic right ventricular cardiomyopathy/dysplasia: proposed modification of the task force criteria. *Circulation.* 2010;121:1533-1541.

TABLE 60-7 ARRHYTHMOGENIC RIGHT VENTRICULAR CARDIOMYOPATHY: CRITERIA FOR DIAGNOSIS OF FIRST-DEGREE RELATIVES WHO DO NOT FULFILL CRITERIA AS PROBANDS*

ARVC in a first-degree relative plus one of the following:	
ECG	T wave inversion in right precordial leads (V_2 and V_3)
Signal-averaged ECG	Late potentials seen on signal-averaged ECG
Arrhythmia	Left bundle branch block–type ventricular tachycardia on ECG, Holter monitoring, or during exercise testing; >200 extrasystoles over a 24-hour period
Structural or functional abnormality of the right ventricle	Mild global right ventricular dilation or reduction in ejection fraction with normal left ventricle; mild segmental dilation of the right ventricle; regional right ventricular hypokinesia

*Any one criterion is adequate for the diagnosis.
ARVC = arrhythmogenic right ventricular cardiomyopathy; ECG = electrocardiogram.
From Hamid MS, Norman M, Quraishi A, et al: Prospective evaluation of relatives for familial arrhythmogenic right ventricular cardiomyopathy reveals a need to broaden diagnostic criteria. *J Am Coll Cardiol* 2002;40:1445-1450.

gene mutations demonstrate left ventricular involvement early in the disease may have a predominant left ventricular dilated cardiomyopathy phenotype.

TREATMENT

Rx

Pharmacologic treatment is the first-line therapy for patients with well-tolerated, non–life-threatening ventricular arrhythmias, such as frequent ventricular extrasystoles. Treatment of patients with symptomatic ventricular arrhythmias is with an ICD, with supplemental sotalol (160 to 240 mg/day) or even amiodarone (maintenance dose of 200 mg/day). Catheter ablation (Chapter 66) is indicated in patients with drug-refractory incessant ventricular arrhythmia or frequent recurrences of ventricular tachycardia after implantation of an ICD, although recurrence is common.

Retrospective analyses of clinical and pathologic series have identified a number of possible predictors of adverse outcome in probands, including an early age of onset of symptoms; competitive sporting activity; a malignant family background; severe right ventricular dilation; left ventricular involvement; syncope; episodes of complex ventricular arrhythmias or VT; and increased QRS dispersion on 12-lead ECG. ICD implantation is recommended for the prevention of sudden cardiac death in patients with documented sustained ventricular tachycardia or ventricular fibrillation and a reasonable expectation of survival with a good functional status for longer than 1 year. ICD implantation may also be appropriate in patients with extensive disease, including those with left ventricular involvement, or undiagnosed syncope when ventricular tachycardia or ventricular fibrillation has not been excluded as the cause.

Standard heart failure therapy, including diuretics, angiotensin-converting enzyme inhibitors, and β-blockers is indicated in patients in whom ARVC has progressed to severe heart failure or biventricular systolic dysfunction (Chapter 59). Anticoagulation should be considered in the presence of atrial fibrillation (Chapter 64), marked ventricular dilation, or ventricular aneurysms. In patients in whom heart failure is refractory, cardiac transplantation (Chapter 82) should be considered.

PROGNOSIS

Most data on prognosis in ARVC are derived from small, high-risk populations. By the age of 40 years, event-free survival is 50 to 60% in patients with Naxos disease and some autosomal dominant forms. In patients who have syncope or sustained ventricular arrhythmias and are treated with an ICD, freedom from appropriate shock therapy is about 75% at 48 months after implantation, with 96% of patients alive. Risk factors for sudden cardiac death include severe right ventricular disease, left ventricular involvement, and a history of unexplained syncope.

Restrictive Cardiomyopathy

DEFINITION AND EPIDEMIOLOGY

The incidence and prevalence of restrictive cardiomyopathy in adults are unknown. Restrictive cardiomyopathies (Table 60-8) are characterized by stiffness, impaired filling, elevated left ventricular diastolic pressures, and reduced diastolic volume of the left or right ventricle despite normal or near-normal systolic function and wall thickness. Primary forms are uncommon, whereas secondary forms, in which the heart is affected as a part of a multisystem disorder, usually present at the advanced stage of an infiltrative disease (e.g., amyloidosis or sarcoidosis) or a systemic storage disease (e.g., hemochromatosis). Idiopathic restrictive cardiomyopathy affects both male and female patients and may manifest in children and young adults.

PATHOBIOLOGY

Approximately 30% of patients with idiopathic restrictive cardiomyopathy have familial disease. Mutations in the gene encoding desmin (an intermediate filament) cause restrictive cardiomyopathy associated with skeletal myopathy and cardiac conduction system abnormalities. Mutations in the cardiac sarcomere protein genes also cause restrictive cardiomyopathy.

The macroscopic features of restrictive cardiomyopathy include biatrial dilation and small ventricular cavities. In many hearts, there is thrombus in the atrial appendages and patchy endocardial fibrosis. The histologic features of idiopathic restrictive cardiomyopathy are typically nonspecific with patchy interstitial fibrosis, but myocyte disarray is not uncommon in patients with pure restrictive cardiomyopathy. Amyloidosis, hemochromatosis, and sarcoidosis are among the systemic diseases that cause restrictive cardiomyopathy (see later).

CLINICAL MANIFESTATIONS

Most patients present with symptoms and signs of heart failure and arrhythmia. Common symptoms include dyspnea on exertion, recurrent respiratory tract infections, general fatigue, and weakness. Symptoms may progress rapidly to dyspnea at rest, orthopnea, and paroxysmal nocturnal dyspnea. Many patients complain of chest pain and palpitation. Syncope is a presenting symptom in 10% of children. Rarely, sudden death is the initial manifestation of the disease.

Physical examination typically reveals an elevated jugular venous pressure, which has a prominent y descent and fails to fall (or rises) during inspiration (Kussmaul's sign). On cardiac auscultation, the pulmonary component of the second heart sound may be loud if pulmonary vascular resistance is high. A third heart sound and occasionally a fourth heart sound commonly produce a gallop rhythm. Peripheral edema, ascites, and hepatomegaly are common.

DIAGNOSIS

The most frequent ECG abnormalities include p-mitrale and p-pulmonale, nonspecific ST segment and T wave abnormalities, ST segment depression, and T wave inversion, usually in the inferolateral leads. Voltage criteria for left and right ventricular hypertrophy may be present, although patients with amyloidosis have low-voltage QRS complexes. Conduction abnormalities include intraventricular conduction delay and abnormal Q waves.

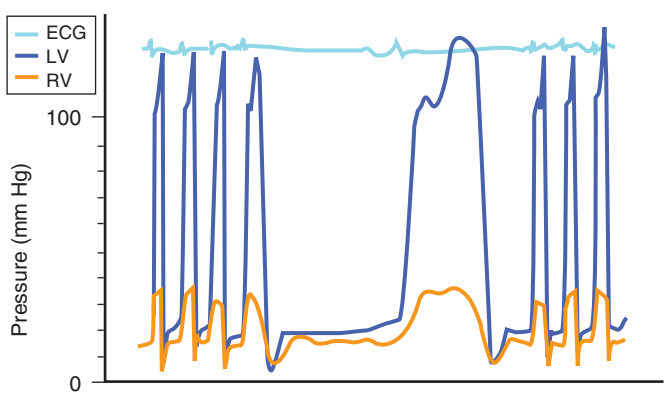

FIGURE 60-4. Idiopathic restrictive cardiomyopathy. Right ventricular (RV) and left ventricular (LV) pressure electrocardiographic (ECG) tracings in a patient with idiopathic restrictive cardiomyopathy. A dip-and-plateau pattern is seen in both ventricles, and diastolic filling pressures are elevated. The plateaus occur at different pressures, approximately 16 mm Hg for the RV tracing compared with 20 mm Hg for the LV tracing. The diagnosis of restrictive disease was confirmed by thoracotomy. (Redrawn from Benofti JR, Grossman W, Cohn PF. The clinical profile of restrictive cardiomyopathy. *Circulation.* 1980;61:1206.)

On cardiac imaging, both atria are markedly dilated and can dwarf the size of the ventricles in patients with normal global systolic function and a nonhypertrophied, nondilated left ventricle. Pulsed-wave Doppler velocities typically show increased early diastolic filling velocity, decreased atrial filling velocity, an increased ratio of early diastolic filling to atrial filling, decreased E wave deceleration time, and decreased isovolumic relaxation time. Pulmonary vein and hepatic vein pulsed-wave Doppler velocities demonstrate higher diastolic than systolic velocities, increased atrial reversal velocities, and an atrial reversal duration greater than mitral atrial filling duration. Tissue Doppler imaging usually shows reduced diastolic annular velocities and an increased ratio of early diastolic tissue Doppler annular velocity to mitral early diastolic filling velocity, reflecting elevated left ventricular end-diastolic pressures.

The characteristic hemodynamic feature on cardiac catheterization is a deep and rapid early decline in ventricular pressure at the onset of diastole, with a rapid rise to a plateau in early diastole ("dip-and-plateau" or "square root sign") (Fig. 60-4). Left ventricular end-diastolic, left atrial, and pulmonary capillary wedge pressures are markedly elevated, usually 5 mm Hg or more above right atrial and right ventricular end-diastolic pressures. Volume loading and exercise accentuate the difference between left-sided and right-sided pressures.

The diagnostic evaluation aims to exclude potentially reversible conditions. In such cases, the cardiac manifestations may provide the clues, but definitive diagnosis relies on the demonstration of disease-specific features, such as amyloid protein in amyloidosis (Chapter 194), noncaseating granulomas in sarcoidosis (Chapter 95), abnormal iron studies in hemochromatosis (Chapter 219), or reduced α-galactosidase A levels in Fabry's disease (Chapter 215). Endomyocardial biopsy is rarely required to make these diagnoses.

TREATMENT

Rx

Diuretics are the main therapy for heart failure symptoms (Chapter 59), but they must be carefully administered so as not to reduce left ventricular filling pressures to the point of hypotension. Angiotensin-converting enzyme inhibitors and β-blockers are commonly recommended despite few data on their benefit. In patients with secondary restrictive cardiomyopathies, specific treatment of the underlying systemic disease is often appropriate (see later). Referral for transplant assessment should be considered early because pulmonary hypertension may develop and necessitate heart and lung transplantation.

PROGNOSIS

In adults with restrictive cardiomyopathy, the clinical course is usually slow and protracted. Survival from the time of diagnosis is often 10 years or more, except for amyloidosis, which progresses much more rapidly. Symptoms of heart failure are generally progressive and respond poorly to treatments for heart failure.

Specific Clinical Syndromes

SARCOIDOSIS

The frequency of myocardial involvement in patients with sarcoidosis (Chapter 95) is difficult to determine because it is frequently subclinical and patchy in nature. Postmortem studies suggest that the heart is involved in at least 25% of patients, but clinical cardiac involvement occurs in fewer than 10% of patients. Clinical manifestations of sarcoid include heart failure, conduction abnormalities, atrial and ventricular arrhythmias, pericardial effusion, valvular dysfunction, and, rarely, sudden cardiac death. Right heart failure secondary to pulmonary hypertension may occur in patients with extensive fibrotic lung disease. Myocardial infiltration by sarcoid granulomas results in restrictive or dilated cardiomyopathy. The most common site is in the lateral wall of the left ventricle. Papillary muscle involvement is responsible for the most common valvulopathy, mitral regurgitation. Granuloma formation in the basal interventricular septum may cause conduction abnormalities. Ventricular arrhythmias are also frequent. Biopsy of extracardiac sites is usually adequate for the diagnosis, but a gallium scan often demonstrates cardiac inflammation. A myocardial biopsy may show granulomas but, because of the focal distribution of the lesions, may be nondiagnostic. Corticosteroid therapy may improve arrhythmias, but heart failure may worsen despite such therapy. An ICD is generally indicated for ventricular arrhythmias.

AMYLOIDOSIS

EPIDEMIOLOGY AND PATHOBIOLOGY

Amyloidosis can result in deposition of amyloid protein in the atria, ventricles, coronary vessels, conduction system, and valves. The degree of cardiac involvement varies among subtypes. Hematologic disorders (Chapter 193) associated with excessive light chain (AL) immunoglobulin production are the most common cause of cardiac amyloid. Familial forms caused by the accumulation of mutant proteins (transthyretin or A-apolipoprotein) (Chapter 194) have variable cardiac involvement. Secondary amyloidosis, due to deposition of serum amyloid A protein in chronic inflammatory diseases, rarely affects the heart. In senile systemic amyloidosis, cardiomyopathy is by caused deposition of normal wild-type transthyretin; this disease nearly always affects elderly persons (>70 years), with a clinical course that is considerably slower than other types of amyloid.

DIAGNOSIS

The ECG tracing in most forms of cardiac amyloid characteristically shows decreased voltage despite increased wall thickness on echocardiography. Characteristic two-dimensional echocardiographic findings in advanced cardiac amyloidosis are biventricular hypertrophy, thickened valves and interatrial septum, dilated atria, and a small pericardial effusion. The myocardium has a hyperreflective granular texture (Fig. 60-5), best seen on digital image

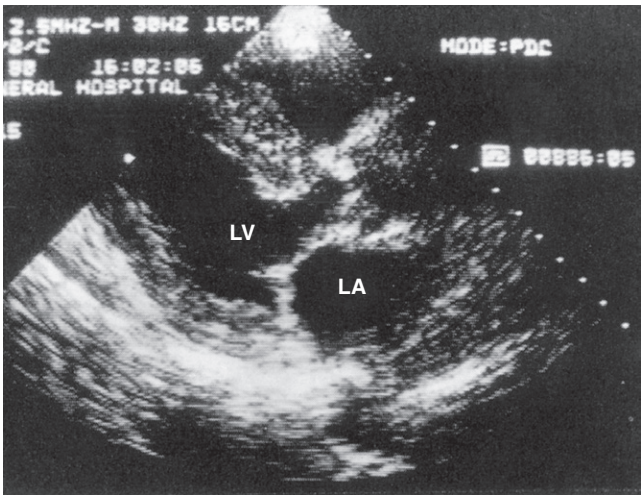

FIGURE 60-5. Amyloidosis. An apical four-chamber echocardiographic image demonstrates biventricular hypertrophy in a patient with biopsy-proved amyloidosis. RA = right atrium; RV = right ventricle. (From Levine RA. Echocardiographic assessment of the cardiomyopathies. In: Weyman AE, ed. *Principles and Practice of Echocardiography,* 2nd ed. Philadelphia: Lea & Febiger; 1994:810.)

analysis. Echo Doppler in advanced disease demonstrates a restrictive left ventricular filling pattern. Cardiac magnetic resonance imaging may show subendocardial late gadolinium enhancement with abnormal gadolinium kinetics. Nuclear scans with ^{123}I-labeled serum amyloid P component are highly specific.

A definitive diagnosis of amyloidosis requires a tissue biopsy, which can be obtained from other sites. For example, fine-needle aspiration of abdominal fat is positive for amyloid deposits in more than 70% of patients with AL amyloidosis. If negative, endomyocardial biopsy has a very high sensitivity.

TREATMENT AND PROGNOSIS

Rx

Specific therapies to impede precursor protein production and fibril formation should be implemented whenever possible (Chapter 194). Diuretics, often in high doses (e.g., furosemide 40 to 80 mg daily), are the mainstay of the palliative heart failure regimen. Angiotensin-enzyme converting or angiotensin II inhibitors should be used very cautiously because they are often poorly tolerated and of unproven efficacy in cardiac amyloid. Aldosterone inhibitors might be helpful in advanced cases. Patients may be hypersensitive to digoxin because of enhanced drug binding with amyloid fibrils. Patients with atrial fibrillation in AL amyloidosis should receive anticoagulation with warfarin (Chapter 37) because of a very high rate of thromboembolism. Cardiac transplantation remains controversial, but heart transplantation (Chapter 82) with high-dose chemotherapy and with stem cell transplantation (Chapter 181) has been used in patients with AL amyloidosis.

Patients with amyloidosis with heart failure have a median survival time of less than 1 year and a 5-year survival rate of less than 5%. Most deaths occur suddenly. Patients with familial amyloidosis have a slower course than do patients with a monoclonal gammopathy.

HEREDITARY HEMOCHROMATOSIS

Hereditary hemochromatosis (Chapter 219) is an autosomal recessive disorder caused by excessive iron deposition in various organs, including the liver, spleen, pancreas, endocrine glands, and heart. In whites, its prevalence is between 1 in 200 and 1 in 500, with an even higher prevalence in the Irish population. The most common form is caused by mutations in the *HFE* gene, with two missense mutations accounting for most cases (C282Y and H63D).

Most patients with classical disease present between the ages of 40 and 60 years with hyperpigmentation, diabetes mellitus, and hepatomegaly. Up to 35% of patients with hemochromatosis experience heart failure, and 36% develop arrhythmias. Restrictive physiologic features dominate early in the disease, followed by ventricular dilation. The diagnosis is generally made from the clinical picture, an elevated serum iron level, and a high transferrin saturation. Genetic testing is helpful, and the diagnosis can be confirmed by endomyocardial biopsy. Phlebotomy and iron chelation therapy with deferoxamine (Chapter 219) may improve cardiac function before cell injury becomes irreversible. Standard heart failure treatment (Chapter 59) is generally recommended. Death from hemochromatosis results more often from cirrhosis and liver carcinoma than from cardiac disease.

Unclassified Cardiomyopathies

LEFT VENTRICULAR NONCOMPACTION

Failure of the trabecular or spongiform layer of the myocardium to compact may occur with congenital heart disease, including atrial and ventricular septal defects and coarctation of the aorta (Chapter 69), and with the rare X-linked multisystem disorder, Barth's syndrome. With recent improvements in imaging technology, it has also been recognized in patients with hypertrophic and dilated cardiomyopathy. The prevalence of localized areas of noncompaction is unknown, but clinically significant isolated left ventricular noncompaction in the absence of other cardiac abnormalities is uncommon.

Areas of noncompacted myocardium may be best delineated from normal myocardium by the demonstration of flow within the myocardium by Doppler or contrast echocardiography. When extensive areas are involved, systolic performance may be impaired, and there is a risk of ventricular arrhythmias and systemic emboli. Treatment, when necessary, is for associated heart failure (Chapter 59), arrhythmias (Chapters 64 and 65), and the risk of emboli (Chapter 59). Natural history and prognosis are not well established.

TAKOTSUBO CARDIOMYOPATHY

Takotsubo cardiomyopathy is a syndrome of transient apical left ventricular dysfunction that mimics myocardial infarction (Chapter 73). Postulated mechanisms include coronary artery spasm, myocarditis, and dynamic mid-cavity obstruction.

The clinical syndrome classically includes chest pain, ST segment elevation, and raised cardiac biomarkers in association with emotional or physical stress. Coronary arteriography reveals normal epicardial vessels. Conservative treatment with rehydration and removal of the determinants of stress usually results in rapid resolution within hours of the symptoms, ECG changes, and wall motion abnormalities.

DISEASES OF THE ENDOCARDIUM

Endocardial fibrosis, fibroelastosis, and thrombosis are subclassified into endomyocardial diseases with hypereosinophilia (hypereosinophilic syndromes) and endomyocardial disease without hypereosinophilia (e.g., endomyocardial fibrosis) (see Table 60-8).

Hypereosinophilic Syndrome

Hypereosinophilic syndromes are a rare and heterogeneous group of disorders defined as persistent blood eosinophilia ($>1.5 \times 10^9$/L) for more than 6 consecutive months, associated with evidence of eosinophil-induced organ damage in the absence of causes of hypereosinophilia, such as allergic, parasitic, and malignant disorders (Chapter 173). Pathogenic mechanisms include stem cell mutations that lead to expression of PDGFRA-containing fusion genes, mainly the *FIP1L1-PDGFRA* fusion gene, with constitutive tyrosine kinase activity and sustained overproduction of interleukin-5 by activated T-cell subsets. Clinically, hypereosinophilic syndrome can be classified into chronic eosinophilic leukemia, lymphocytic hypereosinophilic syndrome, myeloproliferative hypereosinophilic syndrome, and idiopathic hypereosinophilic syndrome. The term *organ-restricted eosinophilic disease*, such as eosinophilic gastroenteritis, dermatitis, or pneumonia, is used when a specific organ or tissue is the exclusive target of eosinophilic infiltration and damage. The term *Löffler's fibroplastic endocarditis* with eosinophilia has been used to describe cardiac damage caused by direct toxicity of circulating eosinophils in patients with persistent hypereosinophilia, but its use is now discouraged.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Hypereosinophilic syndrome is a rare disorder that tends to occur in patients 20 to 50 years of age, but all age groups are affected. Cardiac involvement generally evolves in three phases: an early necrotic stage that involves the endomyocardium, which is usually asymptomatic but can present as acute heart failure; a thrombotic stage, in which thrombi develop on the ventricular endocardium, sometimes causing peripheral emboli; and the final fibrotic stage, endomyocardial fibrosis, which causes restrictive cardiomyopathy and damage to atrioventricular valves. Chest pain, cough, dyspnea or orthopnea, and edema of the lower extremities are typical symptoms. Some patients may develop arrhythmias.

The characteristic two-dimensional echocardiographic findings include endocardial thickening, apical obliteration of one or both ventricles by an echogenic material, hyperdynamic contraction of the spared ventricular walls with bilateral atrial enlargement, and a restrictive pattern on echo Doppler.

TREATMENT

Rx

Patients with the F/P fusion gene chromosomal rearrangement should be treated with the tyrosine kinase inhibitor, imatinib (100 mg daily for 1 week, increasing by 100 mg each week to 400 mg as guided by toxicity and hematologic response); the duration of therapy is still under investigation. Because some patients develop severe congestive heart failure within days after initiation of therapy, pretreatment with corticosteroids is recommended by some authorities. For patients without the F/P fusion gene, corticosteroids (median maximal daily dose of prednisone 40 mg, range 5 to 625 mg; duration 2 months to 20 years; median maintenance dose of 10 mg daily, range 1 to 40 mg/day) are the most common first-line therapy. Steroid-sparing and second-line drugs include hydroxyurea (median maximal daily dose of 1000 mg, range 500 to 2000 mg, adjusted to response), interferon-α (median maximal dose of 14 million units per week, range 3 to 40 million units per week, adjusted to response), and imatinib (as above).

Tropical Endomyocardial Fibrosis

Tropical endomyocardial fibrosis is probably the most common type of restrictive cardiomyopathy worldwide. The disease occurs predominantly within the tropics and affects mostly children and adolescents, usually from low socioeconomic backgrounds. Its cause is unknown, but potential contributors include infection, autoimmunity, genetic predisposition, ethnicity, diet, climate, and poverty.

Severe hypereosinophilia is found in some patients early in the initial stage of the illness, which is characterized by febrile illness, pancarditis, facial and periorbital swelling, pruritus, urticaria, and neurologic symptoms. This phase is followed by ventricular thrombosis that affects the apices and the subvalvular apparatus and then evolves to endocardial fibrosis. The final stage is characterized by restrictive physiology, atrioventricular valve regurgitation, and marked atrial dilation. Death results from complications of chronic heart failure but can occur suddenly owing to thromboembolism or arrhythmia.

Atrial fibrillation is common at presentation. In advanced disease, the ECG shows low-voltage QRS complexes, nonspecific ST-T wave changes, and conduction abnormalities. Echocardiography demonstrates apical obliteration, reduction of ventricular cavity size, and tethering or retraction of mitral or tricuspid leaflets, or both. There is no specific laboratory test, and hypereosinophilia is present only early in the disease.

There is no specific treatment for endomyocardial fibrosis. Medical treatment is used to control the heart failure (Chapter 59) and arrhythmias (Chapters 64 and 65). Surgical endocardial resection, combined with valve repair or replacement, has an early postoperative mortality between 15 and 30%. The overall prognosis is poor, with a 44% mortality rate at 1 year, increasing to nearly 90% at 3 years.

Carcinoid Syndrome

EPIDEMIOLOGY AND PATHOBIOLOGY

Carcinoid tumors are rare (1 in 100,000) neuroendocrine malignancies originating mostly from enterochromaffin cells in the gastrointestinal tract (Chapter 240). Carcinoid syndrome, with flushing, diarrhea, and bronchospasm, occurs after tumor cells metastasize to the liver and the vasoactive substances produced by the tumors enters the systemic circulation through the hepatic vein. Carcinoid heart disease occurs in up to 70% of cases of carcinoid syndrome.

The typical cardiac lesion is the carcinoid plaque, which is composed of smooth muscle cells, myofibroblasts, and elastic tissue that forms a fibrous layer on the endocardial surface of the right ventricle and atrium, the valve leaflets, and the subvalvular apparatus, including the chordae and papillary muscles. The tricuspid valve plaques tend to develop on the ventricular side of the leaflets, where they adhere to the mural endocardium and cause valvular regurgitation. On the pulmonary valve, the predominant lesion is stenosis. In patients with a patent foramen ovale, left-sided valvular involvement can occur. Occasional patients may have concomitant myocardial metastases and pericardial effusions from direct tumor invasion.

The most common presentation is dyspnea with signs and symptoms of right-sided heart failure. The ECG and radiograph are nonspecific. Echocardiography shows thickening of the tricuspid valve, the subvalvular apparatus, and the pulmonary valve. In severe disease, the tricuspid leaflets are retracted and fixed, with loss of normal coaptation. Similar findings can be seen on cardiac magnetic resonance imaging.

TREATMENT AND PROGNOSIS Rx

Treatment of the underlying carcinoid with a somatostatin analogue can improve systemic symptoms (Chapter 240). Valve replacement now has an operative mortality of less than 10% (Chapter 240). Without treatment, patients with carcinoid heart disease have a mean life expectancy of 1.6 years. In one series, cardiac surgery for valve disease was associated with about a 50% risk reduction.

Nonbacterial Thrombotic (Marantic) Endocarditis

EPIDEMIOLOGY AND PATHOBIOLOGY

Platelet-fiber masses that are adherent to the mitral or aortic valves are seen in about 20% of patients with malignant tumors, especially mucin-producing adenocarcinomas, melanomas, leukemias, and lymphomas. The lesions are sterile, commonly verruciform, and without accompanying inflammation.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Nonbacterial thrombotic endocarditis is virtually always asymptomatic but occasionally is a source of systemic emboli. Because of the small size of many of the emboli, the first presentation is often with cerebral symptoms. Larger lesions are detectable by echocardiography, but even transesophageal echocardiography is not sufficiently sensitive to identify lesions that may be found at autopsy and that may have been the source of systemic emboli.

TREATMENT Rx

No treatment has been proved efficacious. However, systemic anticoagulation similar to that used in patients with tumor-associated deep vein thrombosis is often tried (Chapters 81 and 187).

CARDIAC TUMORS

Myocardial Tumors

Most primary cardiac tumors (Table 60-9) are benign. However, all tumors that extend from other tissues into the heart are malignant, as are metastatic lesions.

EPIDEMIOLOGY AND PATHOBIOLOGY

Primary tumors of the heart are unusual, with a prevalence of 1 in 2000 to 1 in 4000 in autopsy series. Nearly all these primary tumors are benign myxomas, although fibromas, lipomas, and fibroelastomas also occur. Rhabdomyomas are seen in children, especially with tuberous sclerosis (Chapter 426). The rare primary malignant tumors include sarcomas, especially angiosarcomas (see Table 60-9). Rarely, a primary mesothelioma or lymphoma may originate in the heart.

Up to 20% of advanced cancers may involve the pericardium, epicardium, or cardiac chambers either by direct extension of the primary tumor or by metastatic disease. Direct extension occurs principally from cancers of the lung, breast, esophagus, and mediastinum. Extension through the inferior vena cava to the right atrium and even to the right ventricle occurs with cancers of the kidney, adrenal gland, and liver. Metastatic spread is most common with melanomas or lymphomas.

Pericardial Tumors

CLINICAL MANIFESTATIONS

Pericardial tumors almost always result from direct extension of tumors, principally lung and breast, which produce a pericardial effusion that can progress to cardiac tamponade (Chapter 77). Patients typically are asymptomatic or minimally symptomatic in terms of the cardiac involvement until the effusion is very large, although they often may be very ill owing to progressive tumor elsewhere.

DIAGNOSIS

The diagnosis is often suspected in a patient with advanced malignant disease based on evidence of heart failure, hypertension, or arrhythmia and is confirmed by echocardiography. The differentiation between pericardial involvement by tumor and postradiation pericarditis depends on pericardiocentesis, often guided by echocardiography, and cytologic examination.

TREATMENT Rx

Cardiac tamponade must be treated with urgent pericardiocentesis, preferably under echocardiographic or radiologic guidance (Chapter 77). Although such a procedure can be life-saving and provide short-term to immediate-term palliation, control of the effusion often requires prolonged drainage, administration of intrapericardial chemotherapeutic agents, or limited or full pericardiectomy (Chapter 77). Some patients with pericardial tumors may respond to aggressive systemic chemotherapy, but recurrent accumulation of fluid is sufficiently likely that creation of a pericardial window should be considered before hospital discharge.

PROGNOSIS

In many cases, a tumor that is causing pericarditis has extended or will eventually extend through the pericardial space and into the myocardium, so no therapy is likely to be successful. The prognosis is very poor, except in unusual cases in which the tumor responds dramatically to systemic therapy.

Intracavitary Tumors

MYXOMA

DEFINITION AND EPIDEMIOLOGY

A *myxoma* is a benign polypoid neoplasm that originates from endocardial cells and is attached to the interatrial septum, usually protruding into the left atrium but occasionally into the right atrium and rarely into the ventricles. Myxomas are more common in women, especially between the ages of 30 and 60 years, than in men. These tumors can be familial and are rarely associated with other systemic abnormalities.

CLINICAL MANIFESTATIONS

Myxomas are slow growing and usually do not produce symptoms or signs until they enlarge. The typical presentation is with a tumor embolus, whereby usually small portions of the myxoma break loose and cause a single embolism or a shower of emboli. However, a large embolism from a myxoma can be of sufficient size to obstruct a medium-sized artery. Some patients have systemic symptoms, including fever, malaise, and arthralgias, as part of a clinical syndrome that may be confused with bacterial endocarditis (Chapter 76) or a collagen vascular disease. Large myxomas can prolapse into the mitral valve orifice during diastole, or they may obstruct blood flow from the left atrium to the left ventricle and mimic rheumatic mitral stenosis.

DIAGNOSIS

A myxoma large enough to obstruct the mitral orifice can produce an audible "tumor plop" when the myxoma prolapses and obstructs blood flow during diastole, at the same time that the opening snap of mitral stenosis would typically be heard. If obstruction is incomplete, the tumor plop may be followed by a diastolic rumble. As obstruction becomes more severe, cardiac output may fall precipitously. Echocardiography (Chapter 53) is usually definitive; transesophageal echocardiography provides a higher sensitivity than does transthoracic echocardiography, and magnetic resonance imaging can be helpful.

TREATMENT Rx

Surgical removal is generally curative, although myxomas can be multiple or recur in about 5% of cases. Follow-up postoperative echocardiography is generally recommended. However, the optimal frequency and duration for follow-up screening are uncertain.

OTHER PRIMARY INTRACAVITARY TUMORS

Papillary fibroelastomas are rare, typically frondlike tumors that may arise from a cardiac valve, often the mitral valve, and are generally detected incidentally by echocardiography. However, like myxomas, they can manifest with systemic or even coronary emboli. Surgical excision is usually successful.

Angiosarcomas, which are more frequent in men than in women, typically involve the pericardium and right atrium. They cause obstruction with clinical signs and symptoms of right-sided heart failure. These sarcomas are generally not amenable to therapy.

EXTENSION OF TUMOR INTO THE CARDIAC CAVITIES

Direct extension of tumor up the inferior vena cava into the right atrium can be seen with renal cell carcinomas and less commonly with liver and adrenal cancers. In some cases, tumor extension is accompanied by adherent clot, and either the tumor or the clot may cause obstruction or pulmonary emboli (Chapter 98). No treatments are generally successful, and the prognosis is grim.

Intramyocardial Tumors

Benign tumors in the myocardium include lipomas, fibromas, and rhabdomyomas. Primary malignant tumors include sarcomas, lymphomas, and mesotheliomas. Metastatic tumors include melanomas, lymphomas, and leukemias. The tumors may be clinically silent, or they may produce arrhythmias or even impinge on coronary arteries, thereby causing ischemic syndromes. Large tumors may protrude into the cardiac chamber and cause obstruction. Therapies are not successful, except for occasional patients whose metastatic tumors may respond to systemic chemotherapy or whose primary tumors have been cured by heart transplantation.

PRINCIPLES OF ELECTROPHYSIOLOGY

HUGH CALKINS

The function of the human heart requires rhythmic beatings occurring on the average 70 times a minute, 24 hours a day, for 80 or more years. The close to 3 billion contractions of the cardiac musculature that must occur without fail are coordinated by an intricate network of specialized electrically active cells that are integrated with the myocytes that comprise the predominant mass of the heart. Any loss of electrical activity, even for a few seconds, results in syncope (Chapters 50 and 62); loss of electrical activity for a few minutes may end in death.

CARDIAC ELECTROPHYSIOLOGY

Ion channels are integral membrane-spanning proteins, which allow the rapid movement of specific ions, most importantly Na^+, K^+, Cl^-, and Ca^{2+}, across the cell membrane at rates of 10^8 ions per second (E-Fig. 61-1). The opening and closing of the channels occur through a process of gating, whereby changes in the voltage, ligand, or receptor associated with the channel lead to alterations in the conformation of the proteins that activate or inactivate the channel pore. Voltage gating is the predominant method of regulating ion channels in the heart and is found in sodium and various potassium channels. Ligand-gated ion channels use ligands such as neurotransmitters, ions such as intracellular calcium, and metabolic products such as adenosine triphosphate (ATP) to activate a variety of channels, including those for potassium. Receptor-gated channels use changes in the physical environment, such as stretch, to activate channels, including those for chloride, which regulate intracellular volume.

The coordinated activity of numerous ion channels contributes to the creation of the cardiac action potential (Fig. 61-1). There are five phases to the cardiac action potential. At rest, the transmembrane potential of the cell exists close to −90 mV (the inside of the cell is positive with respect to the outside). With depolarization of the cell either from depolarization of adjacent cells or from an external change in voltage, sodium channels change from a closed to an open state and rapidly move sodium ions down a gradient into the interior of the cell, creating the sodium current I_{Na} and the rapid upstroke of phase 0 of the action potential. At the peak of depolarization, approximately +40 mV, the sodium current is inactivated, and the transient outward current I_{to} is activated with the opening of various voltage-gated potassium channels, resulting in the rapid decrease in voltage and phase 1 of the action potential. The plateau of the action potential, phase 2, follows and is an amalgamation of multiple currents representing inward and outward movement of ions. Contributors to this phase include the rapid component of the delayed rectifier potassium current I_{Kr}, the slow component of the delayed rectifier potassium current I_{Ks}, the L-type calcium channel, and the Na^+-Ca^{2+} exchanger. As the outward potassium currents increase and the calcium current decreases at the end of phase 2, the action potential progresses to phase 3, the phase of rapid repolarization. The inward rectifier potassium current I_{K1} contributes significantly to this final phase of repolarization and brings the action potential to its resting membrane potential. During phase 4, the heart is in diastole, with most cells at −85 to −90 mV. Specialized cells located in the sinoatrial and atrioventricular nodes repolarize to approximately −60 mV and contain currents that contribute to spontaneous depolarization during phase 4. These pacemaker cells contain the inward activation, or funny, current I_f activated by hyperpolarization and carried by sodium, and the background sodium current $I_{Na\text{-}B}$. The calcium currents $I_{Ca,L}$ and $I_{Ca,T}$, the sodium-potassium pump $I_{Na,K}$, and the sodium calcium exchanger $I_{Na,Ca}$ additionally may contribute to diastolic depolarization.

Variations in the duration and shape of the cardiac action potential depend on its location in the heart (Fig. 61-2). Likewise, alterations of ion channel expression and activity in disease states contribute to prolongation of the action potential. The atrial action potential has a typical duration of 100 to 200 msec, whereas the ventricular action potential typically lasts 250 to 300 msec. Different layers of the ventricle exhibit marked changes in the action potential. Epicardial cells have a prominent phase 1 compared with endocardial cells, in which phase 1 is blunted. The phase 2 plateau is decreased in epicardial cells, leading to less activation of the delayed rectifier currents

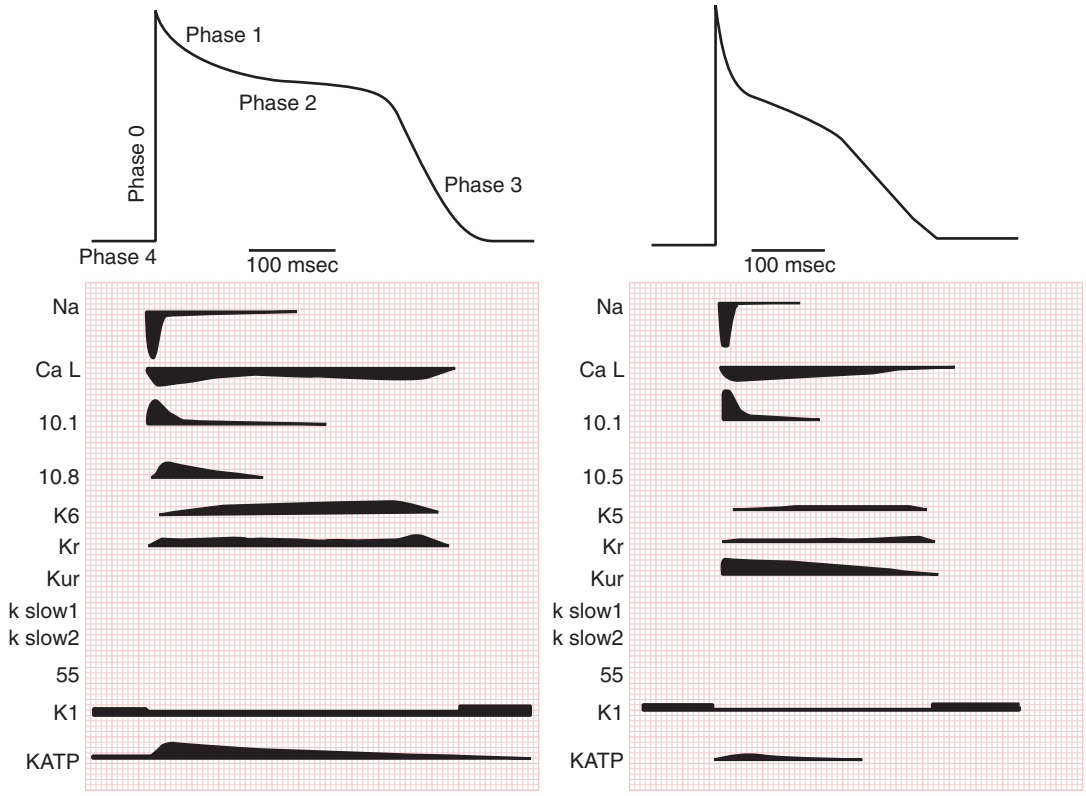

FIGURE 61-1. The cardiac action potential waveforms and underlying ionic currents in adult human and ventricular *(left)* and atrial *(right)* myocytes. The time- and voltage-dependent properties of the voltage-gated inward Na^+ (Nav) and Ca^{2+} (Cav) currents expressed in human atrial and ventricular myocytes are similar. In contrast, multiple types of K^+ currents, particularly Kv currents, contribute to atrial and ventricular action potential repolarization. The properties of the various Kv currents are distinct, and, in contrast to the inward currents, there are multiple Kv currents expressed in individual myocytes throughout the myocardium. (From Kass R. Molecular physiology of cardiac repolarization. *Physiol Rev.* 2005;85:1207.)

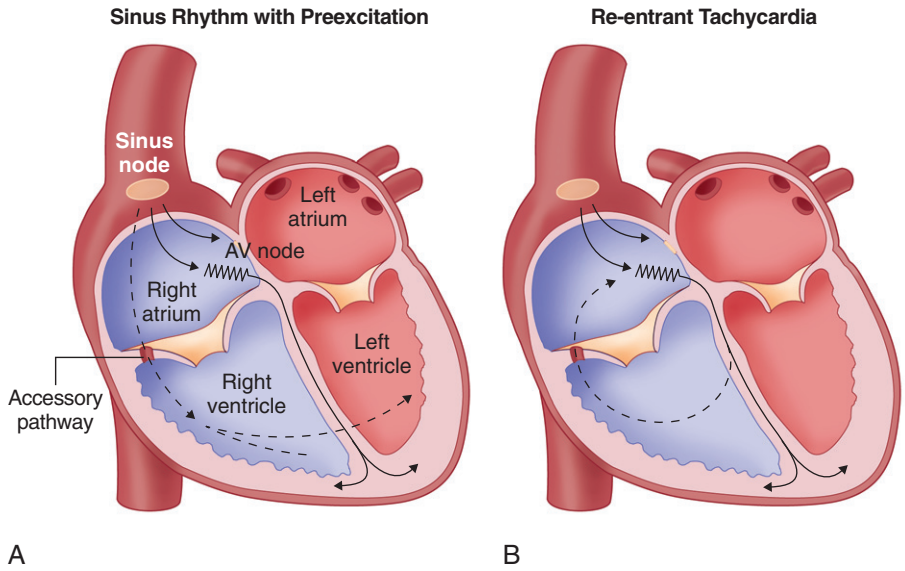

FIGURE 61-2. Accessory pathway in sinus rhythm and in orthodromic re-entrant tachycardia. (From Bassam CT. A molecular basis for Wolff-Parkinson-White syndrome. *N Engl J Med.* 2001;344:1861. Copyright © 2001 Massachusetts Medical Society. All rights reserved.)

and a prolonged action potential in epicardial cells. M cells found in the midmyocardium have the longest action potential duration and may contribute to the U wave seen on the surface electrocardiogram (ECG). The J (Osborne) wave seen on the ECG in cases of hypothermia (see Fig. 109-2 in Chapter 109) may be due to the increased prominence of I_{to} in the epicardial cells. Prolongation of the action potential is seen in cardiac hypertrophy or failure. At the molecular level, downregulation of the transient outward current I_{to} plays a prominent role in these disease states.

In a normal heart, the source of initial depolarizations occurs in the pacemaker cells of the sinus node (E-Fig. 61-2). The sinoatrial (SA) node is found at the lateral border of the superior vena cava and right atrial junction in the sulcus terminalis. It is an ovoid structure measuring up to 2 cm long by 0.5 cm wide. The sinus node artery, branching from either the right coronary artery (55 to 60%) or the left coronary artery (40 to 45%), runs through the middle of the sinus node. Pacemaker cells, seen as spider-shaped and spindle-shaped cells in the node, spontaneously depolarize during diastole. The wave of depolarization spreads through the sinus node and into the surrounding myocardium. The sympathetic and parasympathetic nervous systems affect the sinus rate. Adrenergic stimulation increases the rate by increasing $I_{Ca,L}$ and I_f activity. Cholinergic stimulation decreases the rate by decreasing $I_{Ca,L}$ and I_f activity. Stretch mediators found in the node and coupled to chloride channels also may increase the atrial rate with increasing atrial pressure. The SA node is the predominant pacemaker in the heart owing to its rapid rates of depolarization and overdrive suppression of secondary pacemakers.

Depolarization occurs through the atria to the atrioventricular (AV) node and from the right atrium to the left atrium. Three intra-atrial pathways—anterior, middle, and posterior—connect the right and left atria. Three intranodal pathways—superior, middle, and inferior tracts—also may connect the SA node to the AV node, although various investigators have disputed their presence. The P wave on the ECG is formed by atrial depolarization. The AV node is found at the apex of the triangle of Koch, formed by the tendon of Todaro on one side and the tricuspid annulus on the other, on the right side of the heart and anterior to the os of the coronary sinus. The arterial supply of the AV node arises from the right coronary artery in 85 to 90% of cases. The AV node itself is complex and can be divided into three general regions, with further subdivisions possible. A transitional zone contains multiple atrial inputs that extend to the compact AV node, which penetrates the central fibrous body and becomes the bundle of His. The compact AV node ranges from 5 to 7 mm by 2 to 5 mm in size. At least two distinct populations of AV node cells, rod-shaped and ovoid, have been described. These cells spontaneously depolarize because of a strong I_f current. Most ovoid cells lack I_{Na} and I_{to}, leading to slower depolarization. Conduction is relatively slow through the AV node compared with atrial and ventricular tissue, in part because of the decreased density of gap junction proteins, such as connexin 43, which is 33 times less prevalent in the AV node compared with ventricular cells. This reduction in gap junctions and intercalated discs leads to slower depolarization of neighboring cells. On the surface ECG, most of the PR interval depends on this slow AV node conduction.

The bundle of His arises from the compact AV node as it enters the central fibrous body. Conduction through the His bundle is rapid, on the order of 35 to 55 msec to the ventricles, owing to the presence of rapidly acting sodium channels. The arterial supply of the bundle of His originates from the left anterior descending artery in 90% of cases, with 10% emanating from the right coronary artery. The right and left bundle branches originate from the bundle of His. The left bundle branch further subdivides into the left anterior fascicle and left posterior fascicle before supplying the ventricular endocardium with Purkinje fibers. The right bundle branch trifurcates distally into a network that supplies the anterolateral papillary muscle, the low right septum, and the parietal band. Activation of the His-Purkinje system can be seen as the later portion of the PR interval on the surface ECG.

Ventricular activation occurs first from the left to right septum, followed by the synchronized depolarization of both ventricles from apex to base and endocardium to epicardium. The rapid activation of myocardial cells is due in part to the strong presence of the gap junction protein connexin 43. Knockout mice homozygous for connexin 43 deletions die with conotruncus malformations early in life, whereas mice heterozygous for connexin 43 deletion (Cx43+/−) have significant decreases in ventricular conduction in otherwise normal ventricles. Ventricular depolarization can be seen as the QRS complex on the surface ECG and is followed by repolarization seen as the ST, T, and U waves.

Normally the only connection between the atria and the ventricles is through the AV node and His bundle because the fibrous rings surrounding the tricuspid valve and mitral valve are electrically insulating. In a small percentage of the population (0.15 to 0.25%), anomalous myocardial bypass tracts join atrium to ventricle (Kent bundle) or, less frequently, atrium to AV node (James fiber), atrium to His bundle (Brechenmacher fiber), or AV node or His to Purkinje fiber or ventricle (Mahaim fiber). The classic AV bypass tract involved in the Wolff-Parkinson-White syndrome is composed of fibers containing I_{Na} and conducts rapidly in a nondecremental manner similar to that seen in the atria, His-Purkinje, or ventricular tissue (Fig. 61-2). A missense mutation in the γ2 regulatory subunit of adenosine monophosphate (AMP)-activated protein kinase gene *PRKAG2* can cause the Wolff-Parkinson-White syndrome, with a possible effect of interfering with muscle fiber regression during embryogenesis. The surface ECG often shows a δ wave (see Fig. 64-19 in Chapter 64), the hallmark of ventricular preexcitation, preceding the QRS complex.

The heart is innervated by the sympathetic and the parasympathetic nervous systems, with their influence on ion channels manifested as changes in the heart rate, refractoriness, and contractility. Sympathetic stimulation causes the release of norepinephrine at the postganglionic nerve terminal, leading to β_1-adrenergic and β_2-adrenergic receptor activation, followed by G protein–mediated adenylyl cyclase production, which increases production of cyclic AMP (cAMP), which leads to the activation of protein kinase A, ultimately resulting in the phosphorylation of ion channels, which alter their gating and function. Parasympathetic activity leads to release of acetylcholine at the nerve terminal, which stimulates muscarinic cholinergic receptors, followed by direct G protein–mediated activation of channels, or indirect G protein–mediated secondary messenger activation using cAMP. Multiple membrane currents are influenced by sympathetic or parasympathetic activity. The L-type calcium channel current $I_{Ca,L}$ is increased four

times with β-adrenergic stimulation, leading to increased conduction of the SA and AV nodes. β-Adrenergic stimulation also leads to a cAMP-mediated change in the activation of I_f, with the result being increased activity of cardiac pacemaker cells and higher heart rates. Parasympathetic stimulation leads to activation of the acetylcholine-activated potassium current I_{KACh}, which results in decreased pacemaker activity and slowing of conduction over the AV node. Purinergic receptors are a third family of G protein–coupled receptors that are activated by adenosine. Exposure to adenosine leads to activation of I_{KACh} and inhibition of $I_{Ca,L}$, resulting in slowing of the pacemaker activity for SA and AV nodes and conduction delay through the AV node.

Mechanisms of Cardiac Tachyarrhythmias

A cardiac arrhythmia is an abnormality in the timing or sequence of cardiac depolarization. There are two predominant types of cardiac arrhythmias: (1) tachyarrhythmia—an abnormally rapid cardiac rhythm (heart rate >100 beats per minute) and (2) bradyarrhythmia—a slow cardiac rhythm (heart rate <60 beats per minute) (Chapters 62, 64, and 65). The mechanism of cardiac tachyarrhythmias can be grouped into two general categories, abnormalities of impulse formation and re-entry (E-Fig. 61-3). Abnormalities of impulse formation can be subdivided further into abnormal automaticity and triggered activity. In the normal heart, the sinus node is the predominant pacemaker, with secondary pacemakers located in the atria, AV node, and His-Purkinje system, which function in the event that normal initiation or propagation is affected by disease or drugs. Automaticity is the ability to initiate spontaneous impulses. Under normal circumstances, there is a hierarchical sequence in the rate of firing of the heart cells that have the capacity for automaticity. Normally, spontaneous firing is fastest in the sinus node (70 to 80 beats per minute under resting conditions), and the sinus node is the predominant pacemaker. The AV node and His bundle fire at 50 to 60 beats per minute, and the Purkinje fibers fire at 30 to 40 beats per minute. The lower pacemaker may take over the pacemaking function of the heart if the faster pacemaker fails or slows. Variations in autonomic tone may have a major effect on normal automaticity. In general, activation of the sympathetic nervous system increases automaticity, whereas activation of the parasympathetic nervous system decreases automaticity. Under pathologic conditions that depolarize cells, myocardial cells outside the specialized conduction system also may acquire automaticity, a phenomenon termed *abnormal automaticity*.

Triggered activity is an uncommon mechanism of cardiac arrhythmias. Triggered activity occurs when a preceding depolarization does not repolarize completely before depolarizing again. *Early afterdepolarizations* (EADs) occur during phase 2 and phase 3 of the action potential. The basis for EADs appears to involve the L-type calcium channel. EADs are facilitated by increased repolarization times, as seen in either congenital or acquired long QT syndromes. With drugs that prolong the QT interval, such as erythromycin, quinidine, sotalol, and procainamide, the block of potassium channels involved in repolarization leads to prolongation of the action potential. The ultimate effect of EADs may be in initiating polymorphic ventricular tachycardia or torsades de pointes (Chapter 65). *Delayed afterdepolarizations* (DADs) arise during phase 4 of the action potential, when the cell membrane is completely repolarized. Transient inward currents, which are not normally present, may be initiated by the action of elevated intracellular calcium on the sodium-calcium exchanger or by release of calcium from the sarcoplasmic reticulum, and they may form the basis for DADs. Rapid heart rates, increased extracellular calcium, and adrenergic stimulation all may contribute to DADs. DADs are thought to form the basis of arrhythmias resulting from digitalis, idiopathic ventricular tachyarrhythmias, and idioventricular rhythms, and they may be reduced by drugs that block the uptake of calcium by the sarcoplasmic reticulum. Multifocal atrial tachycardia is another example of an arrhythmia that results from DAD-mediated triggered activity. The third type of automaticity, *depolarization-induced automaticity,* has been reproduced in cardiac tissues but may not lead to clinically relevant arrhythmias. Depolarization-induced automaticity arises from the constant application of current to muscle, a process that leads to spontaneous firing of the muscle.

Re-entry is the most common mechanism of cardiac arrhythmias. Re-entry generally occurs in the setting of abnormalities in impulse conduction. The abnormalities in impulse conduction may result from an anomalous electrical connection in the heart (i.e., an accessory pathway) or from poor impulse propagation. The basis for poor propagation of the depolarizing wave front in the heart may be attributed to pathology, drugs, or hormonal modulation of the conduction system. Fibrosis or calcification of the AV node, His bundle, or right and left bundle branches may lead to AV block or right and left bundle-branch blocks. AV nodal block may be a result of high vagal tone, as seen during sleep or in a well-conditioned athlete, or may be due to agents that act on the AV node, such as digitalis, β-adrenergic blockers, or calcium-channel blockers. Slowing of conduction in the atrium and ventricles also may be affected directly by hyperkalemia or ischemia.

The basis for poor propagation of the depolarizing wave front in the heart usually results from pathologic changes in patients with structural heart disease, including coronary artery disease, left ventricular hypertrophy, and heart failure. Fibrotic changes in the heart, with increases in collagen and intracellular matrix as seen in hypertrophy or infarction, can lead to areas of slow conduction and provide portals for re-entry. Changes in the gap junction proteins have been noted in hypertrophy with increases of connexin 43. These changes typically result from advanced age or the presence of structural heart disease, such as a prior myocardial infarction or a cardiomyopathy. In ischemia, the action potential is abbreviated owing to activation of I_{KACh}; in hypertrophy and failure, action potential prolongation from loss of I_{to} is found. Other influences on remodeling include catecholamines, free radicals, angiotensin-converting enzyme, angiotensin II, aldosterone, cytokines, and nitric oxide. Re-entry occurs when there is continuation of a propagating wave front, which reactivates areas of the heart that previously have depolarized and are not refractory. The refractory period, which is the time interval in which the cells are unable to depolarize after a second stimulus, often persists until the transmembrane voltage is +60mV at the activation threshold of I_{Na}.

Three types of re-entry have been described: circus movement re-entry, reflection, and phase 2 re-entry. The simplest model of circus movement tachycardia, the ring model, requires the presence of unidirectional block, in which the wave front can travel only in one direction, and a long enough circuit, in which recovery from refractoriness occurs before the approach of the leading edge of depolarization (Fig. 61-3). The length of the circuit must be equal to or greater than the wavelength (conduction velocity × refractory period) of the tachycardia. Three criteria for circus movement tachycardia include the presence of unidirectional block, the presence of a distinct path of recurrent propagation, and the fact that disrupting the circuit at any point along the path terminates the tachycardia. AV reciprocating tachycardia is an example of a re-entrant tachycardia (see Fig. 64-20 in Chapter 64). During sinus rhythm, the cardiac impulse activates the ventricle through the AV node and the accessory pathway. The tachycardia is initiated when a premature atrial impulse blocks the accessory pathway and conducts down the AV node (owing to differences in refractoriness). The impulse then returns to the atria by conduction through the accessory pathway, resulting in a re-entrant or circus movement tachycardia. Atrial fibrillation is the most common type of arrhythmia that results from re-entry. In contrast to arrhythmias with an accessory pathway in which there is only a single fixed re-entrant circuit, however, atrial fibrillation results from the presence of many functional re-entrant wavelets that propagate throughout the atria simultaneously. It has been estimated that at least three re-entrant wavelets must coexist for atrial fibrillation to be sustained. *Re-entry resulting from reflection* occurs when an

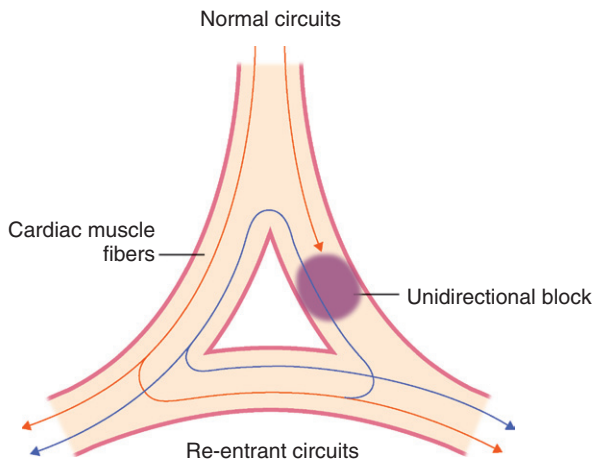

FIGURE 61-3. Unidirectional block as a result of abnormal repolarization, conduction, or intracellular calcium homeostasis. *Red arrows* show normal conduction, and *blue arrows* show re-entry through previously refractory tissue. (From Keating MT, Sanguinetti MC. Molecular and cellular mechanisms of cardiac arrhythmias. *Cell.* 2001;104:569.)

impulse proceeds back and forth over a functionally unexcitable pathway, depolarizing proximal tissue on each return cycle. *Phase 2 re-entry* occurs when an action potential dome during phase 2 is propagated from normal myocytes to myocytes lacking the dome, followed by local reexcitation, extrasystolic beats, and circus movement re-entry. Phase 2 re-entry notably is found in Brugada's syndrome (Chapter 65). Brugada's syndrome is the result of a sodium channel mutation in the α-subunit SCN5A. The hallmark of Brugada's syndrome is ST segment elevation and a right bundle branch pattern in V_1 to V_3 on the ECG. The ECG abnormalities can be explained by the loss of a phase 2 action potential dome in the epicardium but not in the endocardium owing to a failure of I_{Na} to reach a more positive voltage before phase 1. Endocardium-to-epicardium phase 2 re-entry occurs, leading to the ventricular tachycardia or ventricular fibrillation that is seen in Brugada's syndrome.

Multiple intrinsic and extrinsic factors can affect the initiation and propagation of cardiac arrhythmias (E-Fig. 61-4). At the molecular level, multiple mutations contribute to the inherited long QT syndrome and to idiopathic ventricular fibrillation (Brugada's syndrome). Twelve different subtypes of long QT syndrome have been described, and the genetic mutations of each have been identified. Genetic testing now can find a mutation in approximately two thirds of patients with long QT syndrome. The three most common types are LQT1 and LQT2, which account for approximately 90% of genotyped cases, and LQT3, which accounts for an additional 5% to 8% of cases. The mutations in long QT syndrome affect the sodium channel and potassium channels involved in repolarization with either gain of function for the sodium channel or loss of function for the potassium channels, resulting in a prolonged phase 2. The most common subtype, LQT1, is a disorder of the potassium channel α-subunit KVLQT1 responsible in part for I_{Ks}. LQT2 is due to mutations in HERG, a component of I_{Kr}. LQT3 affects the sodium channel SCN5A at a site leading to incomplete inactivation, and a continuing inward current Brugada's syndrome has been shown to be due to mutations in SCN5A, causing faster inactivation of the sodium channel. Familial polymorphic ventricular tachycardia has been linked to mutations in the cardiac ryanodine receptor (*RyR2*) gene of the cardiac sarcoplasmic reticulum, mutations that may lead to changes in calcium-induced activation.

Mechanism of Bradyarrhythmias

Cardiac bradyarrhythmias may result from either abnormalities in impulse formation or abnormalities in impulse conduction. Sinus bradycardia is the most common type of bradyarrhythmia. Sinus bradycardia results from a decreased rate of firing of the sinus node, which may be physiologic and result from increased parasympathetic tone (i.e., during sleep) or pathologic and result from a fibrosis of the sinus node, such as occurs with aging. Bradyarrhythmias also occur when abnormalities of conduction interrupt the normal sequence of cardiac depolarization. Depending on the site of block, subsidiary pacemakers begin to fire, creating an "escape" rhythm. Conduction block usually is due to fibrosis or calcification of the AV node, His bundle, or right and left bundle branches. Conduction block also may result from increased parasympathetic tone, however, as seen during sleep or in a well-conditioned athlete, or may be due to agents that act on the AV node, such as digitalis, β-adrenergic blockers, or calcium channel blockers.

APPROACH TO THE PATIENT WITH SUSPECTED ARRHYTHMIA

JEFFREY E. OLGIN

CLINICAL MANIFESTATIONS

Patients with suspected arrhythmias can present in a variety of ways. Typical symptoms include palpitations, syncope, and presyncope (dizziness). On occasion, arrhythmias can manifest more subtly as exercise intolerance, lethargy, and vague complaints of malaise or without any symptoms at all. Conversely, arrhythmias occasionally manifest as aborted sudden cardiac death (cardiac arrest) (Chapter 63). The specific differential diagnosis, prognosis, and treatment of these symptoms are determined by the severity of the symptom (i.e., whether it results in syncope) and whether the patient has underlying structural heart disease. In general, the likelihood of a life-threatening arrhythmia, such as ventricular tachycardia or ventricular fibrillation, in a patient with symptoms of palpitations or syncope is significantly greater in a patient who has structural heart disease. Therefore, the determination of whether structural heart disease is present is a key step in the diagnosis and prognosis of patients with suspected arrhythmias.

Palpitations

Palpitations, defined as an awareness of an irregular or rapid heartbeat, are most commonly due to ectopic beats—namely, premature atrial contractions (PACs; Chapter 64) and premature ventricular contractions (PVCs; Chapter 65)—or to tachyarrhythmias. A careful history can often distinguish benign palpitations from those that need further evaluation. It can be useful to have the patient tap out with a finger what the palpitations feel like. An irregularly irregular pattern suggests atrial fibrillation, whereas a more regular, rapid pattern suggests a sustained tachycardia. A reliable symptom suggesting that palpitations are caused by a tachyarrhythmia, particularly a supraventricular tachycardia, is the sensation of a regular, rapid-pounding sensation in the neck. Conversely, most patients who complain of symptoms from PACs or PVCs are often more aware of the post-extrasystolic pause or the accentuated output of the post-extrasystolic beat than of the actual premature beat itself. The majority of patients who have symptoms suggestive of premature beats but not of sustained tachycardia do not require further evaluation if they have no other symptoms and no evidence of structural heart disease—that is, an otherwise normal cardiac history, physical examination, and electrocardiogram (ECG) (see Table 50-4 in Chapter 50). If, however, the symptoms are not due to a single occasional extrasystole or are accompanied by presyncope or syncope, further evaluation is required (Fig. 62-1). Antiarrhythmic therapy is usually not necessary to treat PACs or PVCs unless the symptoms are frequent or severe. β-Blockers (e.g., metoprolol 25 mg/day or atenolol 25 mg/day) are first-line therapy in highly symptomatic patients with documented PACs or PVCs.

Palpitations are the most common presentation of tachyarrhythmias. The majority of tachyarrhythmias in patients without structural heart disease are due to supraventricular tachycardias (Chapter 64) that resolve spontaneously within several seconds. When the tachyarrhythmia is more prolonged, it often resolves with simple interventions. Patients themselves can cough several times, perform the Valsalva maneuver, exhale forcefully against a closed glottis for several seconds, or even rub gently on their eyeballs. A physician can use carotid sinus massage (Chapter 64), performed by pressing and rubbing the carotid pulse just below the angle of the mandible for 5 to 15 seconds. This maneuver should be avoided in elderly patients and in patients with a history of cerebrovascular accident, known carotid artery stenosis, or carotid bruit on auscultation. In patients with structural heart disease, palpitations may signify ventricular tachycardia (Chapter 65), particularly if they occur with syncope or presyncope. Rarely do bradyarrhythmias manifest as palpitations.

Presyncope and Syncope

Syncope, defined as a sudden loss of consciousness, and presyncope, or lightheadedness, are caused by global impairment of blood flow to the brain

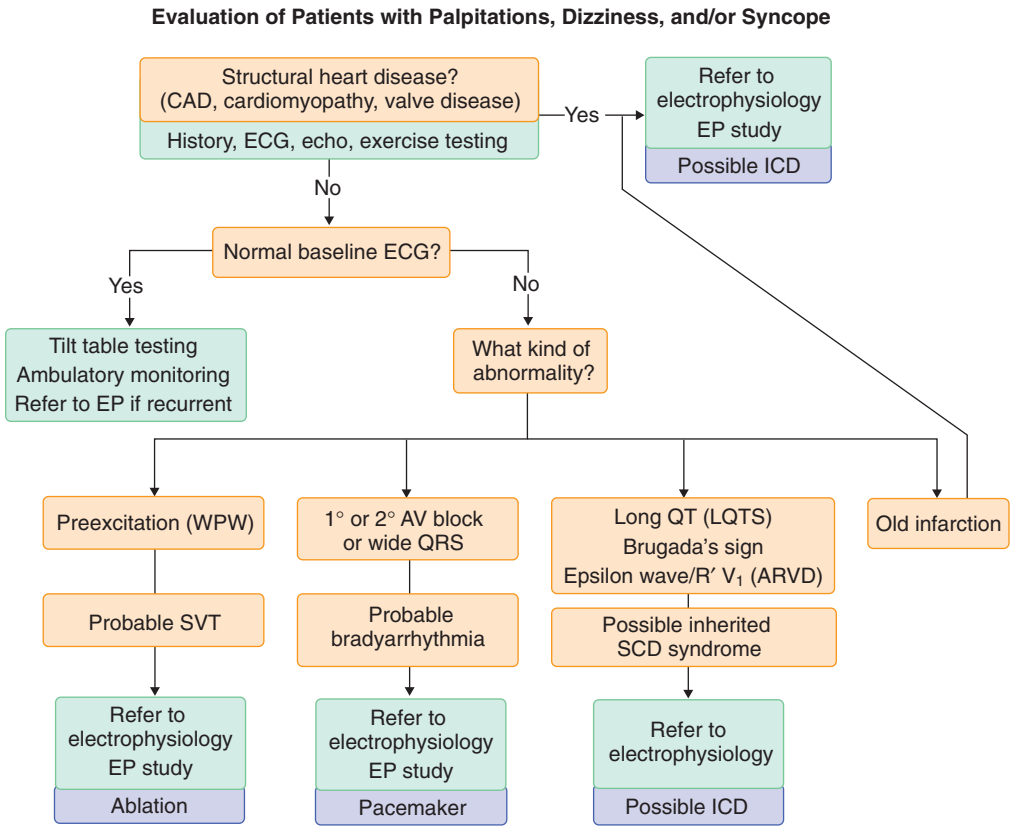

FIGURE 62-1. Algorithm for evaluating patients with symptoms of palpitation, dizziness, or syncope. ARVD = arrhythmogenic right ventricular dysplasia; AV = atrioventricular; CAD = coronary artery disease; ECG = electrocardiogram; echo = echocardiogram; EP = electrophysiology; ICD = implantable cardioverter-defibrillator; LQTS = long QT syndrome; SCD = sudden cardiac death; SVT = supraventricular tachycardia; WPW = Wolff-Parkinson-White syndrome.

(Table 62-1). Syncope can be a manifestation of tachyarrhythmias, bradyarrhythmias, or neurocardiogenic syncope, or it can be unrelated to any arrhythmia. A careful history and physical examination are necessary to exclude other cardiac causes (e.g., acute ischemia, aortic stenosis) or neurologic causes. Important historical features that suggest an arrhythmic cause are an association with palpitations and the lack of any neurologic deficits preceding or following the event. Important differential diagnoses include conditions other than lightheadedness that may be termed dizziness by the patient. Vertigo (Chapter 436), a sense of imbalance or of the "room spinning," and ataxia (Chapter 417) can usually be distinguished by the history and physical examination. The possibility of seizures (Chapter 410) must also be evaluated; syncope from an arrhythmia or neurocardiogenic syncope occasionally results in seizure-like activity, and seizures can sometimes be confused with syncope. The most important distinguishing feature is that postictal symptoms, a key feature of seizure disorders, are absent when syncope is the result of an arrhythmia. Patients with syncope from an arrhythmia usually awaken without any neurologic residual, unless the patient experienced a cardiac arrest with prolonged hypoxia and required resuscitation.

Because most spells of episodic loss of consciousness occur outside medical observation, the history is the most critical part of the evaluation (Table 62-2). Each syncopal episode should be reviewed in detail, with special attention to symptoms preceding the episode, events during unconsciousness, and the symptoms and time course of regaining orientation after consciousness is restored. Information from a witness can be essential to the evaluation.

The patient's presymptomatic activity and positioning, as well as symptoms when the syncopal episode began, are important clues to diagnosis. Seizures or cardiac arrhythmias can occur in any body position, but recumbent patients rarely develop neurocardiogenic (vasovagal) syncope and never have orthostatic hypotension. Prodromal lightheadedness, dizziness (but uncommonly vertigo), bilateral tinnitus, nausea, diffuse weakness, and dimming of vision are symptoms of cerebral hypoperfusion and support the diagnosis of syncope, which may be from a cardiac, orthostatic, or neurocardiogenic cause. Loss of consciousness so rapid that a prodrome is absent may occur with seizures and with some cardiac arrhythmias such as asystole, which typically causes loss of consciousness within 4 to 8 seconds in the

TABLE 62-1 CAUSES OF SYNCOPE AND THEIR PREVALENCE

NEUROCARDIOGENIC CAUSES
Vasovagal (8–41% of patients)
Situational (1–8% of patients)
Micturition
Defecation
Swallow
Cough
Carotid sinus syncope (0.4% of patients)
Neuralgias
Psychiatric disorders
Medications, exercise
ORTHOSTATIC HYPOTENSION (4–10% OF PATIENTS)
DECREASED CARDIAC OUTPUT
Obstruction to flow (1–8% of patients)
Obstruction to left ventricular outflow or inflow: aortic stenosis, hypertrophic obstructive cardiomyopathy, mitral stenosis, myxoma
Obstruction to right ventricular outflow or inflow: pulmonic stenosis, pulmonary embolism, pulmonary hypertension, myxoma
Other heart disease
Pump failure, myocardial infarction, coronary artery disease, coronary spasm, tamponade, aortic dissection
ARRHYTHMIAS (4–38% OF PATIENTS)
Bradyarrhythmias: sinus node disease, second- and third-degree atrioventricular block, pacemaker malfunction, drug-induced bradyarrhythmias
Tachyarrhythmias: ventricular tachycardia, torsades de pointes (e.g., associated with congenital long QT syndrome or acquired QT prolongation), supraventricular tachycardia
NEUROLOGIC AND PSYCHIATRIC DISEASES (3–32% OF PATIENTS)
Migraine
Transient ischemic attacks
UNKNOWN (13–41% OF PATIENTS)

Adapted from Kapoor W. Approach to the patient with syncope. In: Braunwald E, Goldman L, eds. *Primary Cardiology*, 2nd ed. Philadelphia: Saunders; 2003.

TABLE 62-2 CLINICAL FEATURES SUGGESTING SPECIFIC CAUSES

SYMPTOM OR FINDING	DIAGNOSTIC CONSIDERATION
After sudden unexpected pain, fear, or unpleasant sight, sound, or smell	Vasovagal
Prolonged motionless standing	Vasovagal
Well-trained athlete after exertion (without heart disease)	Vasovagal
During or immediately after micturition, cough, swallowing, or defecation	Situational syncope
Syncope with throat or facial pain (glossopharyngeal or trigeminal neuralgia)	Neurocardiogenic syncope with neuralgia
With head rotation, pressure on the carotid sinus (as in tumors, shaving, tight collars)	Carotid sinus syncope
Immediately on standing	Orthostatic hypotension
Medication that may lead to long QT syndrome, orthostasis, or bradycardia	Drug induced
Associated with headaches	Migraine, seizures
Associated with vertigo, dysarthria, diplopia	Transient ischemic attack, subclavian steal, basilar migraine
With arm exercise	Subclavian steal
Confusion after a spell or loss of consciousness for >5 min	Seizure
Differences in blood pressure or pulse in the two arms	Subclavian steal or aortic dissection
Syncope and murmur with changing position (from sitting to lying, bending, turning over in bed)	Atrial myxoma or thrombus
Syncope with exertion	Aortic stenosis, pulmonary hypertension, mitral stenosis, obstructive hypertrophic cardiomyopathy, coronary artery disease
Family history of sudden death	Long QT syndrome, Brugada's syndrome
Brief loss of consciousness, no prodrome, with heart disease	Arrhythmias
Frequent syncope, somatic complaints, no heart disease	Psychiatric illness

From Kapoor WN. Syncope. *N Engl J Med.* 2000;343:1856-1862.

upright position but usually requires 12 to 15 seconds in the recumbent position. Palpitations during the prodrome suggest a tachyarrhythmia. The activity of the patient immediately before the onset of symptoms may also provide clues. Syncope associated with the cessation of exertion or with anxiety or pain suggests neurocardiogenic syncope, whereas symptoms during exertion suggest an arrhythmia. Syncope associated with a change in posture suggests orthostatic causes, whereas syncope while straining at urination suggests situational neurocardiogenic syncope.

A witness's description of the events during the episode of unconsciousness is very helpful. Although body stiffening and limb jerking occur with generalized seizures, similar movements can result from cerebral hypoperfusion, especially if perfusion is not restored rapidly. Such muscle jerking is often multifocal and can be synchronous or asynchronous. In contrast to epileptic seizures, which generally produce tonic-clonic activity for at least 1 to 2 minutes, muscle jerking in syncope rarely persists for longer than 30 seconds. If an arrhythmia continues or the patient is physically maintained upright, tonic stiffening of the body followed by jerking movements of the limbs can occur. Occasionally, motor movements identical to a tonic-clonic seizure occur, and a mistaken diagnosis of epilepsy can be made. Urinary incontinence during the spell is frequently used to support or refute a diagnosis of epilepsy; however, fainting with a full bladder can result in incontinence, whereas seizures with an empty bladder will not. Tongue biting favors seizures.

The time frame over which consciousness and orientation are regained is perhaps the most important clue in differentiating seizures from syncope. Recovery of orientation after neurocardiogenic syncope occurs within seconds of regaining consciousness. Recovery of orientation after self-reversible arrhythmia-associated syncope is usually proportional to the duration of the unconsciousness and is usually rapid (0 to 10 seconds). Life-threatening arrhythmias (e.g., prolonged asystole or ventricular fibrillation) usually do not resolve without resuscitation, and the confusion after regaining consciousness may be permanent owing to ischemic brain injury (Chapter 63). By comparison, the period of confusion after seizures, often accompanied by agitation, continues for 2 to 20 minutes after recovery of consciousness.

DIAGNOSIS

Arrhythmias are generally categorized as bradyarrhythmias (slow heart rates), tachyarrhythmias (fast heart rates), or premature beats (single extrasystoles from the atrium or the ventricle—PACs [see Fig. 64-12 in Chapter 64] or PVCs [see Fig. 65-3 in Chapter 65], respectively) (see Table 62-1). Although not a primary arrhythmia, neurocardiogenic syncope is a related diagnostic and management issue because its symptoms are frequently similar to those of arrhythmias and because neurocardiogenic syncope secondarily results in bradycardia (see later).

Bradyarrhythmias

Bradyarrhythmias (Chapter 64) can be due to dysfunction in the sinoatrial node, atrioventricular (AV) node, or His-Purkinje system (below the AV node). Sinus bradycardia manifests as a slow atrial (sinus) rate and can occur at rest or as an inappropriately slow rate during exercise (chronotropic incompetence). Sinus arrest can be intermittent, when transient loss of sinus activity (loss of the P wave on the ECG) causes brief sinus pauses, or persistent, with prolonged loss of atrial activation. The sinus rate and even the presence of sinus pauses are influenced by autonomic tone. Therefore, healthy individuals—particularly younger patients and well-trained athletes (with high vagal tone)— have occasional sinus slowing, often during sleep. A sinus pause of more than 3 seconds is considered pathologic when it is associated with symptoms. Sinus bradycardia and sinus arrest can also be the result of medications, typically β-blockers and calcium-channel blockers. When not "physiologic" or due to medications, sinus bradycardia and sinus arrest are the result of intrinsic conduction system disease. Sinus bradycardia, especially if it is intermittent, can also signify disease of the right coronary artery.

Bradyarrhythmias from AV nodal disease result from the failure of impulse conduction from the atrium to the ventricle. Like the sinus node, the AV node is dramatically affected by autonomic tone. Mobitz type I second-degree AV block (Wenckebach block; see Fig. 64-8 in Chapter 64) can be seen during periods of high vagal tone and is not necessarily pathologic; for example, it does not progress to complete heart block and is not associated with a widened QRS. Many drugs, such as β-blockers and calcium-channel blockers, commonly cause first-degree AV block and should be considered a potential cause of any degree of AV block. Mobitz type II block (see Fig. 64-9 in Chapter 64) signifies that the level of AV block is below the AV node in the His-Purkinje system, which is not sensitive to autonomic tone; the resulting QRS is widened, and there is a high likelihood of progression to complete heart block (third-degree AV block; see Figs. 64-10 and 64-11 in Chapter 64). Intermittent complete heart block, which can result in drop attacks or Stokes-Adams attacks, is usually preceded by abnormal baseline findings on the ECG, such as a bundle branch block or second-degree AV block. The treatment of choice for symptomatic bradyarrhythmias or those likely to progress to complete heart block is implantation of a permanent pacemaker (Chapter 66).

Tachyarrhythmias

Tachyarrhythmias can arise from the atrium or AV node (supraventricular tachycardia) or from the ventricle (ventricular tachycardia). Supraventricular tachyarrhythmias that may be associated with palpitations, presyncope, or syncope include atrial tachycardia (see Fig. 64-18 in Chapter 64), AV nodal re-entrant tachycardia (see Fig. 64-19 in Chapter 64), AV junctional tachycardia (see Fig. 64-20 in Chapter 64), atrial flutter (see Fig. 64-23 in Chapter 64), and atrial fibrillation (see Fig. 64-24 in Chapter 64), sometimes in association with accessory conduction pathways that facilitate the re-entry needed to sustain the arrhythmia. Ventricular tachyarrhythmias include the various forms of ventricular tachycardia (see Fig. 65-3 in Chapter 65). Treatment is guided by the specific tachyarrhythmia and its underlying cause (see Table 62-3 and Tables 64-6 and 64-7 in Chapters 62 and 64, respectively) (Chapters 63 through 66).

Neurocardiogenic Syncope and Related Syndromes

Neurocardiogenic syncope is the sudden onset of lightheadedness or loss of consciousness as a result of autonomic reflexes and is more common in

TABLE 62-3 ARRHYTHMIC CAUSES OF PALPITATIONS AND SYNCOPE

ETIOLOGY	SPECIFIC ARRHYTHMIA	*Symptoms* PALPITATIONS	DIZZINESS	SYNCOPE	TREATMENT	COMMENTS
BRADYARRHYTHMIAS						
Sinus node dysfunction	Sinus bradycardia	No	Occasional	Rare	Pacemaker (if symptoms)	Can be seen in association with neurocardiogenic syncope
	Sinus arrest	Occasional	Yes	Occasional	Pacemaker	Pause >3 sec
	Sick sinus syndrome	Occasional	Yes	Occasional	Pacemaker	
AV nodal disease	First-degree AV block	No	No	No	None	
	Type I second-degree AV block	Occasional	No	No	None	Can be seen in association with neurocardiogenic syncope
	Type II second-degree AV block	Occasional	Rare	No	Pacemaker if severe	Can progress to complete heart block
	Third-degree AV block	Yes	Yes	Yes	Pacemaker	
Tachy-brady syndrome		Yes	Yes	Occasional	Treat tachycardia if possible Pacemaker	Can also be manifestation of sick sinus syndrome
TACHYARRHYTHMIAS						
SVT	Atrial tachycardia	Yes	Occasional	Rare	Ablation β-Blockers (e.g., metoprolol, atenolol)* Calcium-channel blockers (e.g., diltiazem)*	
	Atrial flutter	Yes	Occasional	Rare	Ablation Antiarrhythmic drugs (e.g., amiodarone)* Cardioversion (acute episode)	Often difficult to control rate
	Atrial fibrillation	Yes	Occasional	Rare	Ventricular rate control Warfarin Antiarrhythmic drugs (e.g., amiodarone)* Cardioversion (acute episode) Ablation	
	AV nodal re-entrant tachycardia	Yes	Yes	Rare	Ablation β-Blockers (e.g., metoprolol, atenolol)* Calcium-channel blockers (e.g., diltiazem)*	
	AV re-entrant tachycardia (WPW)	Yes	Yes	Rare	Ablation Antiarrhythmic drugs*	
VT	Idiopathic (RV outflow tract, fascicular)	Yes	Yes	Occasional	Ablation	Absence of structural heart disease Low risk of sudden death
	VT secondary to CAD, cardiomyopathy	Yes	Yes	Yes	ICD Amiodarone (400 mg qd)* Ablation	Increased incidence of sudden death
	Bundle branch re-entry	Yes	Yes	Yes	Ablation	Usually in the setting of LV dysfunction and baseline intraventricular conduction delay
	Genetic syndromes (e.g., long QT syndrome, Brugada's, arrhythmic right ventricular dysplasia)	Occasional	Yes	Yes	ICD	Not always a clear family history Increased incidence of sudden death
Ectopy	PACs	Occasional	No	No	None β-Blockers (e.g., atenolol, metoprolol) if symptomatic*	
	PVCs	Occasional	No	No	None β-Blockers (e.g., atenolol, metoprolol) if symptomatic*	Benign in absence of structural heart disease
NEUROCARDIOGENIC SYNCOPE		No	Yes	Yes	Behavioral (hydration, avoid triggers, abort episodes) Midodrine (10 mg tid)	

*See Table 64-7 in Chapter 64 for drug doses.
AV = atrioventricular; CAD = coronary artery disease; ICD = implantable cardioverter-defibrillator; LV = left ventricle; PACs = premature atrial contractions; PVCs = premature ventricular contractions; RV = right ventricle; SVT = supraventricular tachycardia; VT = ventricular tachycardia; WPW = Wolff-Parkinson-White syndrome.

younger patients (teenage to third decade of life). It is sometimes called a vasovagal episode, a common faint, or situational syncope if it is clearly induced by a particular activity (e.g., micturition syncope). In this form of neurocardiogenic syncope, heightened parasympathetic output, either due to direct stimulation (e.g., micturition, defecation, abdominal pain or other gastrointestinal conditions) or as a reflex in response to sympathetic stimulation (e.g., seeing blood, abrupt cessation of exercise), results in arterial dilation (called the vasodilatory response) and an inhibition of sinus and AV node activity (the cardioinhibitory response). The result is a transient decrease in blood pressure, often manifested as lightheadedness or syncope. Because they are associated with parasympathetic (vagal) output, episodes are frequently accompanied by nausea, diaphoresis, and salivation.

Treatment of this form of syncope can be challenging. The most effective therapies are behavioral (avoidance of triggers), wearing of compression stockings, and maintenance of adequate hydration and salt intake. Lying down with the feet elevated and performing isometric hand exercises may abort an acute episode. Medical therapy, including β-blockers (pindolol 5 to 15 mg twice daily), mineralocorticoids (fludrocortisone 0.1 mg/day), paroxetine (10 to 20 mg/day), and midodrine (an α-adrenergic agonist and vasoconstrictor; 2.5 to 5 mg three times daily), has shown some efficacy in reducing recurrence rates, although the efficacy of β-blockers for reducing syncopal episodes has been inconsistent. Even though bradycardia is a dominant feature of neurocardiogenic syncope, a pacemaker is not effective for the prevention of episodes because most patients also have a major vasodilatory component.

Rarely, situational syncope is associated with swallowing or coughing. Swallowing can trigger brain stem reflexes that lead to vagally induced bradyarrhythmias, with resultant syncope. This phenomenon may or may not be associated with severe pain in the tonsillar pillar, which may radiate to the ear (i.e., glossopharyngeal neuralgia; Chapter 405). The pain can usually be prevented by carbamazepine (400 to 1000 mg/day orally); in refractory cases, 300 mg/day of phenytoin can be added. Cough-related syncope can occur with severe, repeated coughing, which may increase thoracic pressure and result in increased vagal tone or a transient reduction in outflow from the intracranial veins, followed by a transient increase in intracranial pressure and impaired blood flow.

A related cause of syncope is carotid body hypersensitivity, in which vagal tone is increased by direct stimulation of the carotid body. This condition is frequently seen in older patients (particularly men older than 60 years), in whom episodes are associated with mechanical stimulation of the neck (e.g., turning the head, shaving, wearing a tight collar or necktie). Use of β-blockers, calcium-channel blockers, and digitalis can exacerbate or predispose to this condition. This form of syncope is diagnosed by documenting pauses longer than 3 seconds in response to carotid sinus massage and is curable with a pacemaker because carotid body stimulation does not cause significant vasodilation.

Postural or orthostatic hypotension can result in recurrent syncope. The history confirms that the patient is in the upright posture during spells, that the prodromal symptoms are those of cerebral hypoperfusion, and that the symptoms are relieved with recumbency. The diagnosis is supported by detecting a decrease of 30 mm Hg or greater in systolic blood pressure or a decrease of 10 mm Hg or greater in diastolic blood pressure between recumbent and upright postures. The many causes include drugs, polyneuropathies (Chapter 428), and neurodegenerative disorders (Chapter 416).

Cerebrovascular syncope results from cerebral hypoperfusion due to vascular phenomena, as opposed to generalized hypotension caused by arrhythmias or neurocardiogenic reflexes. Loss of consciousness can be a component of a basilar artery transient ischemic attack, but other brain stem symptoms nearly always precede or accompany the unconsciousness. Vertigo is most frequent, but diplopia or visual field disturbances, hemifacial or perioral numbness, and dysarthria or ataxia are also common. Recovery of consciousness may require 30 to 60 minutes. Although the diagnosis is suggested by the history and clinical presentation, imaging studies can be useful to confirm the diagnosis. Carotid Doppler studies may show various degrees of stenosis, especially in older patients. However, unconsciousness requires bihemispheric dysfunction; thus, unilateral carotid stenosis alone does not cause syncope. Transcranial Doppler studies or magnetic resonance angiography of the basilar artery is indicated only if brain stem ischemic symptoms are present in addition to loss of consciousness; false-positive tests are common, especially with increasing age. These patients, who are at risk for basilar artery stroke, should be treated with aspirin and should be considered for other treatments (e.g., surgery, stent placement) appropriate for their symptoms and anatomy (Chapter 414).

Other syndromes that can cause syncope include subclavian artery stenosis, which may result in retrograde blood flow from the vertebral artery to one arm, with resultant brain stem hypoperfusion (i.e., subclavian steal syndrome). Asymmetry in upper extremity systolic blood pressure, typically averaging 45 mm Hg, is nearly always present. Brain stem symptoms are similar to those in basilar transient ischemic attacks, including loss of consciousness, but a subsequent stroke from subclavian steal is rare. Repair of the stenosis is the treatment of choice. Syncope may also occur in up to 10% of patients with basilar artery migraine (Chapter 405). It can have a postural (orthostatic) manifestation or be associated with other basilar artery symptoms.

Neuropsychiatric syncope is a diagnosis of exclusion but is suggested by young age, frequent spells, multiple symptoms (e.g., dizziness, vertigo, lightheadedness, numbness), and duplication of the patient's symptoms by hyperventilation with the mouth open for 2 to 3 minutes. Whereas syncope and seizures occur with the eyes open, often with gaze deviation, psychogenic events frequently begin with eye closing.

Seizures (Chapter 410) can cause loss of consciousness and occasionally present clinically as syncope. However, seizures usually have a characteristic presentation and include a postictal phase, whereas most patients experiencing a syncopal episode quickly regain consciousness, except when cerebral perfusion is so compromised as to cause a secondary seizure or persistent anoxia and brain damage.

Diagnostic Tests

Electrocardiography

The baseline ECG is critical in the evaluation of a patient with palpitations or syncope. The presence of ventricular preexcitation, as manifested by a short PR interval and a delta wave (see Fig. 64-21 in Chapter 64), establishes the likely diagnosis of Wolff-Parkinson-White syndrome in a patient with palpitations and AV reciprocating tachycardia (Chapter 64); it can also be used to determine the location of the responsible accessory pathway. The baseline ECG provides useful predictive information about the likelihood of conduction system abnormalities being responsible for bradyarrhythmias (e.g., sinus bradycardia suggests sinus node dysfunction, a prolonged PR interval suggests AV nodal disease, and a widened QRS suggests disease below the AV node). The ECG is also useful in diagnosing prior myocardial infarction (i.e., pathologic Q waves), which raises the likelihood of ventricular tachycardia as a potential cause of syncope or palpitations. Abnormalities such as a prolonged QT interval in a patient with syncope and a family history of syncope or sudden death suggest one of the congenital long QT syndromes (Chapter 65). An incomplete right bundle branch block with coved ST segment elevation in ECG lead V_1 or V_2 in a patient with syncope or palpitations suggests Brugada's syndrome, whereas an epsilon wave, incomplete right bundle branch block, and inverted T waves in V_1 are suggestive of right ventricular dysplasia (Chapter 65). All these syndromes carry an increased risk of recurrent syncope and sudden death if untreated (Chapters 63 through 65).

Performing an ECG during an episode of palpitations is extremely useful in making a definitive diagnosis. For narrow–QRS complex tachycardias, the specific supraventricular tachycardia can often be surmised from the 12-lead ECG obtained during symptoms (Fig. 62-2). Moreover, for wide–QRS complex tachycardias, the 12-lead ECG is useful in distinguishing a supraventricular tachycardia (with aberrancy) from a ventricular tachycardia (Fig. 62-3). The presence of fusion beats or AV dissociation during a wide–QRS complex tachycardia leads to the diagnosis of ventricular tachycardia. For ventricular tachycardias, the morphology of the QRS complex is useful in determining the location of the ventricular tachycardia focus and in identifying idiopathic ventricular tachycardia (right ventricular outflow tract or fascicular), which has a much more benign course than ventricular tachycardia in the setting of coronary disease (Chapter 65).

The effect of carotid sinus massage, vagal maneuvers, or adenosine (given as a rapid intravenous bolus of 6 mg and repeated at a dose of 12 mg if the initial dose is ineffective) is also useful in narrowing the differential diagnosis of a tachycardia. These maneuvers slow conduction through the AV node. Therefore, tachycardias that terminate with either maneuver are likely to involve the AV node as a critical component of the re-entrant circuit (AV nodal re-entrant tachycardia or AV re-entrant tachycardia). If the maneuver induces AV block but does not terminate the arrhythmia, likely causes are atrial fibrillation, atrial flutter, and atrial tachycardias (or occasionally ventricular tachycardia if the QRS is wide). On rare occasions, atrial tachycardias and some idiopathic ventricular tachycardias terminate in response to

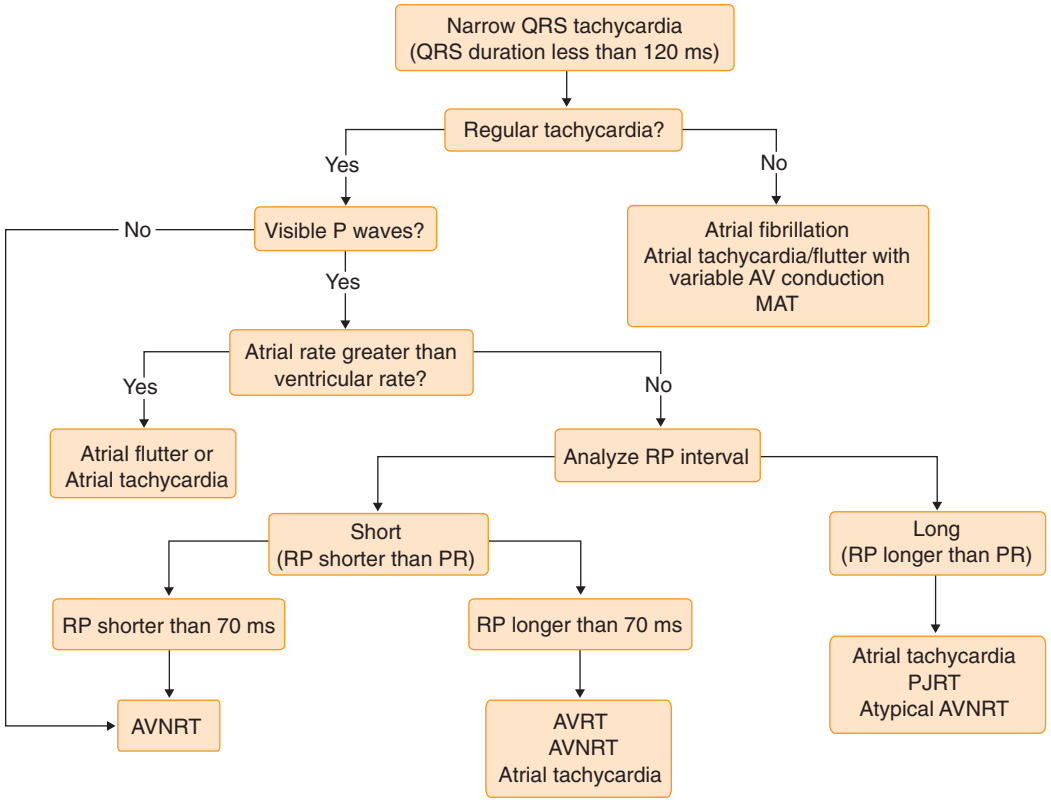

FIGURE 62-2. ECG algorithm for diagnosis of narrow-complex tachycardias. AVNRT = atrioventricular nodal reciprocating tachycardia; AVRT = atrioventricular reciprocating tachycardia; MAT = multifocal atrial tachycardia; PJRT = permanent form of junctional reciprocating tachycardia. (From Blomstrom-Lundqvist C, Scheinman MM, Aliot EM, et al. ACC/AHA/ESC guidelines for the management of patients with supraventricular arrhythmias—executive summary. *Circulation.* 2003;108:1871-1909.)

adenosine. Important clues to the specific mechanism can be obtained at the onset or termination of tachycardia, so obtaining a continuous 12-lead ECG during carotid sinus massage or the administration of adenosine is useful.

During bradycardias, the ECG is useful in determining the level of the conduction system (sinus node, AV node, or His bundle) responsible for the bradycardia. Sinus bradycardia is diagnosed when a slow (<50/minute at rest) atrial rate (P wave) conducts to the ventricle. Sinus arrest or sinus pauses (see Fig. 64-6 in Chapter 64) are diagnosed by absent or dropped P waves. First-degree AV block (see Fig. 64-7 in Chapter 64) is defined as a prolonged PR interval (>200 msec), and second-degree AV block is defined by P waves that occasionally do not conduct to the ventricle (P wave without an ensuing QRS); Mobitz type I second-degree AV block (also known as Wenckebach block; see Fig. 64-8 in Chapter 64) is characterized by progressive lengthening of the PR interval until one P wave does not conduct to the ventricle. This form of AV block is often seen in younger patients, is usually benign, and rarely progresses to complete AV (third-degree) block. Mobitz type II second-degree AV block (see Fig. 64-9 in Chapter 64), which is characterized by the sudden, unexpected loss of conduction of a P wave to the ventricle (dropped QRS), signifies disease of the His-Purkinje system and often progresses to complete heart block. Complete heart block or third-degree AV block (see Figs. 64-10 and 64-11 in Chapter 64) is diagnosed by the dissociation of P waves from QRS complexes, with an atrial rate faster than the ventricular rate.

Ambulatory Monitoring

For intermittent symptoms such as palpitations, dizziness, or syncope, it is often difficult to obtain a 12-lead ECG while the symptoms are occurring. Therefore, ambulatory monitoring, which allows ECG monitoring over long periods, is a vital diagnostic tool. There are currently three types of ambulatory monitors: Holter monitors, which continuously record the ECG for 24 to 48 hours; event recorders, which are wearable loop recorders that record only during specific events (when the patient activates the recorder because of symptoms or the recorder detects a heart rate above or below a specified threshold) and can be worn for 1 month or more; and implantable loop recorders, which function similarly to event recorders but can be used for up to 14 months. More recently, home telemetry units have been developed, allowing patients to undergo prolonged continuous remote monitoring by wireless or Internet connections. The choice of ambulatory monitoring method is largely determined by the frequency of the symptoms and the likelihood of capturing an episode during a given monitoring period.

Ambulatory monitoring is diagnostic only if abnormalities occur during symptoms or if the patient has typical symptoms without any concurrent abnormalities. A "normal" monitoring record is nondiagnostic if the patient does not have symptoms during the period.

Holter Monitors

Holter monitors use either a tape (in older devices) or digital media (in newer devices) to record a 3-, 5-, or 12-lead surface ECG continuously for 24 to 48 hours. Processing, printing, and analysis of the recordings are performed offline with commercial systems. In addition to recording the rhythm, analyses of heart rate variability and ST segment changes and accurate counts of PACs and PVCs can be automated. Some systems allow extrapolation to produce a "virtual" 12-lead recording at any time during the monitoring period. Holter monitoring is useful for detecting symptoms that are frequent (multiple times daily) and for diagnosing sinus node dysfunction (sinus node arrest, sick sinus syndrome) or intermittent AV block. It can also be useful to assess the adequacy of control of the ventricular rate in a patient with atrial fibrillation.

Event Monitors

Event monitors, also known as loop recorders, are designed to record intermittent episodes during long periods (weeks to months) and are thus useful for patients with less frequent symptoms. The system records the ECG into a loop buffer that is continuously updated and overwritten. The duration of memory varies from a few seconds to a few minutes and is usually programmable. When activated, the information is "locked" into memory and continues to record forward for a preprogrammed amount of time. Newer systems allow both patient-activated (when symptoms occur) and event-triggered (when the heart rate is above or below a preset threshold) recording. Some recorders have algorithms to detect and record atrial fibrillation automatically, regardless of the heart rate. After episodes have been recorded, the patient transmits the recording over the telephone to centralized receivers. Some event monitors require leads similar to Holter monitors, whereas others are worn on the wrist or are put into small credit card–sized devices that are placed on the chest during symptoms. The latter type is useful only in patients whose symptoms last for several minutes and who do not have syncope.

IMPLANTABLE LOOP RECORDERS. Implantable loop recorders are small devices with integrated leads that are implanted in a small subcutaneous pocket during a simple surgery, usually performed in the electrophysiology

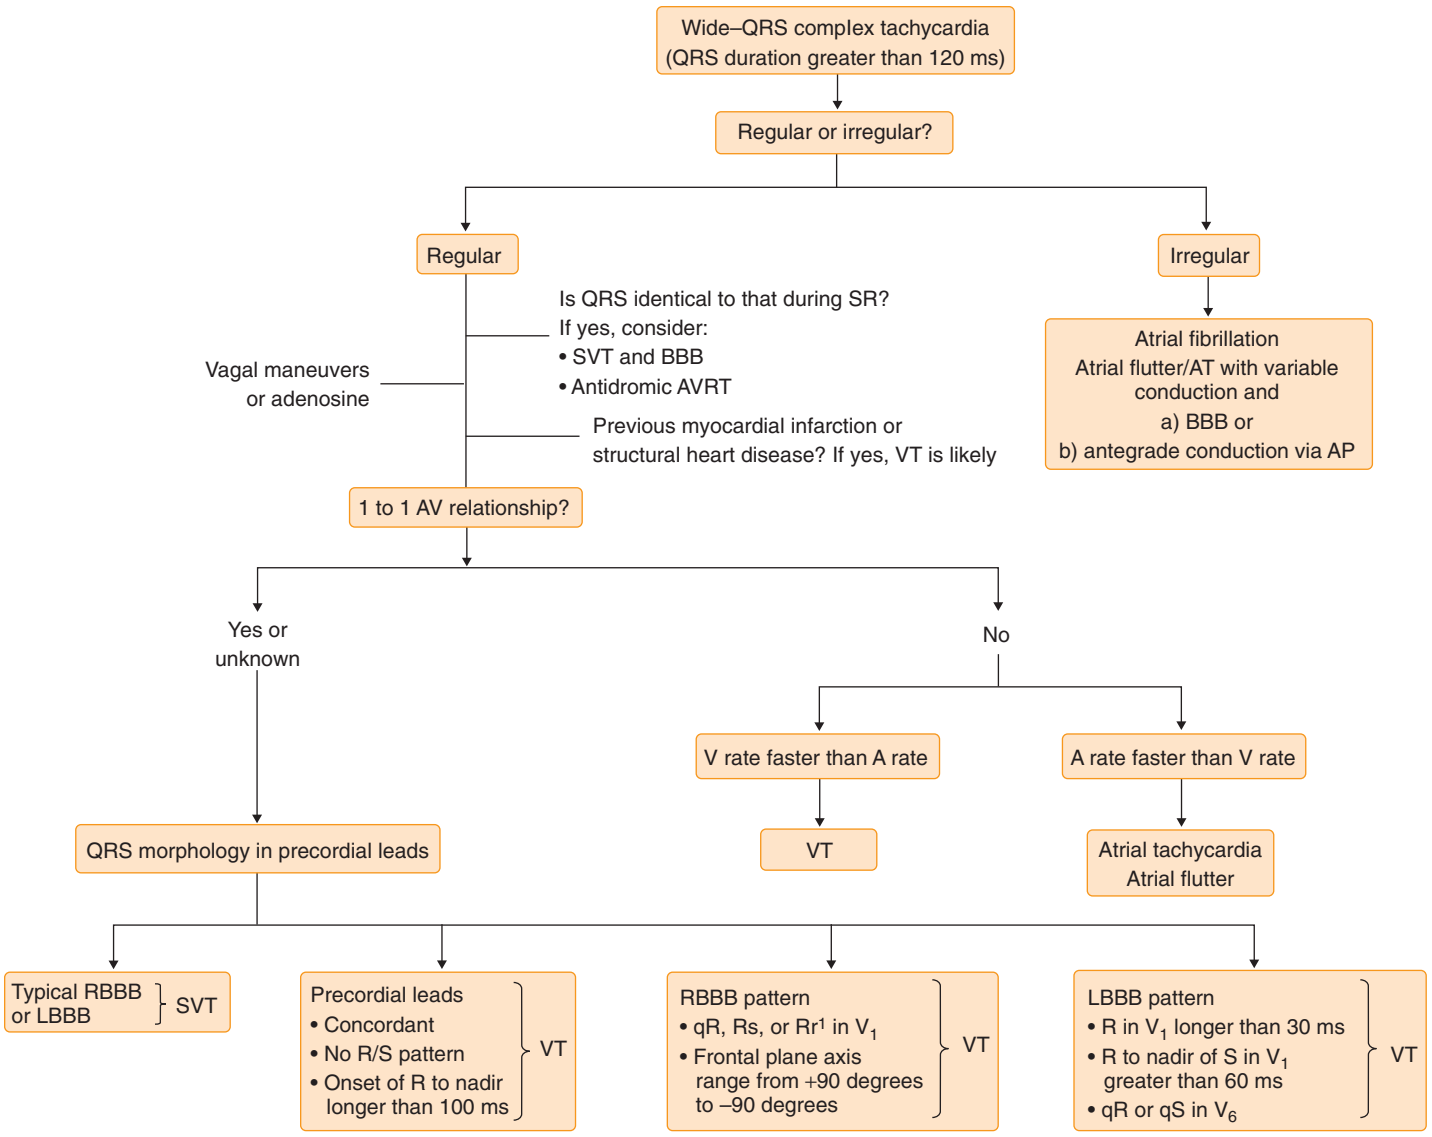

FIGURE 62-3. ECG algorithm for diagnosis of wide-complex tachycardias. A = atrial; AP = accessory pathway; AT = atrial tachycardia; AV = atrioventricular; AVRT = atrioventricular reciprocating tachycardia; BBB = bundle branch block; LBBB = left bundle branch block; RBBB = right bundle branch block; SR = sinus rhythm; SVT = supraventricular tachycardia; V = ventricular; VT = ventricular tachycardia. (From Blomstrom-Lundqvist C, Scheinman MM, Aliot EM, et al. ACC/AHA/ESC guidelines for the management of patients with supraventricular arrhythmias—executive summary. *Circulation.* 2003;108:1871-1909.)

laboratory. They function similarly to event recorders in terms of recording ECGs. Patients can activate the device with a small transmitter, or the device can be autotriggered on the basis of preprogrammed heart rates. The device can be interrogated by a computer, similar to the way pacemakers are interrogated to program the device's parameters and to retrieve ECGs that have been recorded. In patients with recurrent, difficult-to-diagnose syncope, an implantable loop recorder is better than the combination of tilt testing, an external loop recorder, and electrophysiologic testing.■

Tilt Table Testing

Tilt table testing is used to confirm the diagnosis of neurocardiogenic syncope. The test involves continuous heart rate and blood pressure monitoring during head-up tilting. After baseline measurements in the supine position, the patient is tilted head-up at 60 to 80 degrees for 60 minutes. Some laboratories use isoproterenol or nitroglycerin as additional provocation. A positive result is a sudden and precipitous fall in blood pressure and heart rate, with concurrent reproducibility of symptoms (syncope). Because there is an appreciable false-positive rate, the test is best used as a confirmatory test in patients with a history suggestive of neurocardiogenic syncope or in patients with syncope in whom structural heart disease and other causes of syncope have been excluded.

Electrophysiologic Studies

Electrophysiologic studies involve the placement of several transvenous catheters in the heart to make temporary measurements of intracardiac electrograms and to perform pacing. Electrophysiologic studies are useful to identify the precise mechanism of tachyarrhythmias and are a necessary prelude to curative ablation (Chapter 66). Most arrhythmias, especially those with re-entrant mechanisms, can be readily induced during electrophysiologic studies. In addition, the existence and characteristics of accessory AV pathways (i.e., those responsible for Wolff-Parkinson-White syndrome or other re-entrant tachyarrhythmias) can be readily assessed by an electrophysiologic study. In patients with previous myocardial infarction, electrophysiologic studies are useful in determining the existence of a substrate for ventricular arrhythmias (Chapter 65), which may be treated with ablation or implantable defibrillators (Chapter 66). Electrophysiologic studies are also useful to determine the integrity of the conduction system and the precise mechanism of bradyarrhythmias that may be causing syncope. Therefore, electrophysiologic studies are indicated in patients with documented or suspected tachyarrhythmias as a prelude to curative ablation; in patients with a previous myocardial infarction and syncope, presyncope, or palpitations to exclude ventricular tachycardia; and in patients with severe or prolonged symptoms and no apparent diagnosis by history or ambulatory monitoring, especially in the setting of an abnormal ECG.

Other Tests

Echocardiography

Echocardiography (Chapter 55) can be useful to ensure that a patient does not have underlying structural heart disease, which can be an important prognostic factor in patients with ventricular tachycardia or syncope. Echocardiography should be performed in patients who present with syncope that is not obviously neurocardiogenic to ensure that there is no valvular or myocardial cause.

Exercise Testing

Exercise testing (Chapter 50) can be useful to assess arrhythmias, particularly in patients whose symptoms are exercise related. Exercise testing can also be useful in the evaluation of patients with bradyarrhythmias to diagnose chronotropic incompetence, and it can differentiate AV block due to autonomic tone (improves with exercise) from intrinsic conduction disease (generally worsens with an increasing rate).

Neurologic Testing

Routine electroencephalography (Chapter 403) is not helpful because a single study may be normal, even in epileptic patients. Structural brain diseases rarely cause episodic loss of consciousness, and routine brain imaging studies are indicated only in patients with focal neurologic findings. Carotid Doppler (Chapter 414) studies can document stenosis, but unconsciousness requires bihemispheric dysfunction. Transcranial Doppler or magnetic resonance angiography of the basilar artery is indicated only in patients with symptoms suggestive of brain stem ischemia.

TREATMENT

Rx

Treatment of syncope depends on the underlying cause. Proximate to the syncopal episode, hospital admission (e.g., observation in a chest pain unit or its equivalent) is recommended when the cause of syncope is unclear, especially in elderly patients, otherwise fragile or worrisome patients, or those suspected of having a cardiac or cerebrovascular cause, or if the syncope resulted in significant injury. Patients at highest risk have a systolic blood pressure below 90 mm Hg, a history of myocardial infarction or heart failure, a complaint of shortness of breath, an abnormal initial ECG, or a hematocrit less than 30%.

Until the cause of the syncope is determined and treated, patients should be instructed to avoid situations that may cause injury as a result of the syncope, especially if there is no prodrome and episodes are frequent. Careful consideration should be given to driving restrictions, which may be mandatory depending on local laws, and restrictions on dangerous work-related activity (e.g., for pilots, heavy machine operators, bus drivers) until definitive therapy is given.

In patients with a cardiac cause of syncope, targeted treatments include valve replacement for aortic stenosis (Chapter 75); medications for hypertrophic cardiomyopathy (Chapter 60); cardioversion, a pacemaker, an implantable cardioverter-defibrillator, ablation, or medications for tachyarrhythmias (Table 62-3; Chapters 63 through 65); and fluid repletion for orthostatic hypotension.

In patients with neurocardiogenic syncope, behavioral guidance should encourage an increased intake of fluid and salt, as well as the avoidance of situations that precipitate symptoms. Patients should also be taught how to tense their arms and legs and grip their hands during prodromal symptoms to increase peripheral resistance and systemic blood pressure.[A] If neurocardiogenic syncope recurs despite education and lifestyle changes, fludrocortisone (0.1 mg/day, starting dose) can expand intravascular volume but has not been proved to prevent syncope. Midodrine (usually 10 mg three times daily), an α_1-receptor agonist and vasoconstrictor, has shown potential benefit,[B] but other α-agonists have not. Paroxetine (20 mg/day), a selective serotonin re-uptake inhibitor, reduced recurrent neurocardiogenic syncope in one trial of very symptomatic patients but otherwise has been disappointing.[B] In randomized trials, β-blockers have not been useful. Pacemakers do not reduce recurrent neurocardiogenic syncope,[B] but they are very effective in patients with cardioinhibitory syncope as a result of severe bradycardia.[A]

PROGNOSIS

One syncopal event predicts a substantial risk for recurrent syncope. Although syncope itself does not appear to increase the risk of death, patients with cardiac or cerebrovascular causes have higher mortality rates than patients with definable noncardiac causes or those without a definable cause. Among patients who come to an emergency department, the overall death rate of about 7.5% at 1 year reflects patients' underlying abnormalities.

APPROACH TO CARDIAC ARREST AND LIFE-THREATENING ARRHYTHMIAS

ROBERT J. MYERBURG AND AGUSTIN CASTELLANOS

Cardiac arrest is characterized by an abrupt loss of consciousness because of absence of blood flow owing to loss of cardiac pumping action. If not treated promptly, it will lead to central nervous system injury or death within minutes. Cardiac arrest is often forewarned by a change in cardiovascular status, as indicated by the appearance or worsening of symptoms related to transient arrhythmias, such as palpitations, lightheadedness, or near-syncope or syncope (Chapter 62). Other forewarnings may include new or worsening chest pain, dyspnea, or weakness. These warning symptoms, however, are limited by their sensitivity and predictive power in individual patients. Moreover, cardiac arrest may occur unexpectedly as a first cardiac event in an apparently healthy individual, in a patient with known previous cardiac disease, or as the final event in any fatal disease.

The most common electrical mechanisms of cardiac arrest are the ventricular tachyarrhythmias (Chapter 65)—ventricular fibrillation (VF) or pulseless ventricular tachycardia (VT). In a substantial minority of cardiac arrests, severe bradyarrhythmia, asystole, or pulseless electrical activity is the first rhythm abnormality noted. The latter may be the primary mechanism of the cardiac arrest or a result of deterioration of VT/VF. Pulseless electrical activity or asystole may also be seen after termination of VT/VF by electrical cardioversion. Pulseless electrical activity is defined as secondary when it occurs in the setting of predisposing factors, such as hypoxia or other metabolic disorders, and primary when it is the initial rhythm noted in patients with predisposing cardiac disorders. The probability of survival after intervention is far better for ventricular tachyarrhythmias than for bradyarrhythmic or asystolic mechanisms. The interval between cardiac arrest and the initiation of resuscitation and cardioversion is the major determinant of survival.

PREDISPOSING WIDE-QRS COMPLEX TACHYCARDIAS

Sustained tachycardias with wide QRS complexes should be considered of ventricular origin and potentially high risk until determined otherwise. Most wide-QRS tachycardias are initially approached as a medical urgency or emergency, whereas most narrow-QRS tachycardias of supraventricular origin are approached with less urgency (Chapters 64 and 65).

Management of Sustained Ventricular Tachycardia

Sustained VT occurs most commonly in the presence of structural heart disease and must be interpreted as a forewarning of fatal arrhythmia in that setting. It is characterized by QRS complexes that are usually longer than 0.12

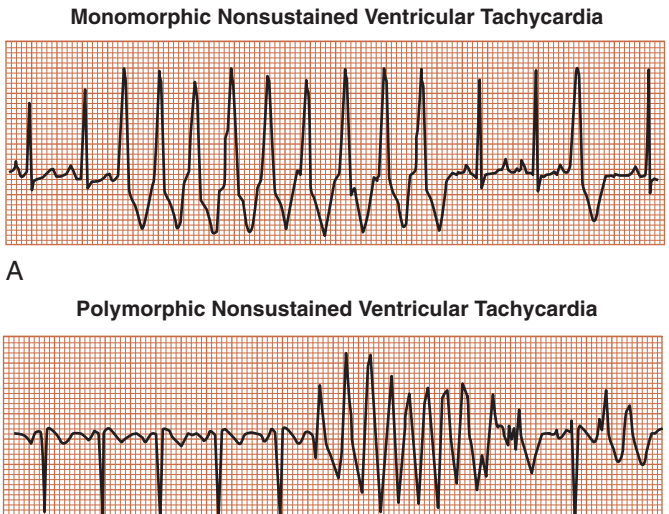

FIGURE 63-1. Nonsustained ventricular tachycardia. Monomorphic patterns **(A)** are characterized by a slower and more stable electrical pattern than polymorphic patterns **(B)**. Both have long-term prognostic implications in patients with advanced structural heart disease, but monomorphic patterns tend to be more stable over the short term.

second, with a mean vector that is markedly different from the QRS vector of normally conducted impulses. The rate of most VTs is between 140 and 200 impulses per minute, but rates may be slower or faster. VT may be electrically stable (such as monomorphic VT patterns at relatively slow rates; Fig. 63-1A) or unstable (such as polymorphic VTs or monomorphic VTs at rates exceeding 190 to 200 per minute; see Fig. 63-1B) (Chapter 65). Slower monomorphic VT may be better tolerated, whereas rapid VT is often associated with hemodynamic instability. In the latter circumstance, VT must be managed as a life-threatening or imminently fatal event, analogous to a VT/VF cardiac arrest (see later) that is usually treated with electrical cardioversion as initial therapy. Long-term management strategies, often involving consideration of implantable cardioverter-defibrillator therapy, are based on consideration of the likelihood of recurrent tachycardias and the extent of underlying disease (Chapter 65). Some well-tolerated, slow monomorphic VTs, especially in the absence of structural heart disease, may be more benign and treated with less urgency, usually with antiarrhythmic drugs or β-adrenergic blocking agents (see Table 64-5 in Chapter 64).

Distinguishing Supraventricular from Ventricular Tachycardias

It is important to distinguish between supraventricular tachycardia (SVT) (Chapter 64) and VT for both risk prediction and therapy. Although it is generally assumed that narrow-QRS tachycardias are supraventricular in origin, VT occasionally has a narrow QRS complex on a one- or two-lead rhythm strip, thereby mimicking SVT. Whenever possible, the diagnosis of tachycardia should be based on a 12-lead electrocardiogram (ECG). However, a standard ECG will not always suffice because patients with intraventricular conduction abnormalities (such as a left or right bundle branch block) will have wide-complex tachycardias during SVTs, usually with a QRS vector similar to that seen in normal sinus rhythm. In addition, when an SVT is very rapid, a functional bundle branch block may generate a widened QRS duration and shift the axis transiently. In both these examples, the wide QRS may mimic VT, and it may be necessary to perform an electrophysiologic study to determine the diagnosis (Chapter 62).

When wide-complex SVT is suspected clinically, transient vagal stimulation by carotid sinus massage or an atrioventricular nodal blocking agent, such as intravenous adenosine (see Table 64-5 in Chapter 64), may be useful for slowing the rate or terminating an SVT. Intravenous calcium-blocking agents generally should not be used for the diagnosis or treatment of wide-QRS tachycardias, especially in the presence of structural heart disease, because of their myocardial depressant effects. The exception is when it is known with certainty that the tachycardia is an SVT in a patient with normal or near-normal left ventricular function.

SVTs can result in a risk for generating life-threatening ventricular arrhythmias in two circumstances. One is in patients with high-grade coronary artery stenoses, in whom rapid heart rates can cause myocardial ischemia because of the dependence of coronary blood flow on the diastolic interval; the arrhythmia should be treated urgently, usually by electrical direct current (DC) cardioversion (Chapter 66), unless specific medical therapy is available and controls the rate promptly (Chapter 64). The second is in patients with Wolff-Parkinson-White syndrome, who may have ventricular rates greater than 300 beats per minute during atrial fibrillation when the accessory pathway has a short refractory period (see Fig. 64-19 in Chapter 64). This arrhythmia, which can cause hypotensive VT or VF, requires prompt therapy (Chapter 64).

GENERAL MANAGEMENT OF CARDIAC ARREST

Basic life-support (BLS) and advanced cardiac life support (ACLS) strategies for initial and definitive responses to cardiac arrest have improved survival in victims of cardiac arrest. The principles of BLS and ACLS apply to both in-hospital and out-of-hospital cardiac arrest, but their applications and outcomes depend on the setting. In the hospital, the probability of survival is determined by the specific patient category (acute syndromes better than end-stage diseases), the mechanism of cardiac arrest (better for tachyarrhythmias than for bradyarrhythmias, asystole, or pulseless electrical activity), and the hospital site (better in intensive care units or other monitored settings than on an unmonitored general care unit). In many acute care settings, including patients with acute coronary syndromes (Chapters 72 and 73), outcomes can be excellent. For other in-hospital settings and most out-of-hospital settings, the absolute number and proportion of survivors remain low, except in unique out-of-hospital settings that can provide an extraordinarily rapid response time to victims in VF or VT. When immediate defibrillation in highly protected environments is available, such as monitored intensive care units and electrophysiology laboratories, where response times of less than 60 seconds are the norm, the survival rate after VF is greater than 90% in the absence of pathophysiologic conditions that favor persistence of the potentially fatal arrhythmia.

Once 2 to 3 minutes have elapsed from the onset of cardiac arrest to attempted defibrillation, the survival probability falls below 50% in most in-hospital and out-of-hospital circumstances. Survival rates continue to fall rapidly thereafter, decreasing to 25% or less by 4 to 6 minutes and less than 10% by 10 minutes. Although immediate defibrillation is the preferred method within the first few minutes after the onset of cardiac arrest, a brief period of cardiopulmonary resuscitation (CPR) to provide oxygenation of the victim improves survivability when the time to defibrillation exceeds 4 to 5 minutes.

Basic Life Support

The activities included within BLS encompass the initial responses for diagnostic evaluation, followed by a seamless flow into establishing ventilation and perfusion through the techniques of CPR or the newly proposed concept of cardiocerebral resuscitation (see later). The first action is to confirm that the collapse is the result of a cardiac arrest. After an initial evaluation for response to voice or tactile stimulation, observation for respiratory movements and skin color, and simultaneous palpation of major arteries for the presence of a pulse, the determination that a life-threatening incident is in progress should immediately prompt a call to an emergency medical rescue system (911).

The absence of respiratory efforts, or the presence of only gasping agonal respirations in conjunction with an absent pulse, is diagnostic of cardiac arrest. Although the absence of a carotid or femoral pulse is a primary diagnostic criterion for the health care professional, palpation for a pulse is no longer recommended for lay responders. The absence of respiratory efforts or severe stridor with *persistence of a pulse* suggests a primary respiratory arrest that may lead to cardiac arrest in a short time; skin color may be pale or intensely cyanotic. In the latter circumstance, initial efforts should include oropharyngeal exploration in search of a foreign body and the Heimlich maneuver, which entails wrapping the arms around the victim from the back and delivering a sharp thrust to the upper part of the abdomen with a closed fist, particularly in a setting in which aspiration is likely (e.g., collapse in a restaurant).

Once a pulseless cardiac arrest is established, a blow to the chest (precordial thump) may be attempted by a properly trained rescuer as part of an initial response when monitoring and a defibrillator are not immediately available. A precordial thump should not be used in an unmonitored patient with a perceptible rapid tachycardia or without complete loss of consciousness because of concern about converting organized electrical activity into VF. The technique involves one or two blows delivered firmly to the junction

of the middle and lower thirds of the sternum from a height of 8 to 10 inches, but the effort should be abandoned if a spontaneous pulse does not immediately occur or if the patient begins to breathe.

The precordial thump should be followed immediately by the initiation of CPR so as to maintain viability of the central nervous system, heart, and other vital organs until a definitive intervention can be carried out. CPR can be performed by professional and paraprofessional personnel, by experienced emergency medical technicians, and by trained laypersons. Time is the key element for success, and there should be minimal delay between the diagnosis and preparatory efforts in the initial response and institution of CPR. If only one witness is present, the only activity that should precede BLS is telephone contact (911) of emergency personnel.

Clearing the airway, which is a critical step in preparing for successful resuscitation, includes tilting the head backward and lifting the chin, in addition to exploring the airway for foreign bodies—including dentures—and removing them. The Heimlich maneuver should be performed if there is reason to suspect a foreign body lodged in the oropharynx, as suggested by severe respiratory stridor rather than by slow agonal respirations or apnea. When the person at the scene has insufficient physical strength to perform the maneuver, mechanical dislodgement of a foreign body can sometimes be achieved by abdominal thrusts with the unconscious patient in a supine position. If there is suspicion that respiratory arrest precipitated the cardiac arrest, particularly in the presence of a mechanical airway obstruction, a second precordial thump should be delivered after the airway has been cleared.

With the head properly placed and the oropharynx clear, mouth-to-mouth respiration can be initiated, but bystander compression-only CPR is as good as, if not better than, compression plus mouth-to-mouth respiration.■ A variety of devices are available for establishing ventilation, including plastic oropharyngeal airways, esophageal obturators for establishing ventilation, a masked Ambu bag, and endotracheal tubes. Intubation is the preferred procedure, but time should not be sacrificed, even in the in-hospital setting, while awaiting an endotracheal tube or a person trained to insert it quickly and properly. Temporary support with Ambu bag ventilation is the usual method in the hospital until endotracheal intubation can be accomplished; in the out-of-hospital setting, mouth-to-mouth resuscitation is performed while awaiting emergency rescue personnel. The lungs should be inflated twice in succession after every 30 chest compressions.

The third element of BLS, circulation, is intended to maintain blood flow until definitive steps can be taken. The rationale is based on the hypothesis that chest compression maintains an externally driven pump function by sequential emptying and filling of its chambers, with competent valves favoring the forward direction of flow. The palm of one hand is placed over the lower part of the sternum while the heel of the other rests on the dorsum of the lower hand. The sternum is then depressed with the resuscitator's arms straight at the elbows to provide a less tiring and more forceful fulcrum at the junction of the shoulders and back. With this technique, sufficient force is applied to depress the sternum about 4 to 5 cm, with abrupt relaxation. The cycle is carried out at a rate of about 100 compressions per minute. In the 2005 modification of guidelines for emergency cardiac care, the integration of respiratory and compression actions was changed to a compression-ventilation ratio of 30 : 2 for single responders to victims from infancy (excluding newborns) through adulthood, and two responders for adults. For two-rescuer CPR for infants and children, the former compression-ventilation ratio of 15 : 2 was retained. Another recently suggested modification, which is intended to encourage more bystander CPR by untrained or remotely trained bystanders who lack confidence, is the "hands-only" (cardiac-only, compression-only) technique, which uses 200 successive compressions without interruption. This variation, which may be more effective than compression-ventilation sequences, also allays concerns about bystander mouth-to-mouth ventilation of unknown victims in the absence of mechanical airway devices.

Automated External Defibrillators—Intermediate Life Support

Because time to defibrillation is the major determinant of survival, despite any temporizing benefit of BLS, and because ACLS strategies are generally implemented by in-hospital personnel or out-of-hospital emergency medical rescue system responders, an intermediate strategy has emerged that is based on the availability of automated external defibrillators (AEDs) for use by nonconventional first responders. Referred to as public access defibrillation or lay first-responder systems, the strategy relies on devices that prompt the user to deliver a defibrillation shock when deemed appropriate by a computerized rhythm detection system in the device. The operators can be trained police officers, security guards, airline personnel, or trained (or even untrained) lay responders (Table 63-1). A number of studies have suggested improved survival rates when such strategies are deployed in public sites, but an initial study of a home deployment strategy was disappointing.■ Further study is warranted because most out-of-hospital cardiac arrests occur at home. AED programs are not a replacement for ACLS (see later), but rather an intermediate supplement to the BLS-ACLS sequence that is intended to attempt earlier defibrillation while awaiting the arrival of ACLS-trained emergency rescue personnel.

Advanced Cardiac Life Support

ACLS methods, other than those directly related to control of tachyarrhythmias, have led to the generation of comprehensive protocols to guide responders over a broad expanse of clinical circumstances and mechanisms of cardiac arrest ranging from transient clinical events to end-stage multisystem disease. The general goals of ACLS are to restore a hemodynamically effective cardiac rhythm, optimize ventilation, and maintain and support the restored circulation. During ACLS, the patient's cardiac rhythm is promptly cardioverted or defibrillated as the first priority, if appropriate equipment is immediately available. If cardiac arrest has lasted for 4 to 5 minutes before the availability of a defibrillator, a short period of closed-chest cardiac compression immediately before defibrillation increases the probability of survival.■ Additional survival benefit has not been observed for delays greater than 10 minutes.

After the initial attempt to restore a hemodynamically effective rhythm, the patient is intubated and oxygenated, if needed, and the heart is paced if a bradyarrhythmia or asystole occurs. An intravenous line is established to deliver medications. After intubation, the goal of ventilation is to reverse hypoxemia and not merely to achieve a high alveolar P_{O_2}. When available, oxygen rather than room air should be used to ventilate the patient, and arterial O_2 saturation should be monitored, when possible. In the out-of-hospital setting, a face mask or an Ambu bag by means of an endotracheal tube is generally used.

TABLE 63-1 AUTOMATED EXTERNAL DEFIBRILLATOR STRATEGIES FOR RAPID RESPONSE TO CARDIAC ARRESTS CAUSED BY VENTRICULAR FIBRILLATION

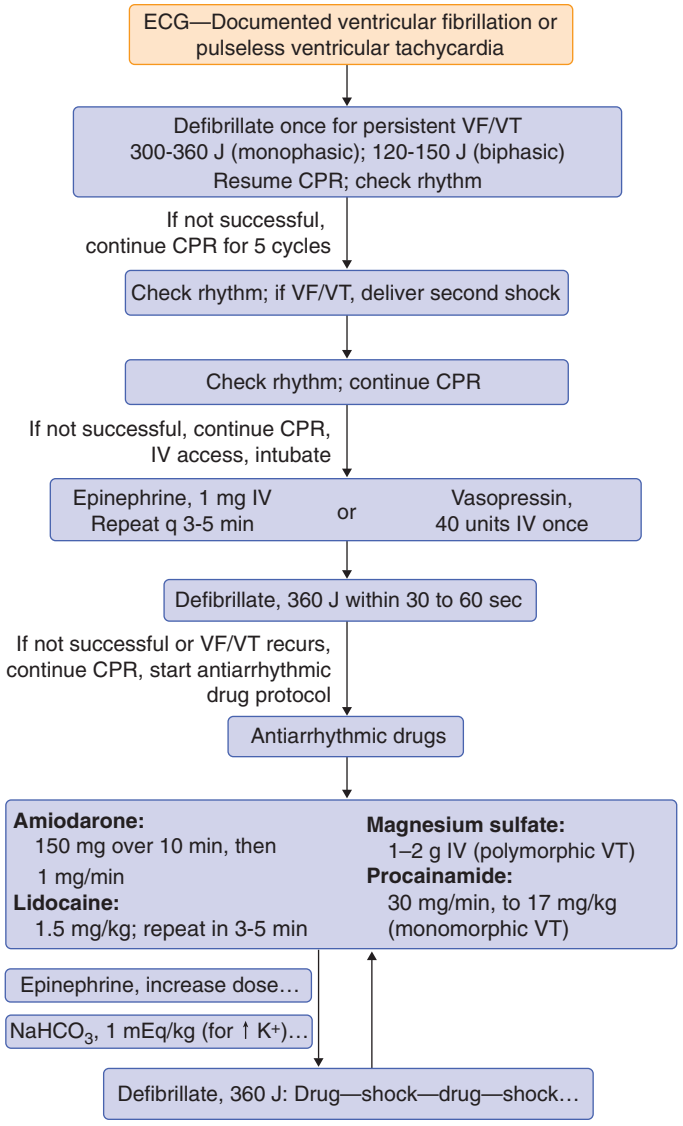

FIGURE 63-2. General algorithm for advanced cardiac life support (ACLS) response to ventricular fibrillation (VF) or pulseless ventricular tachycardia (VT). For more detail, see the ACLS guidelines in Suggested Readings. *Note:* In a 2008 advisory, 200 compression-only sequences were suggested as an alternative to standard CPR cycles between shocks, and this approach is under consideration for future guidelines. CPR = cardiopulmonary resuscitation; ECG = electrocardiogram.

MANAGEMENT OF TACHYARRHYTHMIC CARDIAC ARRESTS

Direct Current Cardioversion

When VF or a rapid VT is identified on a monitor or by telemetry, defibrillation should be performed immediately (Fig. 63-2). When a reversible cause, such as an acute ischemic syndrome or electrolyte disturbance, is the mechanism, normal rhythm can be successfully restored in up to 90% of VF victims weighing up to 90 kg with a DC monophasic shock of up to 360 J, or a with a biphasic shock of up to 200 J, delivered within 2 to 3 minutes. Failure of the initial shock to restore an effective rhythm is a poor prognostic sign. Although some algorithms suggest a succession of monophasic shock energies from 200 to 360 J, or biphasic waveforms from 100 to 200 Joules, during a sequence of attempts to defibrillate, there is little to be gained from beginning with energies less than 300 J monophasic or less than 150 J biphasic during a cardiac arrest response.

After a single shock at 300 or 360 J of monophasic energy, or 150 or 200 J biphasic, the patient should be checked for restoration of a spontaneous pulse; CPR should be continued for five cycles if a pulse remains absent. Subsequently, a second shock should be delivered, followed by epinephrine, 1 mg intravenously (IV). If a pulse is still absent, CPR is repeated for five cycles before the next shock. Epinephrine may be repeated at 3- to 5-minute intervals with defibrillator shocks in between, but high-dose epinephrine does not appear to provide added benefit. Vasopressin, 40 U given IV once, is an equally good alternative to epinephrine,[4] but the combination does not appear to be better than either one alone.[5]

This algorithm is based on the 2005 update. In a 2008 advisory, use of 200 compression-only sequences was suggested as an alternative to standard CPR cycles between shocks.

Pharmacotherapy for Resistant Arrhythmias

For a patient who continues in VF or pulseless VT despite multiple attempts at DC cardioversion after epinephrine, or who has recurrent episodes of VF or VT after cardioversion, electrical stability may be achieved by administering intravenous antiarrhythmic agents while continuing resuscitative efforts (see Fig. 63-2). Amiodarone (150 mg IV over a 10-minute period, followed by 1 mg/minute for up to 6 hours and 0.5 mg/minute thereafter) is the initial treatment of choice.[6] Additional bolus dosing, to a maximum of 500 mg, can be tried if the initial bolus is unsuccessful. Amiodarone need not be given as a routine to individuals who respond to initial defibrillation with a persistently stable rhythm, but it is preferred for those who have recurrent episodes of VT or VF after initial defibrillation and oxygenation.

If there is sufficient clinical evidence that the cardiac arrest was heralded by the onset of an acute coronary syndrome, lidocaine (1.0- to 1.5-mg/kg bolus given IV, with the dose repeated in 2 minutes) may be used instead of amiodarone, or if amiodarone has failed. When acute or intermittent ischemia is not thought to be the mechanism, intravenous amiodarone is the preferred initial drug, but lidocaine may be tried if amiodarone fails. Intravenous procainamide (loading infusion of 100 mg/5 minutes to a total dose of 500 to 800 mg, followed by a continuous infusion at 2 to 5 mg/minute) is now rarely used but may be tried in those with persisting, hemodynamically unstable arrhythmias.

In patients with acute hyperkalemia as the triggering event for resistant VF, hypocalcemia, or arrest potentially caused by excess doses of calcium-blocking drugs, 10% calcium gluconate (5 to 20 mL infused at a rate of 2 to 4 mL/minute) may be helpful. Otherwise, calcium should not be used routinely during resuscitation, even though ionized Ca^{2+} levels may be low during resuscitation from cardiac arrest.

Some resistant forms of polymorphic VT *(torsades de pointes),* rapid monomorphic VT, ventricular flutter (rate > 260/minute), or resistant VF respond to $MgSO_4$ (1 to 2 g IV given over a 1- to 2-minute period) or to β-blocker therapy (propranolol, 1-mg boluses IV to a total dose of up to 15 to 20 mg; or metoprolol, 5 mg IV, up to 20 mg). $MgSO_4$ is specifically indicated for polymorphic VTs due to inherited or acquired (drug-induced) long QT patterns (Chapter 65). This VT pattern also occurs with marked hypokalemia, so 20 mEq/hour of intravenous potassium chloride should be included in the treatment of patients who have a serum K^+ of less than 3 mEq/L and whose polymorphic VT is resistant to other therapies. However, hypokalemia also may follow the acid-base and electrolyte shifts associated with prolonged arrests and should not be considered a primary cause of the cardiac arrest in that circumstance.

MANAGEMENT OF CARDIAC ARREST CAUSED BY ASYSTOLE, BRADYARRHYTHMIAS, OR PULSELESS ELECTRICAL ACTIVITY

The approach to a patient with bradyarrhythmic or asystolic arrest or with pulseless electrical activity differs from the approach to patients with tachyarrhythmic events (VT/VF). Once this form of cardiac arrest is recognized, efforts should focus on first establishing control of the patient's cardiorespiratory status (i.e., continue CPR, intubate, and establish intravenous access), then reconfirming the rhythm (in two leads if possible), and finally taking actions that favor the emergence of a stable spontaneous rhythm or attempt to pace the heart. Possible reversible causes, particularly for bradyarrhythmia and asystole, should be considered and excluded (or treated) promptly (Fig. 63-3), including hypovolemia, hypoxia, cardiac tamponade, tension pneumothorax, preexisting acidosis, drug overdose, hypothermia, and hyperkalemia. Epinephrine (1.0 mg IV every 3 to 5 minutes) and atropine (1.0 to 2.0 mg IV) or isoproterenol (up to 15 to 20 µg/minute IV), which are commonly used in an attempt to elicit spontaneous electrical activity or increase the rate of a bradycardia, have only limited success. In the absence of an intravenous line, epinephrine (1 mg, i.e., 10 mL of a 1 : 10,000 solution) may be given by the intracardiac route, but there is danger of coronary or myocardial laceration. Sodium bicarbonate, 1 mEq/kg, may be tried for known or

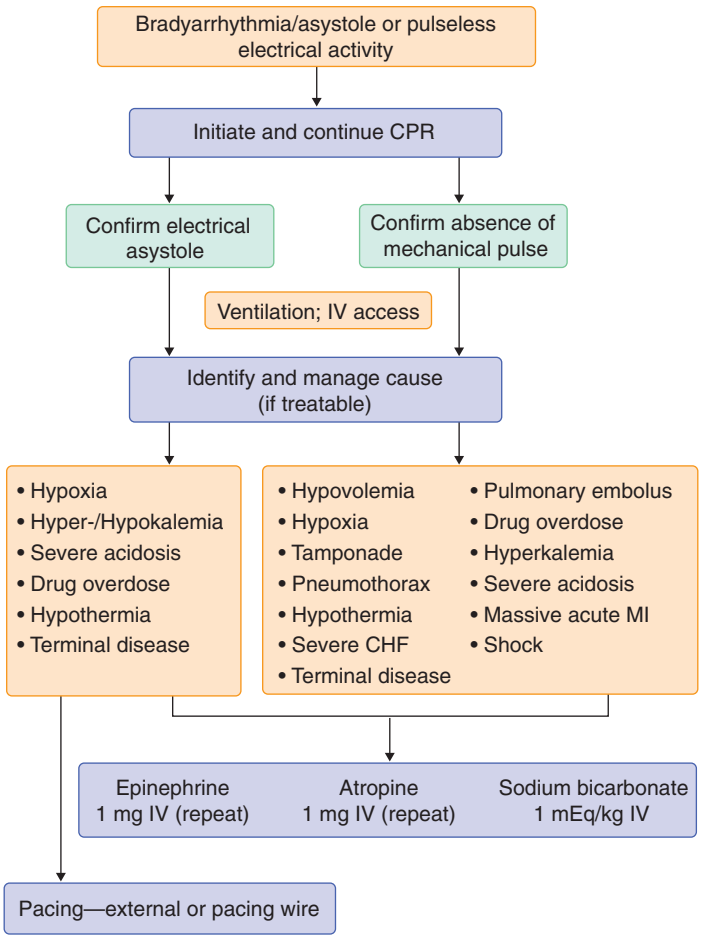

FIGURE 63-3. General algorithm for advanced cardiac life support response to bradycardic or asystolic cardiac arrest or pulseless electrical activity. For more detail, see Suggested Readings. CHF = congestive heart failure; CPR = cardiopulmonary resuscitation; MI = myocardial infarction.

strongly suspected preexisting hyperkalemia or bicarbonate-responsive acidosis.

External pacing systems (Chapter 66) should be used for out-of-hospital bradycardic or asystolic arrest, although its influence on outcome is not well documented. In the hospital setting, external pacing is generally used during the initial response to a bradycardic or asystolic arrest, but it should be superseded by transvenous pacing if the arrest is prolonged, if continuous pacing is needed, or if the external device fails to pace. Unfortunately, an *asystolic* patient continues to have a very poor prognosis despite available techniques.

ADJUNCTIVE THERAPEUTIC ACTIONS

During or after therapy targeted to restoration of an electrically stable cardiac rhythm, the patient's general metabolic state should be addressed by improving oxygenation and reversing acidosis. Intravenous sodium bicarbonate (1 mEq/kg), with up to 50% of this dose repeated every 10 to 15 minutes during the course of CPR, is recommended for patients with known or suspected preexisting bicarbonate-responsive causes of acidosis, for certain drug overdoses (Chapter 110), and after prolonged and unsuccessful attempts at resuscitation. Caution must be exercised, however, because excessive quantities of sodium bicarbonate can be deleterious by causing alkalosis, hypernatremia, and hyperosmolality. When possible, arterial pH, Po_2, and Pco_2 should be monitored during the resuscitation. In addition, moderate therapeutic hypothermia (32° to 34° C) is now recommended for post–cardiac arrest improvement of cerebral function and of survival■ as part of the concept of "cardiocerebral resuscitation."

LONG-TERM MANAGEMENT

Survivors of a cardiac arrest that is not due to transient factors remain at high risk for recurrent cardiac arrest and sudden cardiac death. An implantable defibrillator improves outcomes in survivors of cardiac arrest.■

CARDIAC ARRHYTHMIAS WITH SUPRAVENTRICULAR ORIGIN

PETER ZIMETBAUM

Supraventricular arrhythmias are divided into bradyarrhythmias and tachyarrhythmias. Any rhythm that originates above where the His bundle bifurcates into the right and left bundle branches is considered to be supraventricular in origin.

ANATOMY AND NORMAL ELECTROPHYSIOLOGY

The normal cardiac impulse begins in the sinus node complex, which is located at the junction of the right atrium and the superior vena cava. It then travels through the right atrium and primarily activates the left atrium through the coronary sinus. The time it takes to activate the atria is represented by the P wave on the electrocardiogram (ECG). After depolarizing the atria, the impulse enters the atrioventricular (AV) node, which is located in the inferior septal region of the right atrium, where a delay occurs. This delay allows time for the atria to contract and fill the ventricles. In most individuals, the impulse travels through the AV node over a uniform functional pathway or route. Some people have two or more functional pathways called dual AV nodal pathways (fast and slow pathways). The delay in the AV node represents most of the isoelectric portion of the PR interval on the ECG (E-Fig. 64-1). The usual duration of atrial activation including delay in the AV node is up to 140 msec and can be measured directly as the atrial-His interval. The impulse then travels into the specialized infranodal conducting system, i.e., through the His bundle, then right and left bundle branches, and into the Purkinje network. The Purkinje network extends or fans out throughout the ventricular endocardium. Impulses conduct rapidly through the Purkinje network, thereby allowing nearly simultaneous activation of the ventricles. A small portion of the isoelectric segment of the PR interval represents infranodal conduction. This infranodal conduction through the His-Purkinje system can also be

measured directly (His-ventricle interval) and should take between 40 and 60 msec. Once out of the Purkinje network, the impulse proceeds relatively slowly from the endocardial to epicardial surface of the ventricles. The QRS complex on ECG represents depolarization of the bundle branches and ventricular myocardium. Patients who have ventricular preexcitation activate the ventricles through an alternative route to the normal ventricular conduction system. These patients have bypass tracts or accessory pathways over which the ventricular myocardium can be activated directly rather than traveling over the AV node and His-Purkinje network. These pathways, which develop as a failure of the normal fibrous separation of the atria and ventricles, are located in proximity to the tricuspid and mitral valves. Direct activation of the ventricular myocardium without the usual delay in the AV node results in a slurred upstroke of the QRS complex called a delta (δ) wave (E-Fig. 64-2).

The normal heart rate is generated by tissues or pacemaker cells with intrinsic automaticity. The sinus node cells produce the greatest rate (60 to 100 beats/minute) of automaticity and suppress other potentially automatic (AV junctional, 40 to 55 beats/minute; His-Purkinje cells, 15 to 40 beats/minute) tissues with slower rates of depolarization. The sinus node and AV node are heavily influenced by the parasympathetic (vagal) and sympathetic (adrenergic) nervous system. At rest, the parasympathetic system controls sinus node automaticity. With exertion or emotional or physical stress, a withdrawal of parasympathetic tone and an increase in heart rate, which is then perpetuated by sympathetic tone, further increase heart rate. Sinus arrhythmia refers to the normal variation in heart rate with inspiration and expiration. With inspiration, a withdrawal of vagal tone increases heart rate; by comparison, expiration is associated with a drop in heart rate (Fig. 64-1). During sleep, a dominance of vagal tone slows heart rate.

BRADYARRHYTHMIAS

Bradyarrhythmias may be caused by sinus node, AV node, or His-Purkinje dysfunction (Table 64-1).

Sinus Bradycardia and Sinus Node Dysfunction

Sinus bradycardia (Fig. 64-2) is generally defined as a sinus rate of less than 60 beats per minute. It should be noted, however, that sinus rates as low as 45 to 50 beats per minute, particularly at rest, can be physiologically normal. Sinus node dysfunction encompasses a group of disorders including sinus bradycardia, sinoatrial (SA) exit block, sinus arrest (pause of >2 to 3 seconds) during sinus rhythm, chronotropic incompetence, and tachycardia-bradycardia (tachy-brady) syndrome. Sinus node dysfunction in combination with symptoms such as fatigue, dizziness, near or complete syncope (Chapters 50 and 62), or worsening of heart failure (Chapter 58) is called sick sinus syndrome. The tachy-brady syndrome is often identified by a prolonged delay in sinus node recovery following the termination of atrial fibrillation (AF) (Fig. 64-3). SA exit block refers to the electrophysiologic phenomenon of sinus node firing with delay or block of the impulse as it travels from the sinus node to the surrounding atrial tissue (Fig. 64-4). SA exit block can be first degree, second degree (type 1 or 2), and third degree. First-degree SA block is difficult to diagnose from the surface ECG. Second-degree SA exit block type 1 is manifest by progressive PP shortening preceding the sinus pause. The PP interval following the pause must be greater than twice the PP interval that preceded the pause. Second-degree SA exit block type 2 is characterized by a pause equaling an exact multiple of the sinus rate (i.e., constant PP interval before and after the pause). High-degree SA exit block refers to the absence of multiple P waves with a pause still corresponding to an absolute multiple of the underlying PP intervals, and third-degree AV block results in a complete absence of sinus P waves.

Chronotropic incompetence refers to the inability to increase the sinus rate appropriately in response to exercise or other physiologic demand. In most patients, chronotropic incompetence is manifest by a maximal heart rate of less than 100 beats per minute.

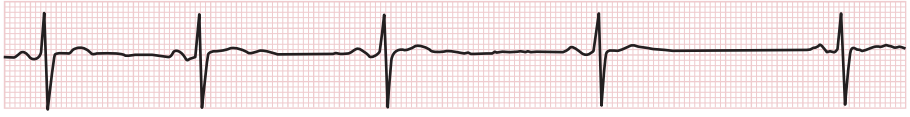

FIGURE 64-2. Sinus bradycardia. Progressive sinus bradycardia—in this case related to heightened vagal tone while sleeping.

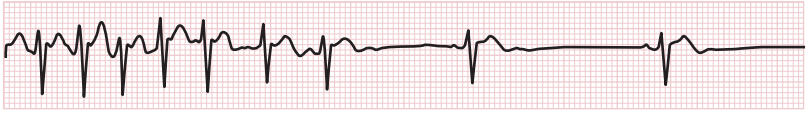

FIGURE 64-3. Electrocardiographic evidence of tachy-brady syndrome. Atrial fibrillation with a tachycardic ventricular response followed by conversion to sinus bradycardia.

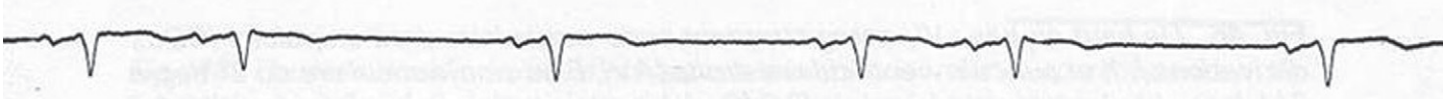

FIGURE 64-4. Sinoatrial block. Sinoatrial exit block, probably type 2, is characterized by a pause equaling an exact multiple of the sinus rate.

FIGURE 64-5. First-degree atrioventricular (AV) block. Note the prolonged (>200 msec) AV conduction.

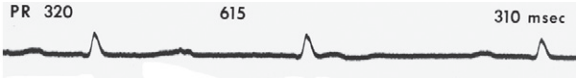

FIGURE 64-6. Mobitz I block. Progressive PR prolongation from 320 to 615 msec, followed by a blocked P wave. The subsequent conducted PR interval is less than the PR interval before the dropped P wave.

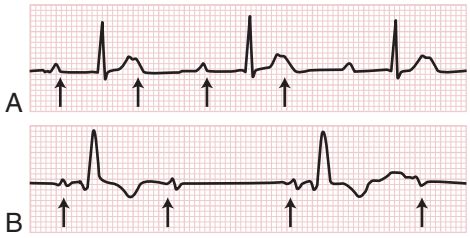

FIGURE 64-7. Two-to-one conduction in the atrioventricular (AV) node and below the AV node. A, Two-to-one conduction, with the conducted beats demonstrating a prolonged PR interval (>300 msec) and a narrow QRS, indicating Mobitz I block in the AV node. **B,** Normal-duration conducted PR interval and a wide QRS duration favoring Mobitz II block into an infranodal site of block.

Atrioventricular Conduction Disturbances

AV conduction disturbances refer to abnormal conduction in the AV node or in the His-Purkinje system (HPS) below the AV node. Electrical transmission through the AV conduction system is primarily limited by the AV node, which conducts in a decremental fashion to prevent excessively rapid conduction to the ventricles. The normal AV node rarely conducts faster than 200 beats per minute and slows with aging. The AV node is heavily influenced by autonomic tone and may conduct more than 200 beats per minute in the presence of heightened sympathetic and withdrawal of parasympathetic tone. Conduction through the HPS system is faster and nondecremental.

The AV blocks are classified as first, second, high, and third degree. First-degree AV block is a misnomer because nothing is actually blocked—rather, there is delay, usually in the AV node, manifest by a prolonged PR interval (Fig. 64-5). Second-degree AV block is divided into Mobitz type I (Wenckebach) or Mobitz type II. Mobitz type I is defined by progressive PR prolongation with eventual block after a P wave (Fig. 64-6). The initial PR prolongation is longest, the subsequent RR intervals shorten, and the PR interval following the blocked P wave is shorter than the last conducted PR interval before the blocked P wave. Mobitz type I usually occurs in the AV node. Mobitz type II, which is characterized by the abrupt failure of conduction after a P wave without preceding PR prolongation, usually represents conduction disease below the AV node. In patients with 2 : 1 block (two P waves for every QRS), it can be difficult to determine whether the block is Mobitz I in the AV node or Mobitz II below the AV node. Clues to conduction disease in the AV node include a prolonged PR interval (i.e., more than 300 msec) and a narrow QRS duration. Clues to conduction disease below the node include a normal PR interval but with bundle branch block (Fig. 64-7).

High-degree or advanced AV block, which is a form of second-degree block with multiple or successive nonconducted P waves, or both (Fig. 64-8), frequently recurs or persists. Third-degree block (or complete heart block) refers to a rhythm in which the atrial and ventricular activity occur independently, and the atrial rate usually exceeds the ventricular rate. Third-degree heart block can be seen with sinus rhythm or any atrial tachyarrhythmia with a regular escape rhythm in the AV junction or below (Fig. 64-9). Sometimes there is no escape rhythm, and heart block results in asystole. Complete heart block, particularly when it is acute and accompanied by an escape rhythm, can be associated with marked QT prolongation, which signifies a risk of torsades de pointes (Chapter 65). For this reason, patients who undergo AV node ablation have their pacemakers set at 80 beats per minute for at least 6 weeks after the procedure to prevent QT prolongation and torsades de pointes. Eventually, the pacing rate can be reduced to more physiologic levels without the ongoing risk of ventricular arrhythmia. Complete heart block and other types of severe bradyarrhythmia may present with syncope if there is a prolonged pause before an escape rhythm develops. More often, these rhythms present with fatigue and dyspnea. The blood pressure is often elevated owing to peripheral vasoconstriction, and there may be renal insufficiency secondary to reduced cardiac output.

The term AV dissociation refers to any rhythm in which the atria and ventricles beat independently of one another. If the atrial rate is faster than the ventricular rate, it is called complete heart block or third-degree AV block. AV dissociation with an atrial rate slower than the subsidiary pacemaker is usually seen with junctional or ventricular tachycardias.

CLINICAL MANIFESTATIONS

Sinus bradycardia and various degrees of AV nodal blocks can occur asymptomatically during sleep in healthy individuals. Asymptomatic first- and second-degree AV block, particularly when partially or completely reversed by exercise, is usually benign. Persistent second-degree and third-degree AV nodal block is abnormal and is often associated with dizziness, fatigue, exertional dyspnea, worsening of heart failure, near-syncope, or syncope. Third-degree AV block with a good junctional escape mechanism that accelerates during exercise, as often noted in patients with congenital AV block, may remain asymptomatic. Patients with congenital heart block may not appreciate their potential for a more active lifestyle because of the lack of a reference point but often feel much better when an appropriate heart rate acceleration can be achieved after pacemaker therapy.

DIAGNOSIS

Bradycardias are typically diagnosed by the ECG. In symptomatic patients with symptoms suggestive of bradyarrhythmia, 24-hour Holter monitoring or prolonged loop monitoring usually can make the diagnosis, but some patients may require formal electrophysiologic testing (Chapter 62). Any bradycardias, including sinus node dysfunction (Table 64-2) and AV nodal block (Table 64-3), can be caused at least in part by vagal influences, such as vasovagal episodes, vomiting, abdominal surgery, and upper and lower gastrointestinal invasive procedures. Syncope, sometimes caused by the bradycardia and sometimes by vasodepression with hypotension, may result (Chapters 50 and 62). Medications, infiltrative diseases, fibrocalcific degeneration, and a variety of other causes must be considered.

TREATMENT Rx

The treatment of sinus node dysfunction and AV blocks consists of first removing any medications that may precipitate dysfunction (see Table 64-2). Although some patients will recover normal conduction, the susceptibility to medications usually indicates an underlying conduction abnormality that may worsen over time.

Asymptomatic sinus node dysfunction requires no therapy. Asymptomatic atrioventricular nodal block can also be managed without intervention unless the QT interval is markedly prolonged, in which case a pacemaker should be considered. For symptomatic sinus node dysfunction and second- and third-degree AV block, acute management includes intravenous atropine (1 mg) or isoproterenol (usually 1 to 2 μ/minute infusion) to increase the heart rate. Temporary cardiac pacing (Chapter 66) may be required. If sinus node dysfunction or AV block is due to transient abnormalities, such as drug-induced or acute ischemic syndromes, temporary pacing is usually sufficient; however, when infra-His or intra-His block is suspected (e.g., exercise-induced AV block or asymptomatic Mobitz type II block) and the site can be documented with His bundle recording, permanent pacing (see Tables 66-1 and 66-2 in Chapter 66) is the only effective chronic therapy, and consensus recommendations for pacemaker implantation should guide its use. For all forms of persistent symptomatic sinus node dysfunction or second- or third-degree AV block, permanent pacing is the therapy of choice (Chapter 66).

FIGURE 64-8. High-degree atrioventricular block. Periods of complete heart block with three nonconducted P waves (the first of which is buried in the first QRS complex) followed by two P waves, the second of which is conducted to the ventricle with a long PR interval. The subsequent three P waves are once again nonconducted, with the last P wave buried in the last QRS complex.

Corrected transposition of the great vessels
Chagas' disease
Some neurologic conditions (especially myotonic dystrophy)
Drugs as in Table 64-2

Supraventricular Rhythms with a Normal Rate

Atrial premature beats (APBs) can arise from the right or left atrium or the pulmonary veins. The P wave, which differs from the P wave of sinus rhythm unless the APB originates near the sinus node, always precedes the QRS complex (Fig. 64-10). If the P wave is blocked, however, it is not followed by a QRS complex. A blocked premature atrial contraction may be confused with second-degree AV block, unless its prematurity is recognized, or with sinus node dysfunction, if it is inconspicuous. Altered appearance of the ST-T segment is often a clue to the presence of a P wave. A premature QRS complex with the morphology of the underlying sinus rhythm in the absence of a premature P wave represents an AV junctional beat (Fig. 64-11).

An ectopic atrial rhythm refers to a nonsinus atrial rhythm from a single focus with a single P wave morphology (Fig. 64-12). Wandering atrial pacemaker refers to an ectopic atrial rhythm with at least three distinct P wave morphologies at rates between 50 and 100 beats per minute (Fig. 64-13).

FIGURE 64-10. Atrial premature beat. Sinus rhythm with an atrial premature beat as the third complex in the rhythm strip. The P wave is buried in the preceding T wave.

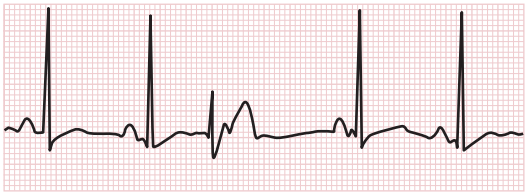

FIGURE 64-11. Junctional premature beat. The premature beat is narrow but slightly different in morphology compared with the surrounding sinus beats. This premature beat is from the atrioventricular junction or slightly more distal in the fascicles. The inverted P wave following the QRS represents retrograde activation of the atria.

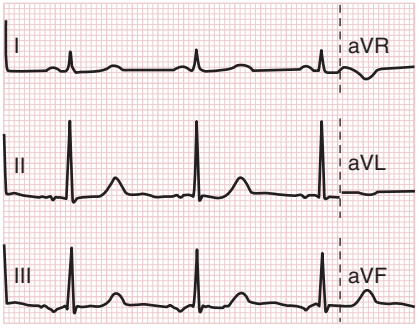

FIGURE 64-12. Ectopic atrial rhythm. The inverted P waves in leads II, III, and aVF indicate a nonsinus P wave originating in the low right atrium.

FIGURE 64-13. Wandering atrial pacemaker. Rhythm with three distinct P wave morphologies.

CLINICAL MANIFESTATIONS

APBs are most often asymptomatic but can occasionally be experienced as palpitations (Chapter 62). Similarly, ectopic atrial rhythms, including a wandering atrial pacemaker, are virtually always asymptomatic. Rarely, ectopic atrial rhythm can be very slow and associated with symptoms of fatigue.

DIAGNOSIS

The diagnosis of atrial premature beats, ectopic atrial rhythms, and wandering atrial pacemakers are all made by ECG or on an ambulatory Holter monitor or loop event recorder (Chapter 62).

TREATMENT

Rx

Premature atrial contractions do not generally require treatment unless they are associated with significant symptoms. Treatment consists primarily of β-blockers (e.g., atenolol, 25 to 100 mg daily) or calcium-channel blockers (e.g., long-acting diltiazem, 180 to 300 mg daily). Ectopic atrial rhythms and wandering atrial pacemakers are rarely symptomatic and are not treated with medications. Rarely, a slow ectopic rhythm associated with fatigue can be treated with atrial pacing at a rate faster than the ectopic atrial rhythm.

Supraventricular Tachyarrhythmias

The supraventricular tachycardias (SVTs) are defined as arrhythmias with three or more beats at a rate of greater than 100 beats per minute (Table 64-4). The beats, which can be regular or irregular, are usually narrow complex but can be wide complex when associated with bundle branch block (aberration) or conduction over an accessory pathway. Atrial dilation, acute myocardial infarction, pulmonary embolism, acute or chronic inflammatory states, or scars from prior surgery involving atrial myocardium or pericardium are among the causes of atrial tachyarrhythmias.

TABLE 64-4 SUPRAVENTRICULAR TACHYCARDIAS

	R-R REGULARITY	P WAVE MORPHOLOGY
ATRIAL TACHYCARDIAS		
Sinus tachycardia	Regular	Positive in II, III, aVF; negative in aVR
Sinus node re-entry	Regular	Positive in II, III, aVF; negative in aVR
Atrial tachycardia, unifocal	Regular	P different from sinus
Atrial tachycardia, multifocal	Irregular	Three or more different P wave morphologies
Atrial flutter, common, counterclockwise	Regular; irregular if variable AV block	Sawtooth flutter waves; regular waveform; negative in II, III, aVF, positive in V_1, negative in V_6
Clockwise		Positive in II, III, aVF; negative in V_1; positive in V_6
Atrial flutter, uncommon	Regular; irregular if variable AV block	Pattern different than common atrial flutter (counterclockwise or clockwise)
Atrial fibrillation	Irregularly irregular	Irregular fibrillation waves
AV JUNCTIONAL TACHYCARDIAS		
AV re-entry (using accessory pathways)		
Orthodromic	Regular	Retrograde P in ST-T wave
Antidromic	Regular preexcited	Retrograde P, short RP
Slow conducting	Regular	Retrograde P at end of T wave or later (long RP)
Atriofascicular (antidromic)	Regular preexcited	Retrograde P, short RP
AV nodal re-entry		
Common (slow-fast)	Regular	Retrograde P obscured by QRS or alters the end of QRS (short RP)
Uncommon (fast-slow)	Regular	Retrograde P at end of T wave or later (long RP)
Others (slow-slow)	Regular	PR-RP approximately equal
Nonparoxysmal junctional tachycardia*	Regular, slow rate	AV dissociation
Automatic junctional tachycardia*	Regular	AV dissociation

*Site of origin usually infranodal.
AV = atrioventricular.

Sinus Tachycardia

Sinus tachycardia (Fig. 64-14) is an arrhythmia that is almost always a physiologic response to an emotional or physical stress such as anxiety, exercise, anemia, hypotension, hypoxemia, fever, thyrotoxicosis, or heart failure. It is characterized by a gradual increase and decrease in heart rate and rarely exceeds 180 beats per minute. In rare cases, it may be a nonphysiologic condition called inappropriate sinus tachycardia, which is characterized by sinus tachycardia that develops in response to minimal stress and that continues beyond the time when the normal response would have slowed. This disorder is difficult to manage but is sometimes responsive to β-blockade.

Sinus node re-entry is a rare form of SVT caused by re-entry in the sinus node. As opposed to physiologic ST, it begins abruptly, is often triggered by a premature atrial beat, and ends abruptly. The P wave morphology is identical to sinus rhythm, and β-blockers are the treatment of choice if required for symptoms.

Atrial Tachycardia

The term atrial tachycardia refers to a group of SVTs that originate from focal anatomic locations in the atria and propagate in a centrifugal pattern (Fig. 64-15). These locations include the pulmonary veins, crista terminalis in the right atrium, tricuspid or mitral annulus, coronary sinus, or regions of scar tissue from previous cardiac surgery. Atrial tachycardias, which are usually regular rhythms that rarely exceed 200 beats per minute, may present in young age but more often develop later in life. Atrial tachycardias can be re-entrant, triggered, or automatic in mechanism. Some forms of atrial tachycardia are incessant and can predispose to a tachycardia-related cardiomyopathy (Chapter 60). Other forms of atrial tachycardia are paroxysmal and may remit spontaneously without treatment. When persistent, atrial tachycardias can be managed with medications (calcium-channel or β-blockers or other antiarrhythmic drugs). Electrical mapping and ablation (Chapter 66) of atrial

FIGURE 64-14. Sinus tachycardia at 120 beats/min.

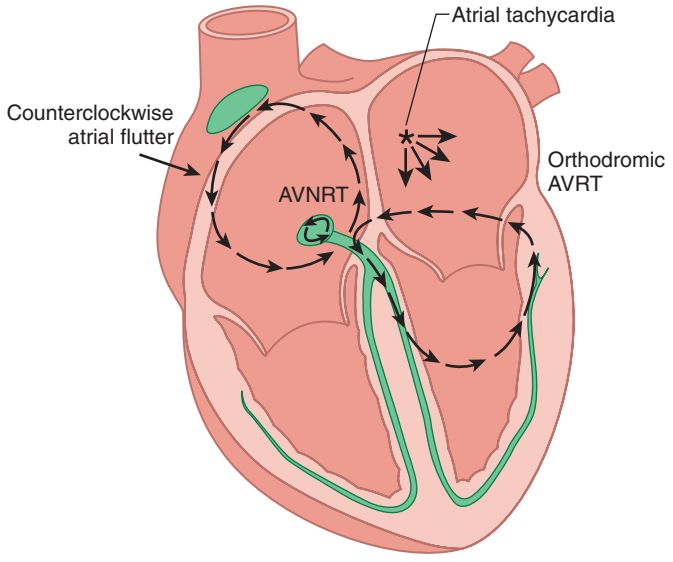

FIGURE 64-15. Diagram of the site and mechanism of common forms of supraventricular tachycardia. AVNRT = atrioventricular nodal re-entrant tachycardia; AVRT = atrioventricular re-entrant tachycardia.

tachycardia are highly effective and are increasingly offered as first-line therapy. Multifocal atrial tachycardia (Fig. 64-16), which is a unique form of atrial tachycardia characterized by three or more P wave morphologies, is distinguished from wandering atrial pacemaker when the rate is 100 beats per minute or more rather than less than 100 beats per minute. It is an irregular rhythm and occurs almost exclusively in patients with advanced pulmonary disease.

Atrioventricular Nodal Re-entrant Tachycardia

Atrioventricular nodal re-entrant tachycardia (AVNRT), which is a common form of SVT in all age groups, presents most often in young adulthood and frequently occurs after a change in position. It is more common in women than men and may develop or be exacerbated by pregnancy or certain phases of the menstrual cycle. Patients with AVNRT have two functional AV nodal pathways (dual pathways). Typically, an atrial premature beat blocks in one pathway (fast pathway) and conducts slowly over the other pathway (slow pathway). If this beat conducts back up the fast pathway and then re-enters the slow pathway, AV nodal re-entry occurs (Fig. 64-17). This re-entrant circuit is confined to the AV node, and the result is that both the atria and ventricles are activated nearly simultaneously. P waves may not be visible on the ECG because they are buried in the QRS complex. When P waves are present, they usually are seen just after the QRS and have a negative or superior axis (negative in leads II, III, and aVF; short RP tachycardia) (see Fig. 64-15). Atypical AVNRT is rare and occurs with conduction down the fast pathway and up the slow pathway, with a long interval between the preceding R wave and subsequent negative P wave (e.g., long RP tachycardia).

Junctional Tachycardia

Junctional tachycardia refers to a focal (non-re-entrant) tachycardia originating in the AV junction (Fig. 64-18). A number of different forms of junctional tachycardia have differing clinical patterns. Nonparoxysmal junctional tachycardia is a benign arrhythmia that rarely exceeds 120 beats per minute and typically exhibits a "warm-up" and "cool-down" pattern. A more rapid paroxysmal form of junctional tachycardia occurs in young adults and is often associated with exercise. Congenital junctional ectopic tachycardia, which occurs in the pediatric population, is associated with very rapid rates and a risk of tachycardia-related cardiomyopathy.

Accessory Pathway Tachycardias

Tachycardias associated with an accessory pathway or bypass tract are called atrioventricular re-entrant tachycardia (AVRT). These tachycardias most often conduct down the normal AV conducting system and back up the accessory pathway (orthodromic AVRT) (see Fig. 64-15). Antidromic tachycardia is rare and represents conduction down the accessory pathway and back up the normal conducting system or less commonly, a second accessory pathway. Wolff-Parkinson-White syndrome is defined by the presence of delta waves or preexcitation on the ECG in sinus rhythm (Fig. 64-19), often with a

FIGURE 64-16. Multifocal atrial tachycardia. An atrial tachycardia with three different P wave morphologies.

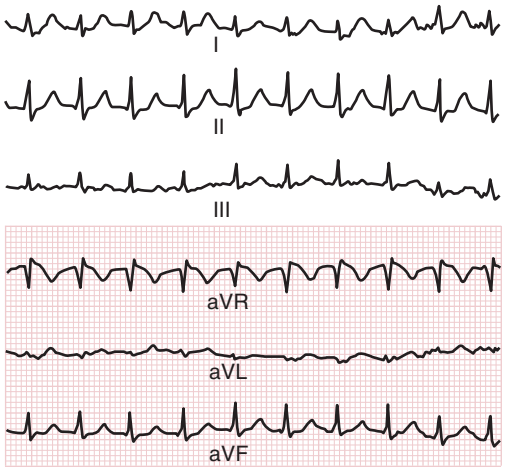

FIGURE 64-18. Junctional tachycardia. A tachycardia without evident P waves. The negative deflections at the end of leads II, III, and aVF represent retrograde P waves. This rhythm is impossible to distinguish from atrioventricular nodal re-entrant tachycardia on the surface electrocardiogram.

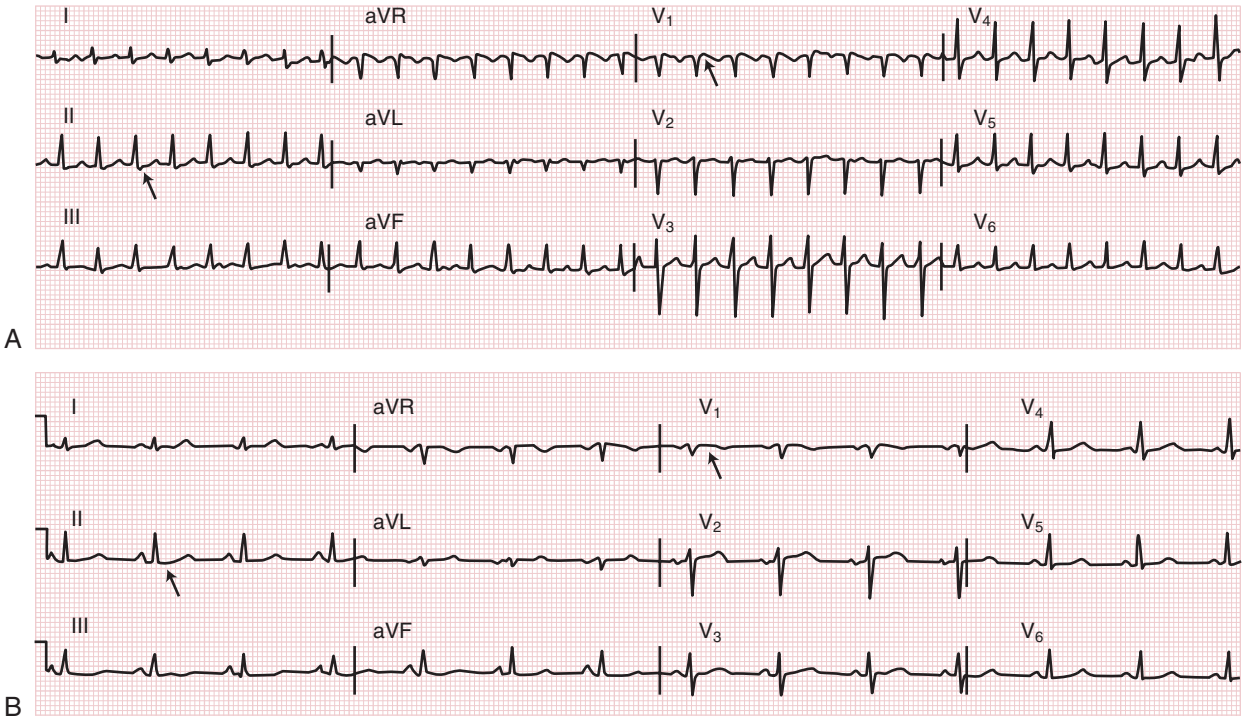

FIGURE 64-17. Electrocardiograms demonstrating different rhythms in the same patient. A, Atrioventricular nodal re-entrant tachycardia, with *arrows* indicating retrograde P waves (negative in lead II, positive in V_1). **B,** Same patient in sinus rhythm. The absence of a negative deflection at the end of the QRS in lead II and positive deflection in V_1 confirms that those findings in panel **A** were retrograde P waves.

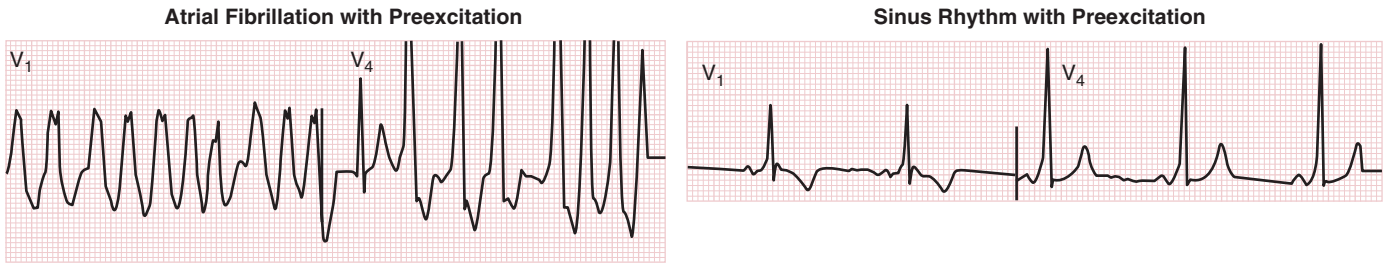

FIGURE 64-19. Two panels of the same patient with ventricular preexcitation. The rhythm on the left is fast, broad, and irregular, indicating atrial fibrillation with conduction over an accessory pathway. The rhythm on the right is sinus with conduction over an accessory pathway.

history of AVRT, but many patients with ventricular preexcitation never get AVRT. Up to 40% of patients with accessory pathways have AF. Because accessory pathway tissue, unlike the AV node, is usually nondecremental, a rapidly conducting accessory pathway may allow AF to conduct to the ventricles at excessive rates and precipitate ventricular fibrillation. Drugs like digoxin, which accelerate accessory pathway conduction, should be avoided in these patients.

The ECG during orthodromic AVRT can have a narrow complex, but a wide QRS complex will be seen if there is aberration from a bundle branch block, especially at more rapid rates. The retrograde P wave is negative in leads I and aVL if it conducts over a left lateral accessory pathway and negative in leads II, III, and aVF if it conducts over a septal or postural septal accessory pathway (Fig. 64-20). The P wave occurs later (after the preceding R wave) compared with AVNRT because in AVRT, the impulse must conduct beyond the AV node and into the ventricle before returning to the atria over an accessory pathway. In antidromic AVRT, the QRS complex is wide with a slurred upstroke and resembles that seen with ventricular tachycardia as opposed to a bundle branch block. Antidromic conduction with AF is often fast, broad, and irregular (see Fig. 64-19).

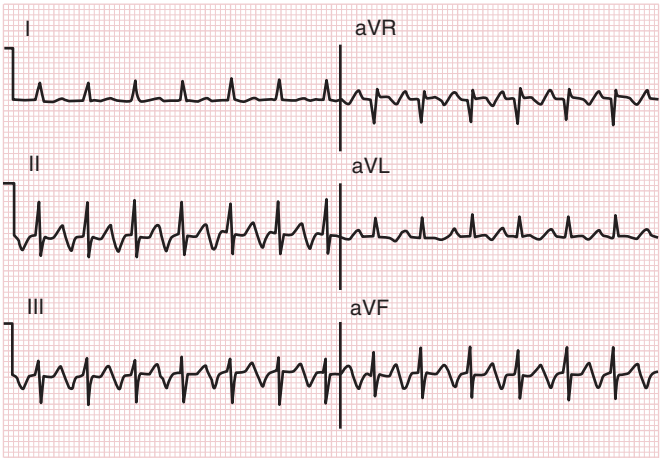

FIGURE 64-20. Atrioventricular re-entrant tachycardia. Negative P waves are seen in leads II, III, and aVF indicative of retrograde conduction to the atria over a septal accessory pathway.

Atrial Flutter

Atrial flutter is an arrhythmia with an atrial rate of approximately 300 beats per minute and a ventricular response of 150 (2:1), 100 (3:1), or slower multiples. Typical atrial flutter is a macro-re-entrant circuit that circulates in the right atrium in a clockwise or counterclockwise loop (Fig. 64-21). The inferior portion of typical flutter uses the narrow region between the inferior vena cava and tricuspid annulus as a critical isthmus of conduction. Typical atrial flutter almost always occurs in patients with underlying cardiovascular or pulmonary disease. It can also develop in patients who receive antiarrhythmic drugs (e.g., sodium-channel blocking drugs) for AF. Atypical atrial flutter refers to macro-re-entrant atrial circuits that do not use this critical cavotricuspid isthmus of tissue. These atypical forms of atrial flutter often occur in the left atrium after mitral valve surgery or catheter ablation of AF. Typical atrial flutter can be recognized by a "sawtooth" P wave morphology, which is predominantly negative in leads II, III, and aVF and positive in V_1 (counterclockwise atrial flutter) or positive in leads II, III, and aVF and negative in V_1 (clockwise atrial flutter).

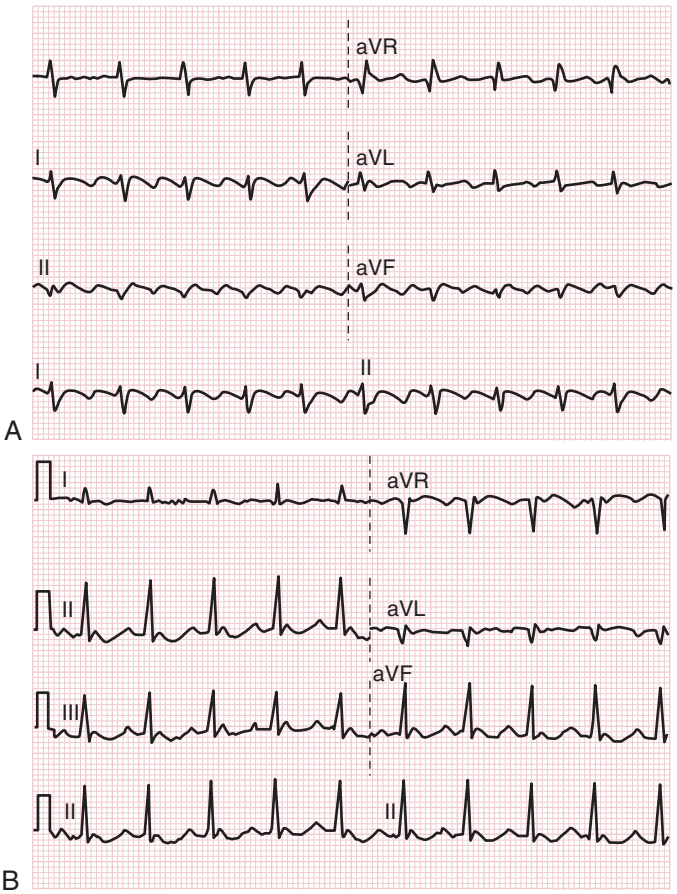

FIGURE 64-21. Two examples of atrial flutter. A, Typical counterclockwise right atrial flutter with classic sawtooth flutter waves seen in leads II, III, and aVF. **B,** Clockwise right atrial flutter.

Atrial Fibrillation

AF is identified by the absence of P waves and the presence of an irregularly irregular ventricular rate. Coarse AF, which describes the presence of residual atrial activity on the ECG, is generally best seen in lead V_1 with the absence of P wave–like activity in other leads (Fig. 64-22). AF can be present with a regular ventricular rate when there is concomitant AV dissociation (e.g., complete heart block or ventricular tachycardia).

AF, which is the most common arrhythmia in clinical practice, afflicts over two million Americans. The likelihood of developing AF increases with aging, with an anticipated three-fold increase in prevalence as the U.S. population ages in the next 20 years. AF is almost always a recurrent disorder with the possible exception of AF that develops in association with hyperthyroidism (Chapter 233) and surgery (Chapter 441). AF can be paroxysmal (terminates spontaneously) or persistent (persists for at least 7 days or until cardioverted). Paroxysmal AF can occur as self-remitting arrhythmia for decades or can progress to permanent AF. Patients with persistent AF generally progress to permanent AF unless sinus rhythm is restored with cardioversion.

In addition to its association with aging, AF frequently occurs in association with hypertension (Chapter 67) or other comorbid conditions such as

FIGURE 64-22. Coarse atrial fibrillation. The wavy baseline is suggestive of atrial activity and can be misinterpreted as P waves or flutter waves. The irregularity of the QRS complexes indicates that this is atrial fibrillation.

diabetes mellitus, thyrotoxicosis, heart failure, coronary artery disease, valvular heart disease, or lung disease such as chronic obstructive pulmonary disease or obstructive sleep apnea. About 20% of patients have no associated comorbidity and have what may be termed *lone AF*. Some patients develop AF after binges of alcohol use ("holiday heart") or after parasympathetic surges such as after vigorous exercise or a large meal (vagally induced AF). Excessive caffeine intake is an often cited but very rare cause of AF. AF requires a trigger in the form of atrial premature depolarizations, which often originate in the pulmonary veins and which, in the susceptible individual, result in AF. The susceptibility to AF may relate to changes in the electrical function of the left atrium. Prolonged periods of AF can lead to electrical and structural remodeling of the atria and promote the further perpetuation of AF ("AF begets AF").

AF results in the loss of the atrial contribution to ventricular filling. This so-called loss of atrial kick is generally well tolerated in normal individuals, in whom only about 15% of ventricular filling is the result of atrial contraction. In patients who have stiff, noncompliant ventricles (e.g., patients with aortic stenosis, hypertrophic or restrictive cardiomyopathy, or long-standing hypertension), however, up to 40% of ventricular filling may be related to atrial contraction, so stroke volume may fall noticeably in such patients.

The primary morbidity associated with AF is thromboembolism. Thromboembolism in patients with nonvalvular AF typically results from thrombus formation in and dislodgement from the left atrial appendage. The risk of thromboembolism is unrelated to the pattern of AF (paroxysmal or persistent) but is increased in the first 3 to 4 weeks after cardioversion, when the gradual return of atrial mechanical function can result in a particularly high risk of thromboembolism. The risk of thromboembolism in AF increases with age, diabetes mellitus, hypertension, previous embolic episodes, and heart failure. The lowest incidence (<1% annually) is in patients younger than 65 years with lone AF.

CLINICAL MANIFESTATIONS

SVTs can produce symptoms specifically related to the rhythm itself, including fatigue, palpitations (Chapter 62), dizziness, shortness of breath, chest discomfort, presyncope, and syncope. These symptoms are mostly related to the rapidity of the ventricular response and are most prevalent at the onset of the arrhythmia. In contrast to other forms of SVT, asymptomatic episodes of AF are common in patients who also have symptomatic AF.

Incessant SVT and uncontrolled ventricular rates can cause tachycardia-related cardiomyopathy, which is reversible with control of these arrhythmias. In some situations, however, the clinical presentation may be dominated by the underlying condition that precipitates the arrhythmia, such as fever, physical stress, hypovolemia, heart failure (Chapter 58), hypoxia, sympathomimetic or parasympatholytic medications, thyrotoxicosis (Chapter 233), and pheochromocytoma (Chapter 235).

Re-entrant tachycardias begin and end abruptly, whether without treatment or when terminated with vagal maneuvers or intravenous medications. An accessory pathway with ventricular preexcitation can be undiagnosed into adulthood, when it can mimic myocardial infarction or right ventricular hypertrophy on the electrocardiogram.

DIAGNOSIS

The key to diagnosis is the 12-lead ECG if the symptoms are very frequent. A Holter monitor is useful if the arrhythmia is likely to be detected by 24 to 48 hours of monitoring, whereas a continuous loop event recorder, which can be worn for up to a month and activated by the patient for symptoms, is preferred if the arrhythmia is less frequent (Chapter 62). Another alternative is a device that records data continuously and transmits to a central station, capturing both symptomatic and asymptomatic arrhythmias over a period of up to a month.

On physical examination, patients with a blocked atrial beat or AVNRT may have large (cannon) "a" waves detected in their jugular veins (see Fig. 50-4 in Chapter 50). Carotid sinus massage, which has a vagal effect on the AV node, can terminate SVTs that depend on the AV node as part of the circuit (AVNRT and AVRT). Carotid sinus massage also can occasionally terminate atrial tachycardia but more often will slow the pulse by reducing the number of atrial inputs conducted through the AV node. Similarly, carotid sinus massage will slow but not terminate atrial flutter and AF.

Electrophysiologic testing (Chapter 66) is the definitive way to distinguish SVT from VT (see Table 65-2 in Chapter 65). The SVT can often be initiated by paced premature beats, after which the mechanism and location of the arrhythmia can be determined.

TREATMENT Rx

Acute Therapy

Sinus, Atrial, Atrioventricular Nodal Re-entrant, and Junctional Tachycardias

Sinus tachycardia rarely should be treated directly. Instead, treatment should focus on identifying and treating any precipitating underlying conditions, especially heart failure, pulmonary disease, fever, and thyroid disease. Multifocal atrial tachycardia is relatively unresponsive to medical therapy, is very difficult to ablate, and is best treated by management of the underlying pulmonary disorder. Nondihydropyridine calcium-channel blocking drugs (diltiazem, verapamil; Table 64-5) are most often used if a therapy is absolutely required.

Sustained or repeated episodes of nonsustained SVT, however, generally require effective therapy. If rapid control is desired (e.g., in patients with myocardial ischemia or hypotension), cardioversion is the best solution (Chapter 66). Atrial tachycardias, including atrial flutter or AF, may also convert spontaneously or convert after treatment of an underlying cause, such as hypoxia or heart failure, or after cessation of precipitating medications.

An acute episode of either AVNRT or junctional tachycardia can often be terminated with vagal maneuvers, such as carotid massage. In most atrial tachycardias, adenosine or vagal stimulation (or both) produces enough AV block to unmask the atrial origin of the tachycardia. However, some atrial tachycardias and most episodes of AVNRT terminate after administration of adenosine. Intravenous β-blockers or calcium-channel blockers (see Table 64-5) can be used for the same purpose. For sustained control of the ventricular rate during atrial tachycardia, intravenous esmolol and diltiazem are effective.

Accessory Pathway Tachycardia

The acute management of SVTs that use an accessory pathway (AVRT) depends on the mechanism of the rhythm. If the tachycardia uses the AV node as one limb of the circuit, it may terminate with vagal maneuvers such as carotid sinus massage. If the tachycardia uses an accessory pathway as the antegrade limb (antidromic AVRT), it is important to avoid measures that may accelerate the conduction properties of the accessory pathway. For example, digoxin and epinephrine will increase conduction over the accessory pathway and potentially accelerate the tachycardia. Patients may have an adrenergic response to a drop in blood pressure induced by the vasodilating properties of β-blockers and calcium-channel blockers, particularly when AF conducts over an accessory pathway. As a result of these potential complications, adenosine (see Table 64-5) is the drug of choice for the acute termination of antidromic AVRT, but a true antiarrhythmic drug, such as intravenous amiodarone, or cardioversion should be considered for antidromically conducted AF. In orthodromic AVRT, in which the AV node is the antegrade limb of the tachycardia, β-blockers or calcium-channel blockers can be used as well as adenosine.

Atrial Flutter

It can be very difficult to control the rate of acute atrial flutter, which generally must be treated by restoring sinus rhythm. Intravenous ibutilide is approximately 60% effective for converting atrial flutter to sinus rhythm. Direct current electrical cardioversion, which is highly (>95%) effective for restoring sinus rhythm, should not be performed unless the episode of atrial flutter is believed to be less than 48 hours in duration, or transesophageal echocardiogram has excluded clot in the left atrial appendage, or until the risk of stroke has been minimized by achieving a therapeutic international normalized ration (INR) of 2 to 3 for the prior 4 weeks.

Atrial Fibrillation

For acute AF without hypotension, rate control is crucial and can be accomplished with esmolol, metoprolol, verapamil, or diltiazem (see Table 64-5); digoxin is usually a third-line agent (Fig. 64-23). All patients with new-onset AF should receive anticoagulation acutely with heparin (Chapter 37). The decision of whether to restore and maintain sinus rhythm or allow recurrences or progression to permanent AF is a fundamental component of AF management. Trials of a strategy of rate control compared with a

TABLE 64-5 ANTIARRHYTHMIC DRUGS: DOSES AND SIDE EFFECTS

ANTIARRHYTHMIC DRUG AND COMMON USE	DOSE/METABOLISM	SIDE EFFECTS AND REQUIRED MONITORING	SELECTED DRUG INTERACTIONS
Quinidine	Hepatic CYP 3A4 (70%), renal (30%) Dose: sulfate—600 mg tid, gluconate—324 to 648 mg q8h Dose reduced for renal failure	Thrombocytopenia Cinchonism Pruritus, rash QT prolongation/torsades de pointes	↑ Digoxin and amiodarone concentrations Quinidine inhibits CYP 2D6 and may increase drugs metabolized by this enzyme, e.g., ↑ effect of tricyclic antidepressants, haloperidol, some β-blockers, fluoxetine, narcotics Quinidine metabolism inhibited by cimetidine Quinidine metabolism increased by phenobarbital, phenytoin, and rifampicin
Procainamide	Mostly hepatic—rapid acetylators produce more NAPA; NAPA renally cleared PO dose: 50 mg/kg/24 hr IV dose: 1 g over 25 min, then 20-60 μg/kg/min infusion Reduce dose for renal dysfunction or low cardiac output	Rash, fever, arthralgias, drug-induced lupus, particularly in slow acetylators Agranulocytosis QT prolongation/torsades de pointes	Procainamide clearance reduced by trimethoprim, cimetidine, and ranitidine
Disopyramide	Renal, hepatic (CYP 3A4) Dose: 100-400 mg q8-12h; max dose, 800 mg/24 hr Reduce dose for renal or hepatic dysfunction	Anticholinergic (contraindicated for narrow-angle glaucoma): dry mouth, urinary retention, constipation, blurry vision QT prolongation/torsades de pointes	None
Propafenone	Hepatic: 150-300 mg q8h or sustained release 225-425 mg bid	Metallic taste, dizziness, SIADH Atrial flutter, ventricular tachycardia	May decrease the metabolism of warfarin Increase digoxin levels
Flecainide	Renal, hepatic CYP 2D6 50-100 mg bid; max dose, 300-400 mg/day	Dizziness, headache, visual blurring Atrial flutter, ventricular tachycardia	May increase digoxin levels Flecainide levels increased by amiodarone, haloperidol, quinidine, cimetidine, and fluoxetine
β-Blockers (selected)	Hepatic, renal Only renal (atenolol, nadolol) IV esmolol: 250-500 μg over 1 min, then 50-300 μg/kg/min over 4 min Acebutolol, 200-600 mg bid; atenolol, 25-100 mg qd; carvedilol, 3.125-50 mg bid; metoprolol, 25-150 mg bid; nadolol, 20-120 mg qd; nebivolol, 5-40 mg qd; propranolol, 10-120 mg bid	Fatigue, depression, bronchospasm, impotence	Minimal, except for carvedilol and metoprolol, whose levels may be increased by amiodarone, propafenone, quinidine, fluoxetine, haloperidol, paroxetine, and cimetidine
Sotalol	Renal: 80-120 mg bid Max dose, 240 mg bid	Bronchospasm QT prolongation/torsades de pointes	No significant interactions
Dofetilide	Renal, hepatic CYP 3A4 CrCl > 60 (500 μg bid), CrCl 40-60 (250 μg bid), CrCl 20-39 (125 μg bid)	QT prolongation and torsades de pointes Three days of in-hospital monitoring is required during drug initiation	Contraindicated with verapamil, ketoconazole, cimetidine, megestrol, prochlorperazine, and trimethoprim Hydrochlorothiazide increases dofetilide levels Must discontinue amiodarone at least 3 mo before dofetilide initiation
Ibutilide	Hepatic CYP 3A4 1 mg IV over 10 min, repeat after 10 min if necessary	Nausea QT prolongation and torsades de pointes Must monitor for 4 hr after drug initiation	None
Amiodarone	Hepatic half-life 50 days PO load 10 g over 7-10 days, then 400 mg for 3 wk, then 200 mg/day for atrial fibrillation Maintenance dose of 400 mg/day for VT Dose reduce load for bradycardia or QT prolongation IV: 150-300 mg bolus, then 1 mg/min infusion for 6 hr, followed by 0.5 mg/min thereafter	Pulmonary (acute hypersensitivity pneumonitis, chronic interstitial infiltrates), hepatitis Thyroid (hypo- or hyperthyroidism) Photosensitivity, blue-gray discoloration with chronic high dose, nausea, ataxia, tremor, alopecia Avoid if identified thyroid nodule LFTs two to three times a year, TFTs twice yearly, PFTs and CXR at initiation and CXR yearly thereafter. QT prolongation expected; reduce dose if exceeds 500 msec	Inhibits CYP 450 enzymes—increases concentrations of warfarin, digoxin, cyclosporine, alprazolam, carbamazepine, HMG-CoA inhibitors, phenytoin, and quinidine
Dronedarone	Hepatic CYP 3A4 half-life 30 hr PO 400 mg bid Improved absorption with food	Reduces the secretion of creatinine without a reduction in GFR Hepatic failure Avoid in heart failure	Increases digoxin levels (dose reduce digoxin by half) May increase myositis with simvastatin Avoid grapefruit
Calcium-channel blocker (nondihydropyridine)	Hepatic Inhibit CYP 3A4 IV diltiazem, 20 mg bolus over 2 min, then 5-15 mg per hour maintenance infusion Verapamil long-acting 120-480 mg qd Diltiazem long-acting 180-300 mg qd	Constipation, rash, peripheral edema	Inhibits CYP 3A4—will increase levels of alprazolam, carbamazepine, dihydropyridine, cyclosporine, HMG-CoA inhibitors. Verapamil (but not diltiazem) increases digoxin levels

TABLE 64-5 ANTIARRHYTHMIC DRUGS: DOSES AND SIDE EFFECTS—cont'd

ANTIARRHYTHMIC DRUG AND COMMON USE	DOSE/METABOLISM	SIDE EFFECTS AND REQUIRED MONITORING	SELECTED DRUG INTERACTIONS
Adenosine	Erythrocyte, endothelial cell 6-mg IV push, followed if necessary by 12 mg after 1-2 min	Nausea, headache, flushing, chest pain, bronchospasm (contraindicated if asthma)	Methylxanthines compete for adenosine receptors with adenosine Dipyridamole decreases the metabolism of adenosine
Digoxin	Renal, hepatic, gastrointestinal, 0.125-375 mg/day	Anorexia, nausea, fatigue, confusion, altered vision with green-yellow halos	Levels of or sensitivity to digoxin increased by hypokalemia, quinidine, verapamil, amiodarone, propafenone, renal failure, hypoxia, decreased muscle mass Levels of or sensitivity to digoxin decreased by malabsorption, hyperkalemia, hypocalcemia

CXR = chest x-ray; CYP = cytochrome P-450; GFR = glomerular filtration rate; HMG-CoA = 3-hydroxy-3-methylglutaryl coenzyme A; IV = intravenous administration; LFT = liver function test; NAPA = *N*-acetyl procainamide; PFT = pulmonary function test; PO = oral administration; SIADH = syndrome of inappropriate diuretic hormone; TFT = thyroid function test; VT = ventricular tachycardia.

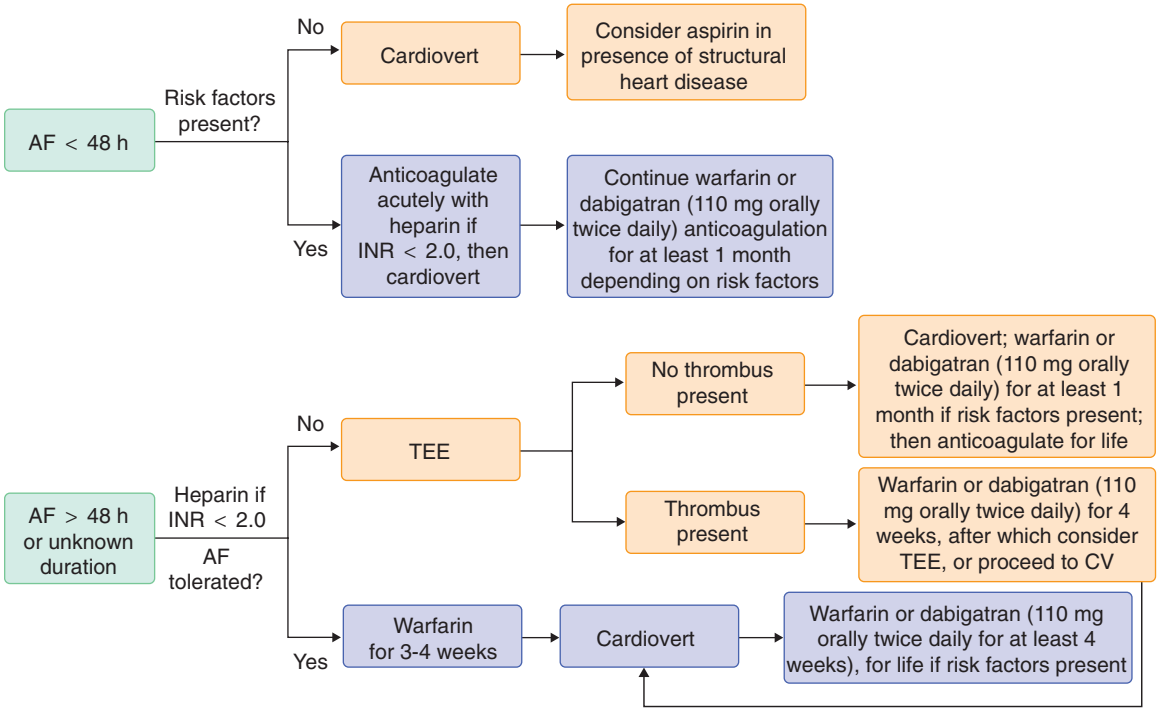

FIGURE 64-23. Management of recent-onset atrial fibrillation (AF). CV = Cardioversion; INR = International Normalized Ratio; TEE = Transesophageal echocardiography.

strategy of rhythm control with antiarrhythmic drugs have demonstrated no difference in total or arrhythmic mortality associated with these two approaches,[1-3] even in patients with a reduced ejection fraction.[4] Because a significant component of the adverse events experienced in the rhythm control arms of these studies was due to stroke in un-anticoagulated patients and toxicity from antiarrhythmic drugs, advances in antiarrhythmic and anticoagulant medications as well as the advent of reliable ablative therapies for AF may necessitate a reevaluation of this question.

If a strategy of rate control is chosen, it is important to confirm a heart rate of 80 to 110 beats per minute at rest and less than 140 beats per minute with exercise, preferably by monitoring the heart rate during exercise on an exercise treadmill test or with an ambulatory monitor. More strict rate control is not beneficial.[5] Failure to confirm rate control can result in the development of tachycardia-induced cardiomyopathy. First-line therapy for rate control includes β-blockers or calcium-channel blockers; digoxin can also be used but is generally less effective. Patients commonly require a combination of mediations to achieve goal heart rates.

If a strategy of rhythm control is chosen, many patients will first require cardioversion, either pharmacologic or electrical (Chapter 66). The risk of clot formation must be mitigated before cardioversion in all patients with AF of more than 48 hours' duration. The first step generally is to perform transesophageal echocardiography (TEE) (Chapter 55). If TEE shows no evidence of a left atrial clot, cardioversion can be undertaken without systemic anticoagulation; if the patient has risk factors for stroke in association with AF, however, most clinicians administer anticoagulation during the cardioversion and for the subsequent 4 weeks. If the TEE shows evidence of clot, 4 consecutive weeks of anticoagulation with an INR of at least 2 is required, and anticoagulation must be maintained for at least 3 to 4 weeks after cardioversion. Electrical cardioversion, which should be performed with a minimum of 200 joules, is successful in more than 90% of cases. Pharmacologic cardioversion can be performed with intravenous drugs such as ibutilide, which is more successful for atrial flutter (60% efficacy) than AF (50%). Oral medications can also be used as a "pill in the pocket" strategy. Patients can take a single dose of propafenone (600 mg) or flecainide (300 mg) with a conversion rate for recent-onset AF (<48 hours' duration) of approximately 50% without the need for a screening TEE. Oral amiodarone (typically loaded with 10 g over the first week, followed by 400 to 600 mg a day for the next 3 weeks) can also be used for cardioversion and is successful in approximately 50% of patients with both recent and more prolonged AF.

Long-Term Management

AVNRT, AVRT, Atrial Tachycardias, and Atrial Flutter

Chronic therapy for AVNRT is guided by the frequency and severity of symptoms. Many patients are able to live with this rhythm with infrequent recurrences, which terminate spontaneously or with adenosine. If chronic therapy is required, β-blockers or calcium-channel blockers and less commonly digoxin are used. Ablation of AVNRT (Chapter 66) is highly effective and should be considered before using sodium- or potassium-channel blocking drugs.

Most patients with symptomatic AVRT are treated with catheter ablation (Chapter 66). Ablation of an accessory pathway located near the AV node or His bundle carries a 1% risk of complete heart block, whereas ablation of accessory pathways on the left side of the heart and distant from the AV node and His bundle region is not associated with a risk of heart block but carries a small risk of stroke. At present, it is not standard of care to ablate accessory pathways in patients without symptomatic arrhythmias.

The long-term management of atrial tachycardia depends on symptoms. If the rhythm is highly symptomatic, it is generally managed with a β-blocker or calcium-channel blocker. If these medications are unsuccessful or not tolerated, ablation is frequently recommended, but antiarrhythmic medications are an alternative.

In patients with atrial flutter, ventricular rate control is possible by achieving AV nodal block with β-blockers, calcium-channel blockers, and digitalis. However, radio frequency ablation, which is curative, is now the preferred choice for most patients with atrial flutter (Chapter 66), especially recurrent atrial flutter. Because atrial flutter carries a 3% per year risk of thromboembolism, patients with atrial flutter should also receive long-term anticoagulation similar to what is recommended for AF (see later). If atrial flutter is successful, the risk of recurrence is very small, and long-term anticoagulation is not necessary.

Atrial Fibrillation

Therapies for the chronic maintenance of sinus rhythm in patients with AF include pharmacologic and procedural approaches. The procedural approaches include catheter-based ablation inside the left atrium with the goal of electrically isolating the pulmonary veins from the left atrium. Similarly, a minimally invasive surgical approach can electrically isolate the pulmonary veins from the external surface of the heart with the additional resection of the left atrial appendage. Both these procedures have become standard options for AF, especially in patients who have recurrent AF despite at least one antiarrhythmic drug.[5-7] The catheter approach carries a small risk of cardiac perforation, including pericardial tamponade and atrioesophageal fistula formation, and a 1% risk of stroke. There is also a small risk of pulmonary vein stenosis, which has been reduced by newer technologies. The surgical approach carries a higher risk of cardiac bleeding, particularly during the resection of the left atrial appendage, and is associated with a significantly longer recovery time than the percutaneous approach. However, there should be no stroke risk associated with the surgical procedure because it is performed completely from the epicardial surface of the heart. In addition, the exclusion of the left atrial appendage may prove protective in regard to future thromboembolic risk.[8] Both procedures appear to be equally effective, with approximately 60 to 70% of patients experiencing a significant reduction or absence of AF following either procedure. It is typical to offer a second procedure to patients who have recurrent AF following a first catheter-based procedure. Finally, a more extensive surgical operation, called the maze procedure, requires a full thoracotomy and is most often performed concomitantly as part of open coronary artery bypass surgery or an open valve operation. In this procedure, electrical lines of block are created in the left atrium to interrupt the perpetuation of AF, the pulmonary veins are isolated, and the left atrial appendage is resected. Success rates for this procedure, which should be reserved for refractory, symptomatic AF, exceed 80%. However, none of these procedures has yet been demonstrated to reduce the risk of stroke risk, so anticoagulation should be maintained for 6 months after the procedure in patients without clinical risk factors for stroke and chronically in patients with risk factors. Catheter-based procedures directed at excluding the left atrial appendage from the systemic blood stream may become options in patients who have a high risk of stroke and who cannot tolerate systemic anticoagulation owing to an excessive risk of bleeding.

The pharmacologic options for the treatment of AF work by blocking sodium, potassium, or a combination of cardiac channels. Blockade of these channels results in slowing of cardiac conduction (sodium channels) and prolongation in cardiac repolarization (potassium channels) as well as additional effects from modulation of the autonomic nervous system. The choice of antiarrhythmic drug is based on the patient's underlying clinical condition (Table 64-6).

Amiodarone is the most widely used medication for AF with an efficacy of 60 to 70% at 1 year. It is associated with a number of drug interactions, most notably with warfarin and digoxin. Its associated risk of thyroid, liver, and lung toxicities, related in part to the iodine moieties on this compound, necessitate careful follow-up. For prevention of recurrent AF, oral amiodarone is significantly more effective than propafenone and sotalol, which are the recommended alternatives. Another alternative is 400 mg twice daily of dronedarone, which is related to amiodarone but has no iodine and a 24-hour half-life, significantly reduced cardiovascular hospitalizations by 16% and death from 3.9% to 2.7% at 21 months in patients with AF.[9] Dronedarone is currently thought to be safe, however, only in patients with an ejection fraction greater than 35% and no evidence of advanced heart failure.

Quinidine, procainamide, and disopyramide are predominantly sodium-channel blocking drugs that also block potassium channels at slow heart rates. Each of these drugs is moderately successful in AF, with about 50% of treated patients in sinus rhythm at 1 year, but each also has idiosyncratic noncardiovascular toxicities that can significantly limit their utility (see Table 64-5). Propafenone and flecainide are also sodium-channel blockers that are widely used for the maintenance of sinus rhythm. These drugs are moderately effective, with a 50% rate of sinus rhythm at 1 year, and are generally well tolerated but must be avoided in patients with structural heart disease, particularly with a history of prior myocardial infarction and impaired left ventricular function, because of a risk for drug-induced ventricular arrhythmia. Dofetilide is a potassium-channel blocking medication that is moderately effective for suppressing AF but carries a dose-dependent risk of QT prolongation and torsades de pointes.

TABLE 64-6 SELECTION OF ANTIARRHYTHMIC DRUGS

PATIENT CHARACTERISTICS	ANTIARRHYTHMIC DRUG CHOICES
No structural heart disease	*First line:* flecainide, propafenone, dronedarone, sotalol *Second line:* amiodarone, dofetilide
Depressed left ventricular ejection fraction with heart failure	*First line:* amiodarone, dofetilide *Avoid:* dronedarone, flecainide, propafenone
Coronary artery disease without congestive heart failure	*First line:* sotalol, dronedarone, dofetilide, amiodarone *Avoid:* flecainide, propafenone
Hypertrophic cardiomyopathy	*First line:* amiodarone, sotalol, dronedarone *Second line:* disopyramide

TABLE 64-7 CURRENT RECOMMENDATIONS FOR THROMBOEMBOLIC PROPHYLAXIS FOR PATIENTS WITH ATRIAL FIBRILLATION BASED ON RISK FACTORS FOR STROKE

No risk	Aspirin (81 to 325 mg/day) or nothing
One moderate risk factor (age ≥ 75 yr, hypertension, heart failure, left ventricular ejection fraction ≤ 35%, diabetes mellitus)	Warfarin (INR 2-3) or dabigatran (110 mg orally twice daily) preferred in patients age ≥ 65 yr with heart failure or age 65-74 yr with diabetes or coronary disease; otherwise aspirin (81 or 325 mg)
At least two moderate risk factors or one high risk factor (prior stroke or transient ischemic attack, mitral stenosis, prosthetic valve)	Warfarin (INR 2-3, or 2.5-3.5 with prosthetic valve) or dabigatran (110 mg orally twice daily)

Anticoagulation

The presence or absence of associated conditions help determine which patients with AF require chronic anticoagulation with warfarin or other systematic coagulants (Table 64-7). Long-term anticoagulation therapy with warfarin or dabigatran is generally recommended in all patients who have persistent or paroxysmal AF, who are older than 65 years, and who have no contraindications to anticoagulation.[10] Warfarin alone is superior to aspirin[11] or the combination of clopidogrel and aspirin, with meta-analysis showing that adjusted-dose warfarin and antiplatelet agents reduce stroke by approximately 60% and 20%, respectively.[12] Although there is some protective effect at an INR as low as 1.8, the target INR for chronic anticoagulation with warfarin should be 2 to 3 to avoid INRs less than 1.8. For patients who do not require or cannot tolerate warfarin, aspirin is a reasonable alternative. Clopidogrel (75 mg/day), in addition to aspirin, reduces the risk of major vascular events from 7.6% per year to 6.8% per year compared with aspirin alone, but increases the risk of major bleeding from 1.3% per year to 2% per year.[13] Dabigatran at 110 mg twice daily is as effective as warfarin but causes less bleeding.[14] Newer alternatives include direct thrombin inhibitors and factor Xa inhibitors. For example, in a randomized study of patients unable to tolerate warfarin, the factor Xa inhibitor apixaban (5 mg daily) reduced stroke and systemic embolism without major increases in bleeding.[15] These new classes of anticoagulants do not require monitoring with blood tests and do not interact with food or medications. Aspirin may be better than no treatment for patients who cannot tolerate warfarin. The addition of aspirin to moderate-intensity warfarin in anticoagulation (INR 2 to 3) can decrease vascular events and is recommended in high-risk patients.[16]

VENTRICULAR ARRHYTHMIAS

WILLIAM G. STEVENSON

Ventricular arrhythmias originate below the atrioventricular (AV) node in the ventricular myocardium or His-Purkinje system. These include premature ventricular beats, ventricular couplets, nonsustained and sustained ventricular tachycardias (VTs), and ventricular fibrillation (VF). These arrhythmias occur in all forms of heart disease and can be the initial presentation of disease. Sustained arrhythmias are an important cause of sudden death. Arrhythmias associated with genetic abnormalities of cardiac ion channels can cause sudden death despite the absence of identifiable structural heart disease. Ventricular arrhythmias that occur in the absence of structural heart disease or a defined ion channel abnormality are referred to as *idiopathic* and are usually benign. Evaluation and management are guided by the risk of arrhythmic death, which is determined by the presenting symptoms, type of arrhythmia, and associated underlying heart disease.

EPIDEMIOLOGY

Premature ventricular contractions (PVCs) are encountered on a standard electrocardiogram (ECG) in fewer than 1% of subjects younger than 20 years of age. The prevalence increases with age to greater than 2% of patients older than 50 years. Premature ventricular beats can be a sign of increased sympathetic tone, myocardial ischemia, hypoxia, and electrolyte abnormalities, particularly hypokalemia (Table 65-1), or underlying heart disease.

Sustained ventricular arrhythmias are usually caused by underlying structural heart disease, and the prevalence of arrhythmias increases with the severity of the heart disease. Ventricular arrhythmias are responsible for most of the 150,000 to 350,000 sudden deaths (Chapter 63) that occur annually in the United States and account for approximately 13% of all mortality. VF due to acute myocardial ischemia (Chapter 73) in the setting of coronary artery disease is the most common cause. The annual incidence of out-of-hospital VF is approximately 8 per 100,000. A 24-hour ECG recording will show premature ventricular beats and nonsustained VT in more than half of patients with advanced heart failure (Chapter 59). In the heart failure population, sustained VT or VF develops at a rate of approximately 2% per year or less when the left ventricular ejection fraction is above about 30%, but the rate doubles for patients with worse ventricular function.

TABLE 65-1 POTENTIAL FACTORS AGGRAVATING VENTRICULAR ARRHYTHMIAS

Elevated sympathetic tone
Acute illness
Central nervous system injury
Hypovolemia
Exertion/emotion

Toxins
Amphetamines, caffeine, ephedrine, pseudoephedrine
QT prolonging drugs/toxins (see Table 65-3)
Digitalis glycosides

PATHOBIOLOGY

Ventricular arrhythmia can be caused by automaticity or re-entry. Purkinje fibers have the capability for spontaneous automaticity that emerges normally at rates slower than 50 beats per minute. Abnormal automaticity occurs in partially depolarized ventricular or Purkinje myocytes. Triggered automaticity results from afterdepolarizations, which may be early or delayed in relation to the completion of ventricular repolarization. Delayed afterdepolarizations, which are membrane depolarizations that follow the completion of repolarization (i.e., usually after the completion of the T wave on the ECG), can occur when intracellular calcium overload increases the activity of the sodium-calcium exchanger, thereby producing a depolarizing inward flux of sodium. This mechanism is implicated in the ventricular arrhythmias seen in digitalis toxicity, familial catecholaminergic polymorphic VT, and some idiopathic right ventricular outflow tract arrhythmias. Rapid pacing and β-adrenergic stimulation promote delayed afterdepolarizations, so these arrhythmias are often exercise induced. Early afterdepolarizations occur before the completion of repolarization, that is, before the end of the T wave on the ECG, because a prolonged time to repolarization allows recovery of ion channels before the end of repolarization. Early afterdepolarizations are involved in the genesis of polymorphic VT associated with QT prolongation in the long QT syndromes and possibly during myocardial ischemia.

Re-entry in regions of myocardial scar is the most common cause of sustained VT associated with structural heart disease. The scar contains areas of fibrous tissue as well as surviving myocyte bundles that can create channels for propagation through the scar. Separation of myocyte bundles by fibrous tissue and uncoupling of adjacent bundles leads to slow conduction through these regions, thereby promoting re-entry (Fig. 65-1).

Re-entry can also occur in the absence of a fixed structural abnormality in the tissue. Spiral wave re-entry is one such formation that can be provoked in normal tissue by electrical stimulation (Fig. 65-2). The core of the spiral wave may wander through the tissue, thereby changing the ventricular activation sequence and producing polymorphic VT (see later). Alternatively, the spiral wave may anchor on anatomic discontinuities to produce a consistent beat-to-beat ventricular activation. Spiral waves that encounter refractory tissue can break into daughter waves and disorganize to VF.

CLINICAL MANIFESTATIONS AND DIAGNOSES

Ventricular arrhythmias can be asymptomatic and be detected by an irregular pulse, on a routine ECG, on routine monitoring in the hospital, or on an exercise test. Ventricular arrhythmias also can present symptomatically as palpitations (Chapters 50 and 62), dizziness, exercise intolerance, syncope (Chapters 50 and 62), or sudden cardiac arrest (Chapter 63). The diagnosis should be confirmed with an ECG. Individuals often have substantial hour-to-hour and day-to-day variation in the frequency of ventricular arrhythmias, so ambulatory monitoring is useful to record the cardiac rhythm at the time of symptoms (Chapter 62) if the arrhythmia is not present on the resting ECG. Exercise testing should be considered in patients with exercise-induced symptoms.

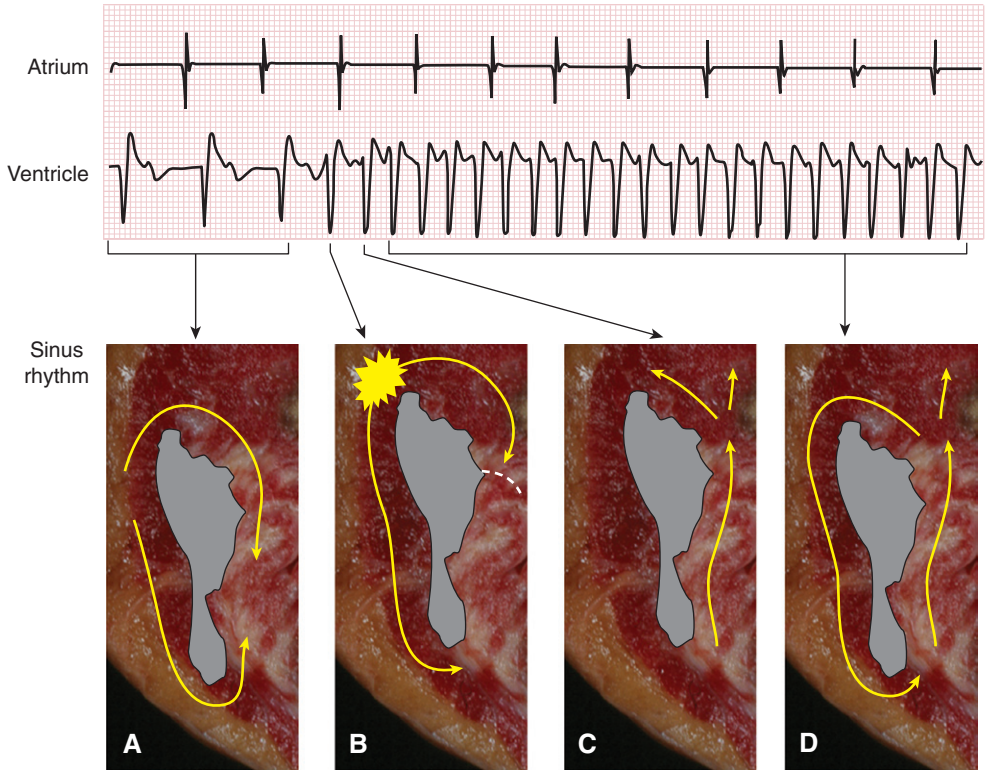

FIGURE 65-1. Initiation of scar-related re-entry. At the *top* are cardiac electrograms recorded by an implanted cardioverter-defibrillator. The *top tracing* is an atrial electrogram. The *bottom tracing* is the electrogram recorded from the lead in the right ventricular apex. Three beats of sinus rhythm are followed by a premature beat, which initiates ventricular tachycardia. The schematics below the tracings illustrate a potential mechanism of initiation of scar-related re-entry. In each panel, a cross section through the myocardium includes a region of scar *(white and gray regions)* that contains surviving myocyte bundles. A dense region of fibrosis *(solid gray region)* causes conduction block that creates a channel for conduction along the right-hand side of the fibrosis region. **A,** During sinus rhythm, wave fronts *(yellow arrows)* enter the channel from both sides and collide within the channel, thereby preventing re-entry. **B,** A premature beat *(star)* produces a wave front that reaches the superior end of the channel and finds it refractory, where it blocks *(dashed white line)*. The wave front that reaches the lower end of the channel enters the channel. **C,** Conduction through the channel is slow, allowing time for the initial region of block to recover. The wave front emerges from the exit of this channel, where it produces the first beat of ventricular tachycardia. **D,** The complete re-entry circuit.

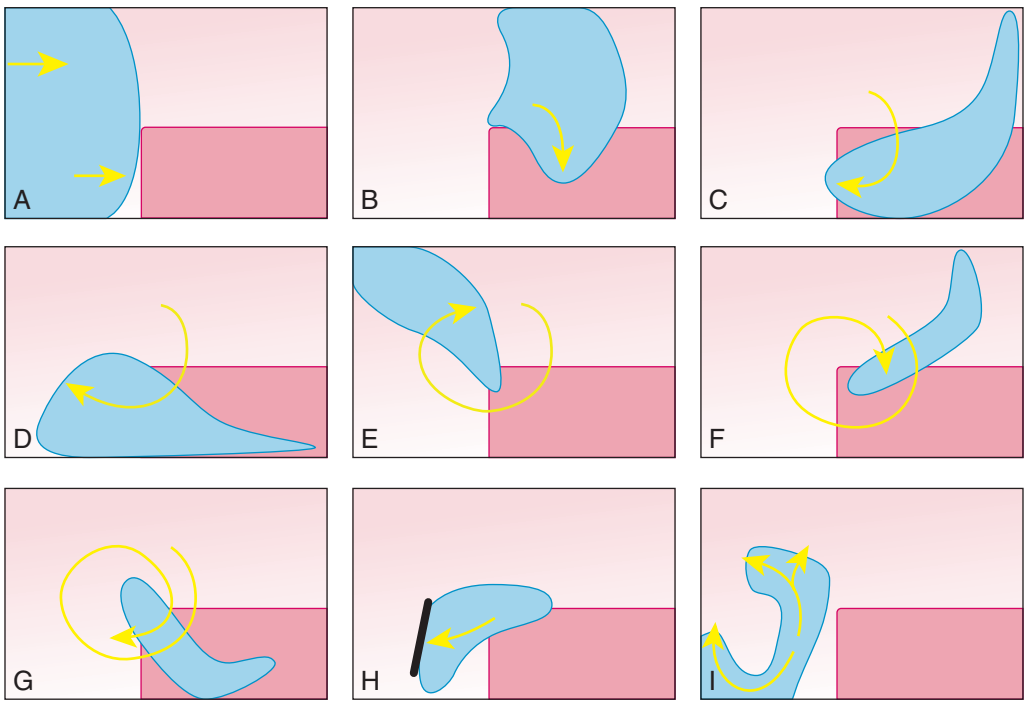

FIGURE 65-2. Spiral wave re-entry. The area of *blue* represents an excitation wave of depolarization. **A,** A wave front propagates from left to right and encounters a region of incompletely recovered tissue *(dark red region)*. **B,** The wave front propagates along the margin of refractory tissue until it reaches recovered tissue and propagates inferiorly (**C**). **D** to **G,** The wave front continues re-entering and establishing a circuit that continues to spiral through the tissue *(yellow arrow)*. **H,** The spiral wave encounters a region of block *(black line)*, which splits the wave front (**I**). Multiple potential wave fronts can be generated, thereby leading to fibrillation.

FIGURE 65-3. Ventricular arrhythmias. A, Multifocal premature ventricular beats. **B,** Nonsustained monomorphic ventricular tachycardia. Note dissociated P waves indicated by *arrows*. **C,** Sustained monomorphic ventricular tachycardia. Dissociated P waves are indicated by *arrows*.

TYPES OF VENTRICULAR ARRHYTHMIAS

A single beat is referred to as a *premature ventricular* beat (Fig. 65-3). Two consecutive beats are *ventricular couplets.* Three or more consecutive beats at a rate faster than 100 beats per minute are *VT* (see Fig. 65-3B and C). Three or more consecutive beats at slower rates are designated *idioventricular rhythms.* VT that terminates spontaneously within 30 seconds is *nonsustained* (see Fig. 65-3B), whereas *sustained VT* persists longer than 30 seconds.

The QRS morphology of the arrhythmia is determined by the sequence of ventricular activation. Conduction through the ventricular myocardium is slower than activation of the ventricles over the Purkinje system, so the QRS complex will be wide, typically more than 0.12 second. When VT is caused by repetitive activation from the same source, the QRS complexes are the same from beat to beat, and VT is monomorphic (see Fig. 65-3B and C). A continually changing activation sequence produces polymorphic VT with a changing QRS morphology (Fig. 65-4A). VF has continuous irregular activation with no discrete QRS complexes (see Fig. 65-4D). Although underlying structural heart disease is usually present, these arrhythmias do not require a fixed structural substrate.

The QRS morphology of an individual beat is determined largely by the site of initial ventricular activation. Arrhythmias that originate from the right ventricle or septum result in late activation of much of the left ventricle, thereby producing a prominent S wave in V_1, referred to as a *left bundle branch block–like configuration* (Fig. 65-5). Arrhythmias that originate from the free wall of the left ventricle have a prominent positive deflection in V_1, thereby producing a right bundle branch block–like morphology (Fig. 65-6). The axis of the QRS is also useful. A frontal plane axis that is directed inferiorly, as indicated by dominant R waves in leads II, III, and aVF, suggests initial activation of the cranial portion of the ventricle, whereas a frontal plane axis that is directed superiorly (dominant S waves in II, III, and aVF) suggests initial activation at the inferior wall.

Very rapid monomorphic VT has a sinusoidal appearance, also called *ventricular flutter,* because it is not possible to distinguish the QRS complex from the T wave (see Fig. 65-4B). Relatively slow sinusoidal VTs have a wide QRS indicative of slowed ventricular conduction (see Fig. 65-4C). Hyperkalemia, toxicity from excessive effects of drugs that block sodium channels (e.g., flecainide, propafenone, or tricyclic antidepressants), and severe global myocardial ischemia are causes.

PREMATURE VENTRICULAR CONTRACTIONS AND NONSUSTAINED VENTRICULAR TACHYCARDIA

PVCs can be due to automaticity or re-entry. PVCs that have the same QRS morphology, which indicates that they have the same origin, are unifocal PVCs (see Fig. 65-5). PVCs from more than one focus give rise to PVCs with different QRS morphologies and are known as *multifocal premature ventricular beats* (see Fig. 65-3A).

During myocardial ischemia or in association with other heart disease, PVCs can be a harbinger of sustained VT or VF. When encountered during acute illness or as a new finding, the possibility of myocardial ischemia and other aggravating factors (Table 65-1) should be considered, and evaluation for underlying heart disease is warranted.

Three or more consecutive ventricular beats that occur at a rate faster than 100 beats per minute and that terminate spontaneously are nonsustained VT (see Fig. 65-3B). In patients with heart disease, nonsustained VT is associated with more severe disease and increased mortality. However, suppression of nonsustained VT with antiarrhythmic drugs does not improve survival. In ambulatory patients, nonsustained VT is usually monomorphic, with rates of less than 200 beats per minute and a duration of less than 8 beats. Nonsustained VT that is rapid, polymorphic, or with a first beat that occurs before the peak of the T wave ("short coupled") (see Fig. 65-4A) is uncommon and should prompt careful evaluation for causes of sustained VT and diseases associated with a high risk of sudden death (Table 65-3).

Idiopathic PVCs and nonsustained VT occur in the absence of structural or genetic heart disease. Most frequently, these PVCs originate from the right ventricular outflow tract and have a left bundle branch block configuration, with an inferiorly directed frontal plane axis (see Fig. 65-5). Less common sites of origin are the aortic and mitral valve annuli, the left ventricular papillary muscles, and the Purkinje system.

Once the diagnosis is established, further evaluation assesses the possible presence and severity of underlying heart disease. A family history of sudden death should prompt evaluation for genetic syndromes associated with sudden death, including cardiomyopathy (Chapter 60), long QT syndrome (see later), and arrhythmogenic right ventricular cardiomyopathy (Chapter 60). Any abnormality on the 12-lead ECG warrants further evaluation. Repolarization abnormalities are seen in a number of genetically determined syndromes associated with sudden death, including the long QT syndrome, Brugada's syndrome, arrhythmogenic right ventricular cardiomyopathy, and hypertrophic cardiomyopathy (Chapter 60). An echocardiogram (Chapter 55) is often warranted to assess ventricular function, wall motion abnormalities, and valvular heart disease. Cardiac magnetic resonance imaging is also useful for this purpose and for the detection of ventricular scarring that is the substrate for sustained VT. Exercise stress testing should be performed in patients who have exertional symptoms and for those who are at risk for coronary artery disease.

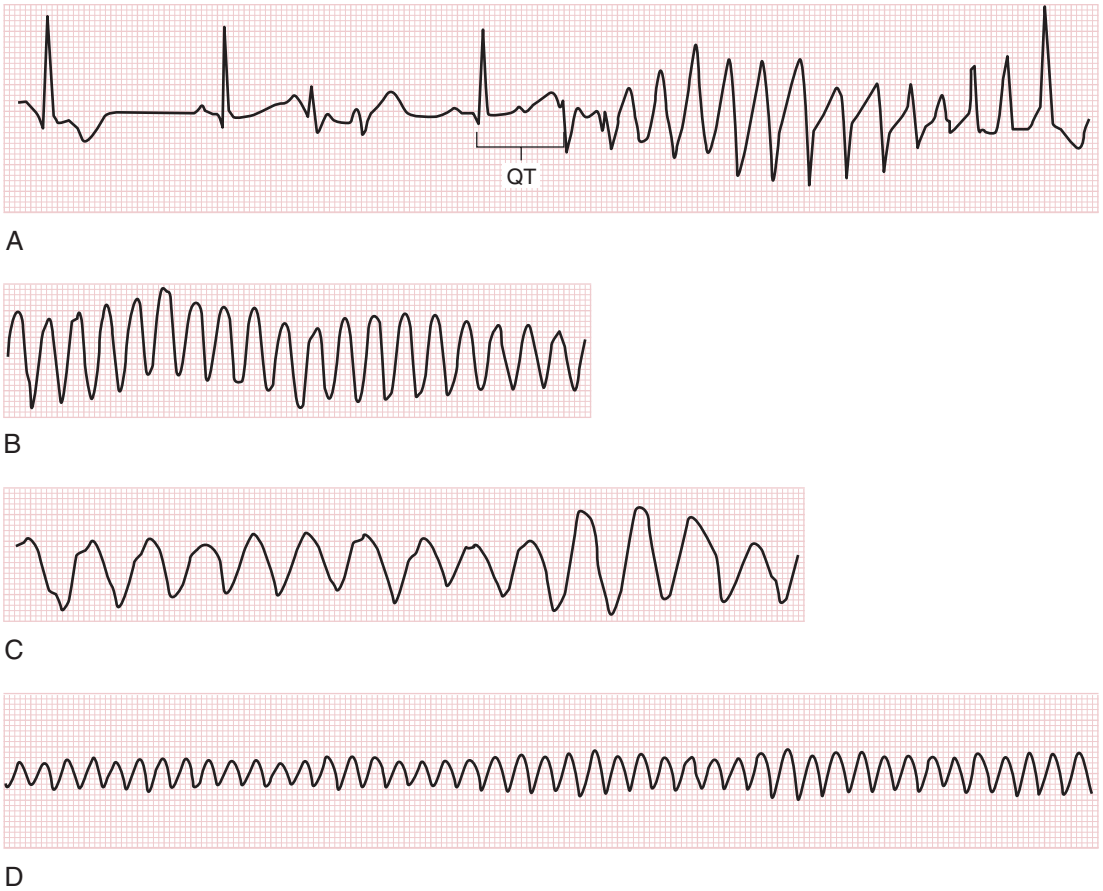

FIGURE 65-4. **A,** Polymorphic ventricular tachycardia associated with QT prolongation. Sinus rhythm, with a couplet of premature ventricular contractions, is followed by a sinus beat, and then by a polymorphic ventricular tachycardia. The QT interval of the sinus beats is markedly prolonged, exceeding 0.56 second. **B,** Rapid sinusoidal ventricular tachycardia with a rate approximating 250 beats/minute. **C,** Sinusoidal ventricular tachycardia owing to hyperkalemia. The rate is slower than 150 beats/minute, but the QRS duration exceeds 200 msec, thereby creating the sinusoidal appearance. **D,** Ventricular fibrillation.

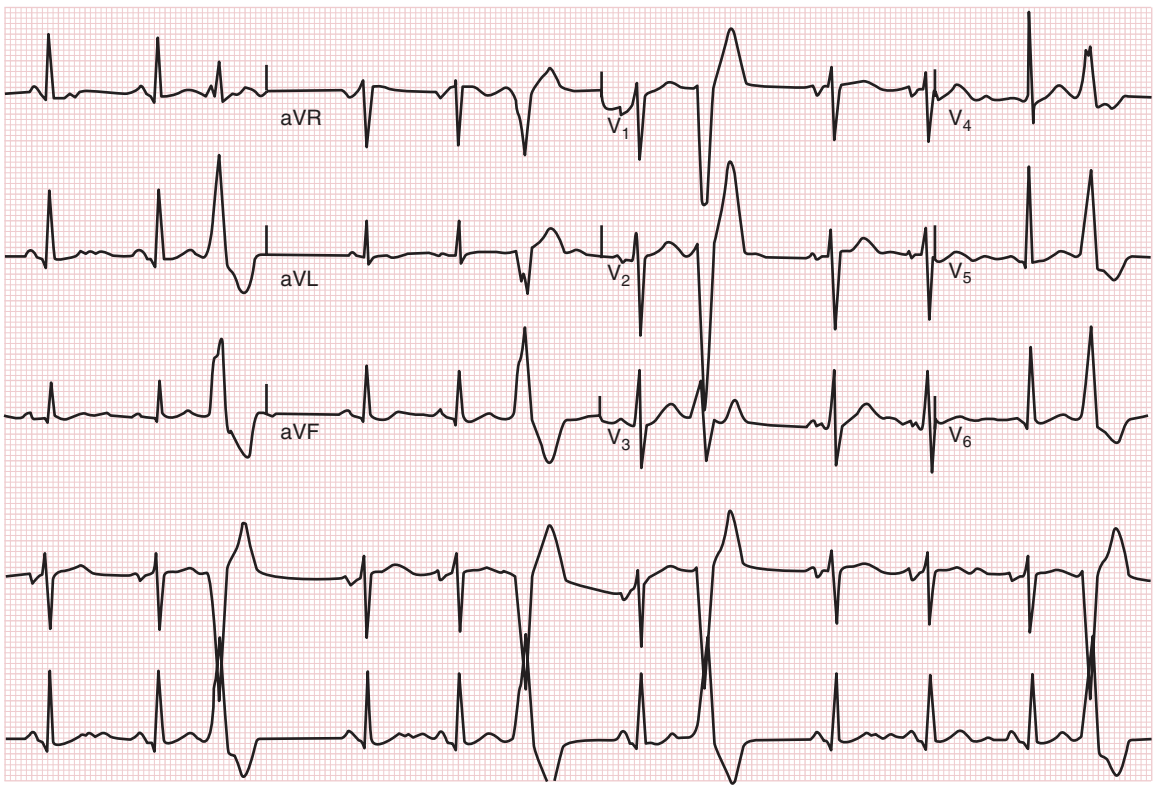

FIGURE 65-5. **Twelve-lead electrocardiogram with simultaneous two-lead rhythm strip (V_2 and V_5) showing premature ventricular beats that originated from the right ventricular outflow tract.** Sinus rhythm and frequent premature ventricular beats are present. The premature ventricular contractions all have the same morphology, best appreciated in the bottom two continuous leads, with a left bundle branch block–like configuration in V_1 consistent with an origin in the right ventricle or septum. The frontal plane axis is directed inferiorly, indicating initial depolarization from the cranial aspect of the ventricle.

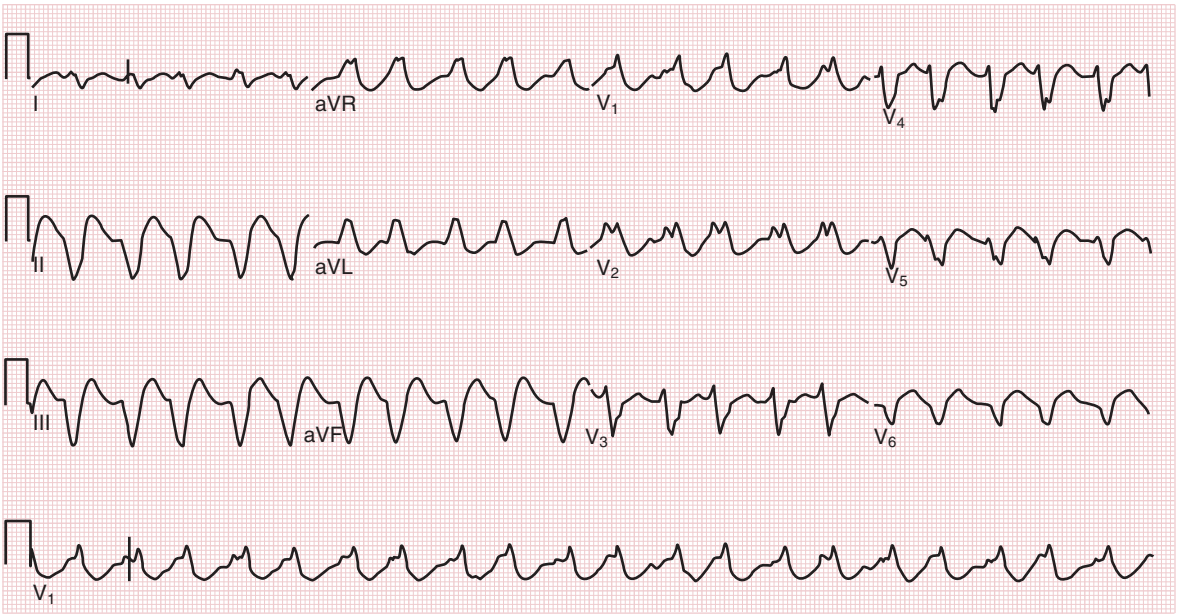

FIGURE 65-6. Sustained monomorphic ventricular tachycardia (VT) originating from an inferior left ventricular infarct region. VT has a right bundle branch block–like configuration in V_1, consistent with an origin in the left ventricle. The frontal plane axis is directed superiorly, consistent with initial depolarization of the inferior wall of the left ventricle.

TABLE 65-2 DISTINGUISHING VENTRICULAR TACHYCARDIA FROM SUPRAVENTRICULAR TACHYCARDIA WITH ABERRANT CONDUCTION

VENTRICULAR TACHYCARDIA	SUPRAVENTRICULAR TACHYCARDIA
AV dissociation	Same QRS morphology as preexisting bundle branch block in sinus rhythm
AVR: initial R > S or initial r or q > 40 msec	
V_1 to V_6: absence of rs	
V_1 to V_6: onset of R to S > 100 msec in any lead	
V_6: QS or QR	
	V_1: rsR′

TREATMENT

Idiopathic Ventricular Tachycardia

For idiopathic PVCs and nonsustained VT in the absence of underlying heart disease, no specific therapy is needed unless the patient has significant symptoms or evidence that ectopy is depressing ventricular function. Reassurance that the arrhythmia is benign is often sufficient to allow the patient to cope with the symptoms, which will often wax and wane in frequency over years. Avoiding stimulants, such as caffeine, is helpful in some patients. If symptoms require treatment, β-adrenergic blockers and nondihydropyridine calcium-channel blockers (verapamil and diltiazem) are sometimes helpful (see Table 64-7 in Chapter 64). Suppression with more potent antiarrhythmic drugs can be effective but warrants careful consideration of the risks. Catheter ablation can be considered, particularly if unifocal PVCs are causing significant symptoms or contributing to depressed ventricular function, but the potential benefit must be carefully weighed against the procedure risks (Chapter 66).

For PVCs and nonsustained VT that have an impact on quality of life or are extremely frequent such that they may be contributing to ventricular dysfunction, chronic therapy with β-adrenergic blockers (Table 64-7) should be considered. Amiodarone and catheter ablation may be considered if β-adrenergic blockers are ineffective (see later).

Acute Coronary Syndromes

During and early after acute myocardial infarction (MI) (Chapter 73), PVCs and nonsustained VT are common and can be an early manifestation of ischemia and a harbinger of subsequent VF. Treatment with β-adrenergic blockers and correction of hypokalemia and hypomagnesemia reduce the risk of VF. Routine administration of the antiarrhythmic drug lidocaine does not reduce mortality.

Following recovery from acute MI, frequent PVCs (typically more than 10 PVCs per hour), repetitive PVCs with couplets, and nonsustained VT are markers for depressed ventricular function and increased mortality, but suppression of the arrhythmias with antiarrhythmic drug therapy does not improve survival and is not recommended. For survivors of an acute MI, an implantable cardioverter-defibrillator (ICD) reduces mortality in certain high-risk groups: patients who have survived more than 40 days after the acute MI and have a left ventricular ejection fraction of 30% or less or who have an ejection fraction of less than 0.35% and have symptomatic heart failure (functional class II or III); and patients more than 5 days after MI who have a reduced left ventricular ejection fraction, nonsustained VT, and inducible sustained VT or VF on electrophysiologic testing.[1] ICDs do not reduce mortality when routinely implanted soon after MI or in patients after recent coronary artery revascularization surgery.[2]

Depressed Ventricular Function and Heart Failure

Premature ventricular beats and nonsustained VT are common in patients with depressed ventricular function and heart failure, in whom they are markers for disease severity and increased mortality. Suppression of PVCs with antiarrhythmic drug therapy does not improve survival and is not routinely warranted. For example, in patients with prior MI and a depressed left ventricular ejection fraction, chronic antiarrhythmic drug therapy with the sodium-channel blocking antiarrhythmic drugs flecainide or moricizine increases mortality despite suppression of ventricular ectopy, apparently because of their proarrhythmic and negative inotropic effects. Therefore, antiarrhythmic drugs whose major action is blockade of the cardiac sodium channel (flecainide, propafenone, mexiletine, quinidine, disopyramide) are avoided in patients with structural heart disease. Therapy with dofetilide (see Table 64-7 in Chapter 64), which blocks the repolarizing current IKr, does not improve survival. In patients with heart failure and depressed left ventricular function, amiodarone suppresses ventricular ectopy and reduces sudden death but does not appear to improve survival,[3,4] whereas insertion of an ICD reduces the mortality rate by 20%, from 36% to 29%, over 5 years.[5]

Other Cardiac Disease

Ventricular ectopy is associated with increased mortality in patients with *hypertrophic cardiomyopathy* (Chapter 60) or with *congenital heart disease* (Chapter 69) associated with right or left ventricular dysfunction. In these patients, management is similar to what is recommended in patients with ventricular dysfunction. Pharmacologic suppression of the arrhythmia does not improve mortality, and ICDs are warranted for high-risk patients.

Premature Ventricular Contraction–Induced Ventricular Dysfunction

Very frequent ventricular ectopy can depress ventricular function, probably by a mechanism similar to that by which any chronic tachycardia causes tachycardia-induced cardiomyopathy. PVCs rarely contribute to depressed ventricular function unless they account for more than 10% of beats. The PVCs that cause ventricular depression typically are unifocal, most commonly originating from the left ventricular papillary muscles or outflow tract regions. The distinction between PVC-induced ventricular dysfunction compared with a cardiomyopathy that causes ventricular dysfunction independent of the ventricular arrhythmia is difficult and often can be made only retrospectively by observing an improvement in ventricular function after the arrhythmia is suppressed with amiodarone or catheter ablation.

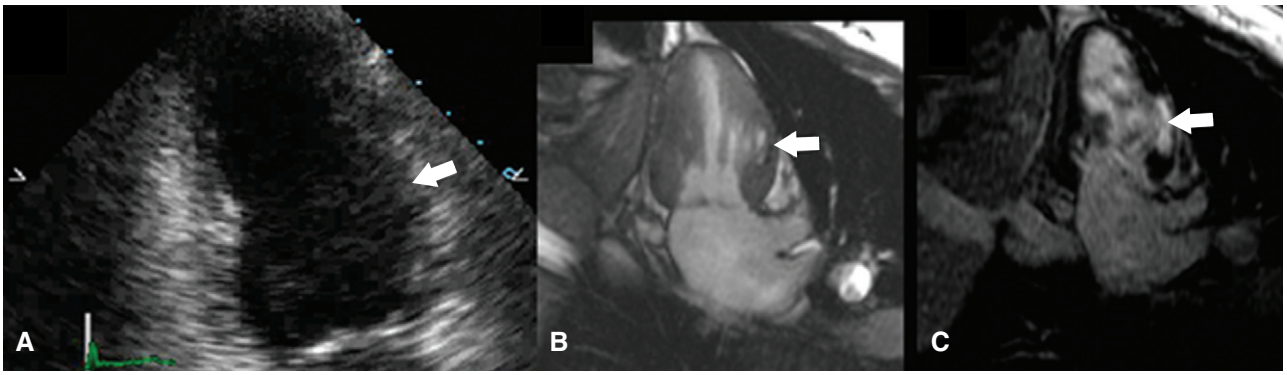

FIGURE 65-7. Images from a patient with an area of scar in the anterior left ventricular wall. A, Echocardiography shows a region of akinesis *(arrow)*. **B,** Cardiac magnetic resonance imaging shows the same area of akinesis *(arrow)*. **C,** Magnetic resonance imaging after administration of gadolinium contrast shows a region of delayed enhancement *(arrow)* consistent with scar.

IDIOVENTRICULAR RHYTHMS

Three or more ventricular beats at a rate slower than 100 beats/minute is an *idioventricular rhythm*. Automaticity is the likely mechanism. Idioventricular rhythms are common during acute MI (Chapter 73), when atropine therapy is occasionally indicated, and are seen as an escape rhythm during bradycardias. This rhythm is more common in patients with cardiomyopathies or sleep apnea, and it also can be idiopathic, often emerging when the sinus rate slows during sleep. Therapy targets any underlying cause and correction of bradycardia (Chapter 64).

SUSTAINED MONOMORPHIC VENTRICULAR TACHYCARDIA

CLINICAL MANIFESTATIONS

Sustained monomorphic VT presents as a wide QRS tachycardia. Presentations include palpitations, dyspnea, lightheadedness, syncope (Chapters 50 and 62), cardiac arrest, and sudden death (Chapter 63). During cardiac arrest, VT often deteriorates to VF, which may be the initial cardiac rhythm recorded. Structural heart disease with ventricular scarring that allows re-entry is the most common cause. Scars can be due to prior MI (Chapter 73), cardiomyopathies (Chapter 60), sarcoidosis (Chapter 95), and prior ventricular surgery, such as repair of tetralogy of Fallot (Chapter 69). Less commonly, VT is related to re-entry or automaticity in a diseased Purkinje system. Idiopathic VT occurs in the absence of structural heart disease. Management is determined by the underlying heart disease and the frequency and severity of symptoms.

DIAGNOSIS

All patients with monomorphic VT must be evaluated for possible underlying heart disease. When left ventricular function is depressed or there is evidence of structural myocardial disease, scar-related re-entry is the most likely diagnosis. Scars are suggested by pathologic Q waves on the ECG (see Fig. 73-1 in Chapter 73), segmental left or right ventricular wall motion abnormalities on echocardiogram (Fig. 65-7) or nuclear imaging, and areas of delayed gadolinium enhancement during magnetic resonance imaging (see Fig. 65-7). Patients who present with sustained VT associated with coronary artery disease typically have had large MIs and may present years after the acute infarct with a remodeled ventricle and markedly depressed left ventricular function.

TREATMENT AND PROGNOSIS

Rx

Initial management is according to advanced cardiac life support (ACLS) guidelines (Chapters 7 and 63). Following restoration of sinus rhythm, hospitalization and evaluation to define underlying heart disease are required. Sustained monomorphic VT must be distinguished from supraventricular tachycardia with aberrancy (Chapter 64) to guide further therapy. The presence of AV dissociation is the most reliable maker for VT (see Fig. 65-3C), but P waves can be difficult to define, and 1:1 conduction from ventricle to atrium occurs in some VTs, so a 1:1 relationship of P waves to the QRS does not exclude the diagnosis of VT. A number of QRS morphologic criteria for distinguishing VT from supraventricular tachycardia with aberrancy (Table 65-2) have been described but are less reliable in patients with severe heart disease. The presence of underlying structural heart disease, particularly a history of prior MI, favors a diagnosis of VT rather than supraventricular tachycardia with aberrancy. An electrophysiologic study (Chapter 62) is sometimes required for definitive diagnosis.

Following restoration of sinus rhythm, assessment of cardiac biomarkers for evidence of MI (Chapter 72) is appropriate, but acute MI is rarely a cause of sustained monomorphic VT, and elevations in troponin or CK-MB are more likely to indicate MI that is secondary to hypotension and ischemia from the VT. Even when there is evidence of acute MI, a preexisting scar from previous MI should be suspected as the cause of the VT. Scar-related re-entry is not dependent on recurrent acute myocardial ischemia, so coronary revascularization cannot be anticipated to prevent recurrent VT, even when it may be appropriate for other indications (Chapter 74).

Scars provide a durable substrate for sustained VT, and up to 70% of patients have a recurrence of the arrhythmia within 2 years. Most patients with sustained monomorphic VT have depressed ventricular function, which is a risk factor for sudden death. ICDs reduce annual mortality from 12.3% to 8.8% and reduce arrhythmic deaths by 50% in patients with hemodynamically significant sustained VT or a history of cardiac arrest compared with pharmacologic therapy,[3] and they are usually warranted in such patients, provided that there is a reasonable expectation of survival with acceptable functional status for the next year after recovery from the VT episode. Chronic amiodarone therapy may be considered for patients who are not candidates for or who decline ICD placement.[4] Patients with frequent symptomatic VT require antiarrhythmic drug therapy or catheter ablation[5,6] to reduce recurrences.

Following ICD implantation, patients remain at risk for heart failure, recurrent ischemic events, and recurrent VT, with a 5-year mortality rate that exceeds 30%. Attention to therapies with survival benefit, including β-adrenergic blocking agents, angiotensin-converting enzyme inhibitors, and statins (Chapter 73) is critical.

Nonischemic Dilated Cardiomyopathy

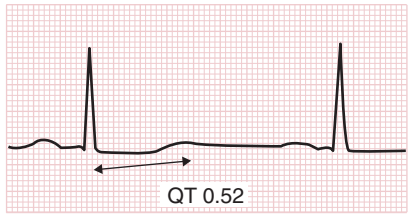
Sustained monomorphic VT associated with cardiomyopathy is usually due to areas of ventricular scar. The etiology of scar is often unclear, but progressive fibrosis is a potential cause. On magnetic resonance imaging, scars are detectable as areas of delayed gadolinium enhancement and are more often intramural or subepicardial in location compared with those in patients with prior MI. Scars that cause VT are often located adjacent to a valve annulus and can occur in either ventricle. Any cardiomyopathic process can cause scars and VT, but cardiac sarcoidosis (Chapters 60 and 95) and Chagas' disease (Chapter 355) are particularly associated with monomorphic VT. An ICD is usually warranted.[7] Antiarrhythmic drugs and catheter ablation are used to control recurrent episodes in patients with an ICD.

Arrhythmogenic Right Ventricular Cardiomyopathy

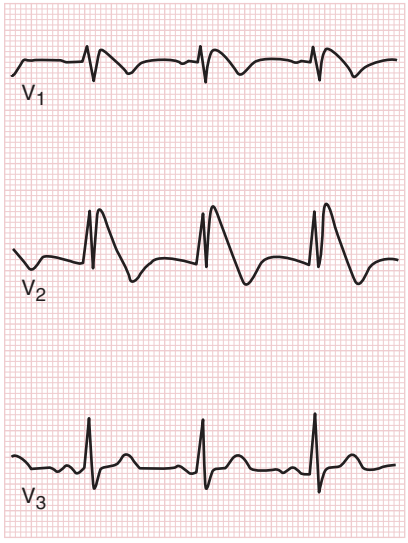
Arrhythmogenic right ventricular cardiomyopathy (ARVC) (Chapter 60) is a rare genetic disorder with an estimated prevalence of 1 in 5000. Patients typically present between the second and fifth decades with palpitations, syncope, or cardiac arrest owing to sustained monomorphic VT, although polymorphic VT can also occur. Most cases are due to genetic mutations involving desmosomal proteins, including plakoglobin, plakophilin-2, desmin, desmocollin, and desmoglein-2. Inheritance is usually autosomal

dominant with variable penetrance. Fibrosis and fibrofatty replacement of right ventricular myocardium, and less often the left ventricle, provide the substrate for reentrant VT that usually has a left bundle branch block–like configuration, consistent with a right ventricular origin.

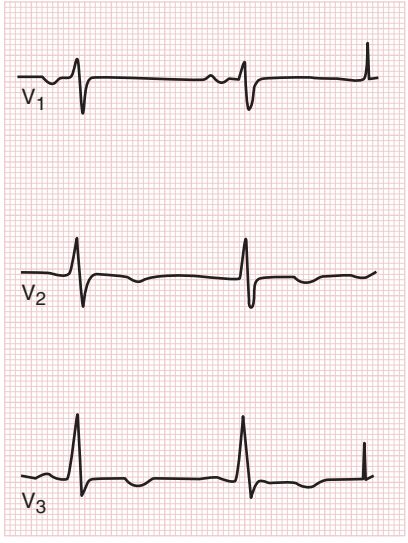
The sinus rhythm ECG suggests the disease in more than 90% of patients, most often showing T wave inversions in V_1 to V_3 (Fig. 65-8C). Delayed activation of the right ventricle may cause a widened QRS (≥110 msec) in the right precordial leads and a prolonged S wave upstroke in those leads. Cardiac imaging may show right ventricular enlargement or areas of abnormal motion, or reveal areas of scar on magnetic resonance imaging with gadolinium. Distinction from idiopathic right ventricular outflow tract VT can be difficult.



A



B



C

FIGURE 65-8. Sinus rhythm electrocardiogram findings in three genetic sudden death syndromes. A, QT prolongation during sinus rhythm in a patient with long QT syndrome. **B,** ST elevation in V_1 and V_2 in a patient with Brugada's syndrome. **C,** T wave inversion in V_1-V_3 in a patient with arrhythmogenic right ventricular dysplasia.

Left ventricular function is usually preserved, heart failure is rare, and survival to advanced age can be anticipated provided that VT can be controlled. An ICD is routinely recommended. When VT is exercise induced, it may respond to β-adrenergic blockers and prohibition of exercise. Sotalol, amiodarone, and catheter ablation have been used to reduce recurrences.

Tetralogy of Fallot

Ventricular tachycardia occurs in approximately 3 to 14% of patients late after repair of tetralogy of Fallot (Chapter 69) and contribute to a 2% per decade risk of sudden death. Factors associated with VT risk include age more than 5 years at repair, high-grade ventricular ectopy, inducible VT on an electrophysiologic study, abnormal right ventricular hemodynamics, and sinus rhythm QRS duration of more than 180 msec. An ICD is usually warranted for patients who have a spontaneous episode of VT, but criteria for a prophylactic ICD in other patients has not been established.

Bundle Branch Re-entry Ventricular Tachycardia

Re-entry through the Purkinje system occurs in approximately 5% of patients with monomorphic VT in the presence of structural heart disease. The re-entry circuit typically revolves retrograde up the left bundle and anterograde down the right bundle, thereby producing VT that has a left bundle branch block configuration. Catheter ablation of the right bundle branch abolishes this VT. Other scar-related VTs are often present and may require additional therapy.

IDIOPATHIC MONOMORPHIC VENTRICULAR TACHYCARDIA

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Idiopathic VT in patients without structural heart disease usually presents with palpitations, lightheadedness, and occasionally syncope, often provoked by sympathetic stimulation during exercise or emotional upset. The QRS morphology of the arrhythmia suggests the diagnosis (see later). The sinus rhythm ECG is normal. Cardiac imaging shows normal ventricular function and no evidence of ventricular scar. Occasionally, a patient with structural heart disease is found to have concomitant idiopathic VT, unrelated to the structural disease. Sudden death is rare.

TREATMENT

Rx

Treatment is required for symptoms or when frequent or incessant arrhythmias depress ventricular function. β-Adrenergic blockers are first-line therapy. Nondihydropyridine calcium-channel blockers (diltiazem and verapamil) are sometimes effective. Catheter ablation is warranted for severe symptoms or when β-blockers or calcium-channel blockers are not effective or not desired. Efficacy and risks of catheter ablation vary with the specific site of origin of the VT, being most favorable for arrhythmias originating in the right ventricular outflow tract.

Outflow tract VTs originate from a focus, usually with features consistent with triggered automaticity. The arrhythmia may present with sustained VT, nonsustained VT or PVCs, often provoked by exercise or emotional upset. Repeated bursts of nonsustained VT, which may occur incessantly, are known as repetitive monomorphic VT and can cause tachycardia-induced cardiomyopathy with depressed ventricular function that recovers after suppression of the arrhythmia.

Origin in the right ventricular outflow tract, which is the most common site of origin, gives rise to VT that has a left bundle branch block configuration in V_1 and an axis that is directed inferiorly, with tall R waves in leads II, III, and aVF (see Fig. 65-5). The arrhythmia can also arise in the left ventricular outflow tract or in sleeves of myocardium that extend along the aortic root. Left ventricular origin should be suspected when lead V_1 or V_2 has prominent R waves. Although the typical outflow tract QRS morphology favors idiopathic VT, cardiomyopathies can also cause PVCs or VT from this region; in such cases, management is the same as for arrhythmias in patients with structural heart disease (see earlier).

Left ventricular intrafascicular verapamil-sensitive VT arrhythmia presents with sustained VT that has a right bundle branch block–like configuration. It is often exercise induced and occurs more often in men than women. The mechanism is re-entry in or near the septal ramifications of the left ventricular Purkinje system. VT can be terminated by intravenous administration of verapamil, although chronic therapy with oral verapamil is not always effective. Catheter ablation is recommended if β-adrenergic blockers or calcium-channel blockers are ineffective or not desired.

TABLE 65-3 POLYMORPHIC VENTRICULAR TACHYCARDIA

ETIOLOGY	MECHANISM/CAUSES	CLINICAL FEATURES
Acute myocardial infarction/ischemia	Re-entry through the ischemic border zone	VT degenerating to VF, greatest risk during the first hour of infarction Common cause of sudden death
Ventricular hypertrophy, cardiomyopathy, heart failure, myocarditis	Multiple factors likely contribute (ion channel remodeling, abnormal calcium handling, ischemia)	Sudden death
Idiopathic VF		PVCs from the Purkinje system or RVOT initiating VF
Idiopathic VT with acquired QT prolongation	Early afterdepolarizations Bradycardia Hypokalemia, hypomagnesemia, hypocalcemia Antiarrhythmic drugs: disopyramide, dofetilide, ibutilide, procainamide, quinidine, sotalol, amiodarone (rare) Psychotropic drugs: haloperidol, droperidol, phenothiazines, pimozide, mesoridazine, tricyclic antidepressants Antibiotics: chloroquine, erythromycin, pentamidine, halofantrine, sparfloxacin, trimethoprim-sulfamethoxazole Other drugs: arsenic, methadone, others	Torsades de pointes causing syncope or cardiac arrest
GENETIC SUDDEN DEATH SYNDROMES		
Congenital long QT syndrome LQTS-1 LQTS-2 LQTS-3	Abnormal gene and ion current *KCNQ1* Iks *KCNQ2* Ikr *SCN5A* Ina	Sudden death or syncope due to torsades de pointes Events during swimming, exertion Events with emotional or auditory stimuli Events at rest and sleep
Short QT syndrome	Mutations affecting IKr, IKs, IK1	QTc < 320 msec
Brugada's syndrome	*SCN5A* mutations affecting INa account for approximately 25% of cases	J-point elevation in leads V_1-V_3 Events at night, during fever
Catecholaminergic polymorphic VT	Mutations affecting the ryanodine receptor or calsequestrin	Events during exertion or emotional upset

LQTS = long QT syndrome; PVC = premature ventricular contraction; RVOT = right ventricular outflow tract; VF = ventricular fibrillation; VT = ventricular tachycardia.

POLYMORPHIC VENTRICULAR TACHYCARDIA

Sustained polymorphic VT (see Fig. 65-4A) can be seen with any form of structural heart disease. However, unlike sustained monomorphic VT, polymorphic VT does not always indicate a structural abnormality or focus of automaticity. Re-entry with multiple or moving wave fronts, spiral wave re-entry (see Fig. 65-2), and multiple automatic foci are potential mechanisms. Sustained polymorphic VT usually degenerates rapidly into VF. Causes include acute MI or ischemia, ventricular hypertrophy, and a number of gene mutations that affect cardiac ion channels (Table 65-3).

Acute Myocardial Infarction and Ischemia

Acute MI or ischemia is a common cause of polymorphic VT and always should be considered immediately. Approximately 10% of patients with acute MI develop VT that degenerates to VF, related to re-entry through the infarct border zone. The risk is greatest in the first hour of acute MI. Following resuscitation (Chapter 63), management is as for acute MI (Chapter 73). β-Adrenergic blockers, intravenous amiodarone, and correction of hypokalemia and hypomagnesemia are warranted. Repeated episodes of polymorphic VT suggest ongoing myocardial ischemia and warrant assessment of whether coronary reperfusion has been re-established. Episodes that occur within the first 48 hours of acute MI do not necessarily confer a long-term risk, and long-term therapy usually is not required after recovery from the MI.

Acquired Long QT Syndrome

QT prolongation is associated with polymorphic VT that often has a characteristic waxing and waning QRS amplitude (see Fig. 65-4A) and is called *torsades de pointes* (twisting about the points). The VT often has a characteristic initiation sequence of PVCs that induces a pause, followed by a sinus beat that has a longer QT interval and interruption of the T wave by the PVC that is the first beat of the polymorphic VT. This characteristic initiation is called *pause dependent.* Causes of QT prolongation include electrolyte abnormalities, chronic bradycardia, and a large number of medications that block repolarizing potassium currents, notably the antiarrhythmic drugs sotalol, dofetilide, and ibutilide, but also a number of other medications used for noncardiac diseases, including erythromycin, pentamidine, haloperidol, phenothiazines, and methadone (see Table 65-3). Individual susceptibility may be related to genetic polymorphisms or mutations that influence repolarization.

Patients present with near-syncope, syncope, or cardiac arrest. Sustained episodes degenerate to VF requiring defibrillation. PVCs and nonsustained VT often precede episodes of sustained VT. Prevention of further episodes can usually be achieved by administration of 1 to 2 g of $MgSO_4$ intravenously. If bradycardia is present, the heart rate should be increased sufficiently to suppress PVCs, often to 100 beats per minute, with temporary pacing or administration of isoproterenol (starting at 1 μg/minute and titrating to the desired heart rate, up to 10 μg/minute). Rapid pacing in addition to $MgSO_4$ (1 to 2 g) administration is sometimes required. Potential contributing factors should be corrected, including removal of all medications that prolong the QT interval and correction of electrolyte abnormalities. Drug interactions that elevate levels of the offending agent are an important cause. Patients who experience a polymorphic VT induced by QT prolongation should be considered to have a susceptibility to the arrhythmia, and medications known to prolong the QT interval are contraindicated.

Congenital Long QT Syndrome

The congenital long QT syndrome (LQTS) is caused by mutations that interfere with ventricular repolarization, prolong the QT interval, and predispose to polymorphic VT. The syndrome is rare, with a prevalence of approximately 1 in 7000. The most frequently encountered mutations, LQTS-1 and -2 (see Table 65-3), cause abnormalities of potassium channels, but mutations affecting the sodium channel (LQTS-3) and calcium channels have also been described.

Patients present with syncope or cardiac arrest, often in childhood. In LQTS-1, episodes tend to occur during exertion, particularly swimming. In LQTS-2, sudden auditory stimuli or emotional upset predispose to events. Asymptomatic patients may be discovered in the course of family screening or on a routine ECG. Penetrance is variable, such that the QT interval is usually, but not always, prolonged to more than 0.44 second (see Fig. 65-8A). LQTS-1 responds well to chronic therapy with β-adrenergic blockers (e.g., nadolol, 0.5 to 3.5 mg/kg daily). ICDs are recommended for patients with arrhythmias despite β-adrenergic blocker therapy or other high-risk disease features, including a (QTc > 0.5 second). Family members of the proband should be screened with an ECG. The type of LQTS identified by genetic testing can help guide management decisions and family screening, but the clinical utility of genotype-phenotype correlations are still being defined. All

mutations have not been identified, and failure to identify a known mutation does not exclude the syndrome.

Brugada's Syndrome and Other Repolarization Syndromes

Brugada's syndrome is a rare familial syndrome characterized on the ECG by more than 0.2 mV of ST segment elevation with a coved ST segment and negative T wave in more than one anterior precordial lead (V_1 to V_3) (see Fig. 65-8B) and clinically by episodes of polymorphic VT that present as syncope or cardiac arrest in the absence of structural heart disease. Cardiac arrest may occur during sleep or be provoked by febrile illness. Males are more commonly affected than females. Mutations involving cardiac sodium channels are identified in approximately 25% of cases. Distinction from patients with similar ST elevation owing to left ventricular hypertrophy, pericarditis (Chapter 77), myocardial ischemia or MI (Chapter 72), hyperkalemia (Chapter 119), hypothermia (Chapter 109), right bundle branch block (see Fig. 54-8B in Chapter 54), and ARVC is often difficult. Furthermore, the characteristic ST segment elevation can wax and wane over time. Administration of sodium-channel blocking drugs, such as flecainide, causes further ST elevation in affected individuals. An ICD is recommended. Quinidine has been used successfully to suppress frequent VT.

The short QT syndrome is a very rare familial disorder characterized by a short QTc interval (<0.32) and susceptibility to polymorphic VT and sudden death due to mutations involving cardiac potassium channels. Rare patients with idiopathic polymorphic VT and VF associated with ST elevation in inferior and lateral ECG leads have been reported. This type of ECG pattern, known as *early repolarization,* can also be a normal variant.

Catecholaminergic Polymorphic Ventricular Tachycardia

This rare familial syndrome causes exercise-induced PVCs, a characteristic VT with alternating QRS morphologies termed *bidirectional tachycardia*, polymorphic VT, and VF. Mutations involving the cardiac ryanodine receptor and calsequestrin are identified causes. Patients usually present during childhood with exercise- or emotion-induced palpitations, syncope, or cardiac arrest. β-Adrenergic blockers (e.g., nadolol, 1 to 2 mg/kg/day, or propranolol, 2.5 to 3.5 mg/kg/day) and an implantable defibrillator are recommended. Verapamil (240 to 480 mg daily), or flecainide (50 to 100 mg twice daily), or surgical left cardiac sympathetic denervation reduces or prevents recurrent VT in some patients.

VENTRICULAR FIBRILLATION

VF is characterized by disordered electrical ventricular activation without identifiable QRS complexes (see Fig. 65-4C). Spiral wave re-entry (see Fig. 65-2) and multiple circulating re-entry wave fronts are possible mechanisms. Sustained polymorphic or monomorphic VT that degenerates to VF is a common cause of out-of-hospital cardiac arrest. Treatment follows ACLS guidelines (Chapters 7 and 63), with defibrillation to restore sinus rhythm. If resuscitation is successful, further evaluation is performed to identify and treat underlying heart disease and potential causes of the arrhythmia, including the possibility that VF was initiated by monomorphic or polymorphic VT. If a transient reversible cause, such as acute MI, is not identified, therapy to reduce the risk of sudden death is often warranted. An ICD is often warranted provided the patient has reasonable expectation for survival over the following year with acceptable functional capacity. Chronic amiodarone therapy may be considered for individuals who are not ICD candidates.■

INCESSANT VENTRICULAR TACHYCARDIA AND ELECTRICAL STORM

VT is incessant when it continues to recur shortly after electrical, pharmacologic, or spontaneous conversion to sinus rhythm. "VT storm" or "electrical storm" refers to three or more separate episodes of VT within 24 hours. Slow incessant VT is sometimes asymptomatic, but it can cause heart failure or tachycardia-induced cardiomyopathy. More commonly, these presentations are life-threatening and require emergent therapy. Measures to reduce sympathetic tone, including β-adrenergic blockade, sedation, and general anesthesia, have been used effectively. Intravenous administration of amiodarone can be effective. Urgent catheter ablation can be life-saving. Rare patients with idiopathic VF due to rapid polymorphic VT from the Purkinje system or outflow tract in the absence of heart disease benefit from catheter ablation of the initiating focus.

VENTRICULAR ARRHYTHMIAS IN PATIENTS WITH IMPLANTABLE DEFIBRILLATORS

ICDs effectively terminate VT when it occurs and markedly reduce the risk of death from arrhythmias. ICDs do not, however, prevent the arrhythmia. ICDs can be programmed to provide antitachycardia pacing in an attempt to terminate VT by rapid pacing (Fig. 65-9B), which is painless and often asymptomatic. If antitachycardia pacing fails or is not a programmed treatment for rapid VT or VF, an ICD shock is administered. Interrogation of the ICD, which commonly can be performed remotely and communicated by the Internet, allows assessment of any arrhythmias detected by the ICD and of therapies delivered (Fig. 65-9).

Despite effective termination of VT by the ICD, the occurrence of VT predicts an increased risk of mortality and heart failure. VT episodes can be evidence of deteriorating heart failure or myocardial ischemia. Evaluation for progression of heart disease and optimization of medical therapy are warranted.

ICD shocks are painful, reduce quality of life, and can cause post-traumatic stress syndrome. Patients with recurrent episodes of symptomatic VT warrant therapy to prevent episodes. Amiodarone is more effective than β-adrenergic blockers or sotalol.[5] Changes in antiarrhythmic drug therapy can alter the VT rate and the energy required for defibrillation, thereby necessitating programming changes in the ICD algorithms for detection and therapy. Catheter ablation reduces episodes of VT in more than 70% of patients with monomorphic VT.[6]

ANTIARRHYTHMIC DRUGS FOR VENTRICULAR ARRHYTHMIAS

Use of antiarrhythmic drugs (see Table 64-5 in Chapter 64 for dosing) is based on consideration of the risks and potential benefit for individual patients. Many drugs have the potential to induce "proarrhythmia," thereby increasing the frequency of the arrhythmia or causing a new arrhythmia, such as torsades de pointes for QT interval–prolonging drugs.

β-Adrenergic Blockers

Many ventricular arrhythmias are sensitive to sympathetic stimulation, and β-adrenergic stimulation also diminishes the electrophysiologic effects of many antiarrhythmic drugs. The safety of β-blocking agents makes them the first choice of therapy for most ventricular arrhythmias. They are particularly effective for exercise-induced arrhythmias and idiopathic arrhythmias. Bradyarrhythmias are the major cardiac toxicity.

Calcium-Channel Blockers

The nondihydropyridine calcium-channel blockers diltiazem and verapamil can be effective for ventricular arrhythmias and for some idiopathic ventricular arrhythmias.

Sodium-Channel Blockers

Antiarrhythmic drugs with prominent sodium-channel blocking effects can suppress ventricular arrhythmias. Mexiletine, quinidine, disopyramide, flecainide, and propafenone are available for chronic oral therapy. Quinidine, disopyramide, and procainamide also have potassium-channel blocking effects that prolong the QT interval. These agents have potential proarrhythmic effects and, with the possible exception of quinidine, also have negative inotropic effects that may contribute to the increased mortality observed in patients with prior MI. Long-term therapy is generally avoided in patients with structural heart disease but may be used to reduce symptomatic arrhythmias in some patients with ICDs. Lidocaine and procainamide can be used for acute intravenous therapy.

Potassium-Channel Blockers

Sotalol and dofetilide block the delayed rectifier potassium channel IKr, thereby prolonging the QT interval. Sotalol also has nonselective β-adrenergic blocking activity. Sotalol has been shown to reduce ICD shocks, but it is less effective than amiodarone for this purpose.■ Proarrhythmia with torsades de pointes occurs in 3% of patients. These drugs are excreted by the kidney, so dose adjustment is required according to renal function. These drugs must be avoided in patients with other risk factors for torsades de pointes, including QT prolongation and hypokalemia.

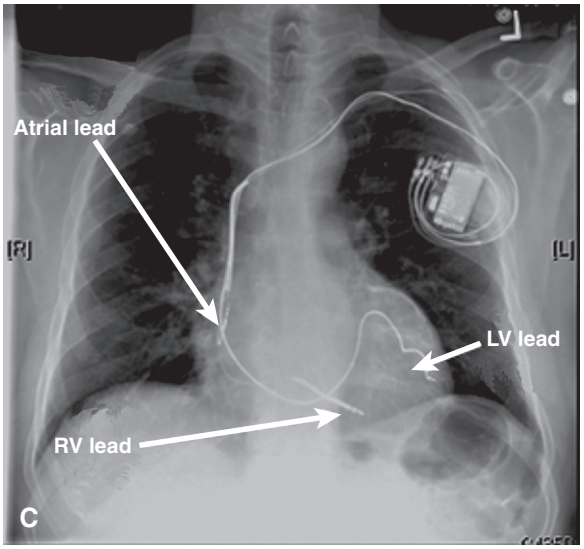

FIGURE 65-9. Implantable cardioverter-defibrillator (ICD). A, An electrocardiogram (ECG) tracing of sustained monomorphic ventricular tachycardia (VT) terminated by a shock from an ICD. **B,** Two-lead ECG tracing showing sustained monomorphic VT that is detected by the implanted ICD. A burst of rapid pacing terminates VT. The ICD then provides atrioventricular (A-V) pacing to prevent bradyarrhythmia. **C,** Anterior-posterior radiograph showing an ICD that incorporates a lead to the right atrium, right ventricular (RV) apex, and through the coronary sinus to an epicardial vein over the lateral left ventricle (LV). The pulse generator is evident in the left infraclavicular region.

Amiodarone and Dronedarone

Amiodarone, which blocks multiple cardiac ionic currents and has sympatholytic activity, suppresses a variety of ventricular arrhythmias. It is administered intravenously for life-threatening arrhythmias. During chronic oral therapy, electrophysiologic effects develop over several days, depending on dosing. It is more effective than sotalol in reducing ICD shocks and is the preferred drug in patients who are not candidates for an ICD.[3,4] Bradyarrhythmia is the major cardiac adverse effect. Ventricular proarrhythmia can occur, but torsades de pointes is uncommon. Noncardiac toxicities contribute to drug discontinuation in approximately one third of patients during long-term therapy. Pneumonitis or pulmonary fibrosis occurs in approximately 1% of patients. Photosensitivity is common, and neuropathy and ocular toxicity can occur. Systematic monitoring is recommended during chronic therapy: assessment for thyroid and liver toxicity with thyroid-stimulating hormone and aminotransferase levels every 6 months, and lung toxicity with a chest radiograph and determination of lung diffusing capacity annually. In a randomized study, dronedarone, which is related to amiodarone but without iodine in it, resulted in a 2.13-fold increase in mortality in patients with heart failure.[7,8]

ELECTROPHYSIOLOGIC INTERVENTIONAL PROCEDURES AND SURGERY

FRED MORADY

PACEMAKERS

Pacemaker Generators and Leads

Pacemaker batteries, which are lithium iodide cells that typically have a lifespan of 7 to 8 years, now often weigh less than 30 g. They are usually implanted subcutaneously in the infraclavicular area (Fig. 66-1). The programmability of many different variables has become standard, as has the ability of the pacemaker to provide diagnostic and telemetric data.

Pacemaker leads are generally bipolar, with the distal electrode serving as the cathode. Unipolar leads are less commonly used because of the potential for pacing chest wall muscles and for inhibition of pacing by skeletal muscle myopotentials. The leads are inserted into the heart either percutaneously through a subclavian vein or by cutdown into a cephalic vein. Atrial leads are usually positioned in the right atrial appendage, and ventricular leads are placed in the right ventricular apex. Fixation to the myocardium is achieved either passively with tines or actively with a screw mechanism. Newer lead and electrode designs, such as high-impedance leads and carbon-tipped electrodes, have resulted in lower acute and chronic pacing thresholds.

FIGURE 66-1. Site of implantation of a permanent pacemaker or automatic implantable cardioverter-defibrillator. The pacemaker is usually implanted in the left pectoral region, but it may be placed elsewhere if necessary. (From Forbes CD, Jackson WF. *Color Atlas and Text of Clinical Medicine,* 3rd ed. London: Mosby; 2003.)

Pacing Modes

The mode of pacing is described in shorthand fashion by a three- to five-letter code. The first letter designates the chamber being paced (A for atrium, V for ventricle, D for dual chamber); the second letter designates the chamber in which the depolarizations are sensed by the pacemaker (A, V, D, or O for no sensing); the third letter designates whether the pacemaker functions in an inhibited (I) or tracking mode (T), in both modes (D), or asynchronously (O); and the fourth letter indicates whether the pacemaker is capable of rate modulation independent of atrial activity. An additional fifth letter may be used to designate the capability for antitachycardia pacing (P), delivery of shocks (S), or both (D). The most commonly used pacing modes are VVI (pacing and sensing within the ventricle in inhibited fashion), VVIR (VVI plus rate responsiveness), and DDD (pacing and sensing of the atrium and ventricle in both inhibited and tracking fashion).

The most appropriate pacing mode must always be determined on an individual basis, the goal being to meet the patient's physiologic needs with the simplest system possible. For example, in a patient with chronic atrial fibrillation who has symptomatic pauses but not chronotropic incompetence, a VVI pacemaker is sufficient. However, if the patient also has chronotropic incompetence, a VVIR pacemaker is necessary to restore a normal rate response to exercise. In a patient with a high-degree atrioventricular (AV) block and normal sinus node function, DDD pacing is optimal. However, if a patient with a high-degree AV block also has sinus node dysfunction, the ideal pacing mode is DDDR.

In patients who have paroxysmal atrial fibrillation and a high-degree AV block, no single pacing mode is optimal. DDD pacing is ideal when the patient is in sinus rhythm, but during atrial fibrillation, DDD pacing may result in tracking of the atrium at the upper rate limit of the pacemaker. Conversely, VVIR pacing, which is ideal during atrial fibrillation, will not provide AV synchrony during periods of sinus rhythm. The development of mode-switching pacemakers has solved this dilemma. Mode-switching pacemakers are capable of pacing in the DDD mode during sinus rhythm and automatically switching to rate-responsive ventricular pacing during atrial fibrillation or other supraventricular arrhythmias (Fig. 66-2).

The choice between ventricular (VVIR) and atrial (AAIR) or dual-chamber (DDDR) pacing remains controversial. Although a randomized trial of 225 patients with sinus node dysfunction reported a significant reduction in cardiovascular death at 8 years with AAIR versus VVIR pacing,■ studies of nearly 5000 patients have shown no survival differences when patients were randomized to DDDR or VVIR pacing. Dual-chamber pacing, like atrial pacing, reduces the incidence of atrial fibrillation and appears to result in slightly better quality of life.■ In these randomized trials, 5 to 25% of patients who initially received VVIR pacemakers "crossed over" to DDDR pacing because of physician-diagnosed pacemaker syndrome (see Complications of Pacemakers).

Several studies have demonstrated that the ventricular dyssynchrony induced by right ventricular pacing may have deleterious effects on ventricular function and functional capacity and may also predispose to the development of atrial fibrillation. Therefore, pacemakers should always be programmed to minimize the amount of ventricular pacing.

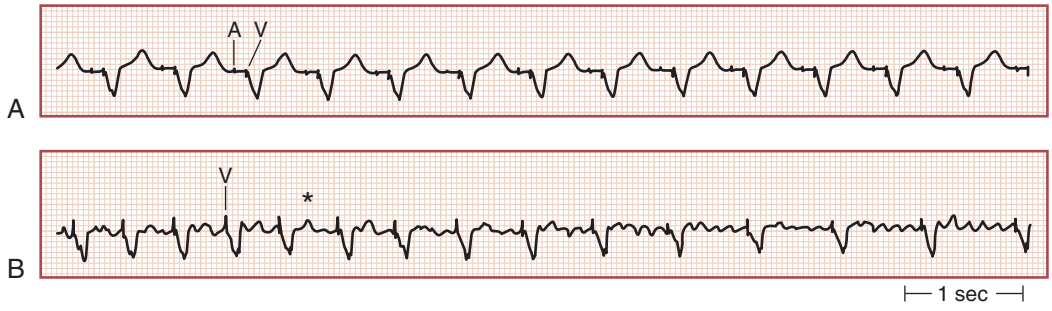

FIGURE 66-2. Rhythm strips from a Holter monitor in a patient with complete atrioventricular block, sinus bradycardia, paroxysmal atrial fibrillation, and a rate-responsive dual-chamber pacemaker with mode-switching capability. A, When the patient is in sinus rhythm, the pacemaker functions in a DDDR mode, with synchronized atrial and ventricular pacing at 105 beats per minute while the patient is walking. **B,** At the onset of an episode of atrial fibrillation, there is tracking of the atrium that results in ventricular pacing at 140 beats per minute, which is the upper rate limit of the pacemaker. Within 2 seconds *(asterisk),* the mode-switch feature results in VVIR pacing, and the ventricular pacing rate gradually falls to 70 beats per minute, which is the lowest rate limit of the pacemaker. A = atrial stimulus; V = ventricular stimulus.

TABLE 66-1 CLASS I INDICATIONS* FOR IMPLANTATION OF A PERMANENT PACEMAKER

SINUS NODE DYSFUNCTION

1. Symptomatic sinus bradycardia
2. Symptomatic chronotropic incompetence
3. Symptomatic sinus bradycardia resulting from required drug therapy

ATRIOVENTRICULAR (AV) BLOCK

1. Third-degree and advanced second-degree AV block associated with symptomatic bradycardia
2. Third-degree and advanced second-degree AV block in an awake patient with asystole of >3 seconds or an escape rate of <40 beats per minute or with an infranodal escape rhythm
3. Atrial fibrillation with a pause of ≥5 seconds
4. Third-degree and advanced second-degree AV block due to postoperative AV block that is not expected to resolve
5. Third-degree and advanced second-degree AV block with neuromuscular diseases such as myotonic muscular dystrophy, Kearns-Sayre syndrome, and Erb dystrophy
6. Asymptomatic third-degree AV block if cardiomegaly or left ventricular dysfunction is present, or if the block is below the AV node

CHRONIC BIFASCICULAR BLOCK

1. Advanced second-degree or intermittent third-degree AV block
2. Type II second-degree AV block
3. Alternating bundle branch block

AFTER ACUTE PHASE OF MYOCARDIAL INFARCTION

1. Second-degree infranodal AV block with alternating bundle branch block
2. Third-degree infranodal AV block
3. Transient advanced second-degree or third-degree infranodal AV block and associated bundle branch block
4. Persistent symptomatic second-degree or third-degree AV block

CAROTID SINUS SYNDROME

1. Recurrent syncope caused by spontaneous carotid sinus stimulation or carotid sinus pressure that induces asystole of >3 seconds in duration

*Class I indications are conditions for which a pacemaker is indicated.
Adapted from Epstein AE, DiMarco JP, Ellenbogen KA, et al. ACC/AHA/HRS 2008 guidelines for device-based therapy of cardiac rhythm abnormalities: executive summary. *J Am Coll Cardiol.* 2008;51:2085-2105.

TABLE 66-2 CLASS IIA INDICATIONS* FOR IMPLANTATION OF A PERMANENT PACEMAKER

SINUS NODE DYSFUNCTION

1. Heart rate of <40 beats per minute when a clear association between symptoms consistent with bradycardia and the actual presence of bradycardia has not been demonstrated
2. Syncope of unclear etiology when sinus node dysfunction is demonstrated by electrophysiologic testing

ATRIOVENTRICULAR (AV) BLOCK

1. Persistent third-degree AV block with an escape rate of >40 beats per minute in an asymptomatic adult without cardiomegaly
2. Asymptomatic second-degree infranodal AV block
3. First-degree or second-degree AV block associated with symptoms similar to pacemaker syndrome
4. Asymptomatic type II second-degree AV block with a narrow QRS

CHRONIC BIFASCICULAR BLOCK

1. Syncope, when other potential causes of syncope have been excluded
2. An HV interval of ≥100 msec
3. Pathologic pacing-induced infranodal AV block during electrophysiologic testing

CAROTID SINUS SYNDROME

1. Syncope without clear provocative events and with asystole of >3 seconds during carotid sinus pressure

*Class IIA indications are conditions for which a pacemaker is reasonable.
Adapted from Epstein AE, DiMarco JP, Ellenbogen KA, et al. ACC/AHA/HRS 2008 guidelines for device-based therapy of cardiac rhythm abnormalities: executive summary. *J Am Coll Cardiol.* 2008;51:2085-2105.

Indications for a Permanent Pacemaker

In general, pacemakers are implanted either to alleviate symptoms caused by bradycardia or to prevent severe symptoms in patients in whom symptomatic bradycardia is likely to develop (Tables 66-1 and 66-2). The most common bradycardia-induced symptoms are dizziness or lightheadedness, syncope or near-syncope (Chapters 50 and 62), exercise intolerance, and symptoms of heart failure. Because these symptoms are nonspecific, documentation of an association between symptoms and bradycardia should be obtained before pacemaker implantation. If the bradycardia is persistent, such as in a patient with a complete AV block, a simple electrocardiogram may be sufficient to document the need for a pacemaker. If the bradycardia is intermittent, other diagnostic testing, such as 24-hour ambulatory monitoring, a continuous loop recorder, an implantable event monitor, or an electrophysiology test (Chapter 62), may be needed to document a relationship between symptoms and bradycardia.

After a symptomatic bradycardia has been documented, a correctable cause for the bradycardia should be excluded before a pacemaker is implanted. Correctable causes of symptomatic bradycardia include hypothyroidism, an overdose with drugs such as digitalis, electrolyte disturbances, and several categories of medications, most commonly β-adrenergic blocking agents (administered either orally or in the form of eyedrops for glaucoma), calcium-channel blocking agents, and antiarrhythmic medications (Chapter 64). At times, a pacemaker is necessary to allow continued treatment with a medication that is responsible for the bradycardia, such as in a patient in whom symptomatic sinus bradycardia develops after initiation of therapy with a β-adrenergic blocking agent for paroxysmal atrial fibrillation associated with a rapid ventricular response.

Complications of Pacemakers

Complications related to the implantation procedure occur in less than 2% of patients and include pneumothorax, perforation of the atrium or ventricle, lead dislodgement, infection, and erosion of the pacemaker pocket. Thrombosis of the subclavian vein occurs in 10 to 20% of patients and is more likely in the presence of multiple leads; it rarely causes symptoms.

Pacemaker-mediated tachycardia is a possible complication of DDD pacing when the atrial lead senses retrograde depolarizations because of ventriculoatrial conduction. The resulting tachycardia often has a rate equal to the upper rate limit of the pacemaker. Pacemaker-mediated tachycardia can be eliminated by various reprogramming maneuvers, such as lengthening of the postventriculoatrial refractory period. Patients with dual-chamber pacemakers for sinus node disease are at risk for future atrial fibrillation. In a randomized study, minimizing dual-chamber ventricular pacing reduced the risk of atrial fibrillation by 40%.[3]

The pacemaker syndrome consists of symptoms of weakness, lightheadedness, exercise intolerance, or palpitations caused by the absence of AV synchrony during ventricular pacing. It is treated by restoring AV synchrony with DDD pacing or, if AV conduction is intact, with AAI pacing. During long-term follow-up after pacemaker implantation, potential problems include failure to pace, failure to capture, and changes in the pacing rate. These problems may be a manifestation of suboptimal programming, fracture of a lead or a break in the insulation, generator malfunction, or battery depletion.

Temporary Pacemakers

Temporary pacemaker leads are generally inserted percutaneously into an internal jugular or subclavian vein or by cutdown into a brachial vein and then positioned under fluoroscopic guidance in the right ventricular apex and attached to an external generator. Temporary pacing is used to stabilize patients awaiting permanent pacemaker implantation, to correct a transient symptomatic bradycardia caused by drug toxicity or a metabolic defect, or to suppress torsades de pointes by maintaining a rate of 85 to 100 beats per minute until the causative factor has been eliminated. Temporary pacing may also be used in prophylactic fashion in patients at risk for symptomatic bradycardia during a surgical procedure or high-degree AV block in the setting of an acute myocardial infarction. The most common complication of temporary pacemakers is infection; this risk is minimized by limiting the use of a pacemaker lead to 48 hours. In emergency situations, ventricular pacing can be instituted immediately by transcutaneous pacing with electrode pads applied to the chest wall.

TRANSTHORACIC CARDIOVERSION AND DEFIBRILLATION

Mechanism of Action

Direct current defibrillators store an electrical charge and discharge it across two paddle electrodes in a damped, sinusoidal waveform. The shock terminates arrhythmias caused by re-entry by simultaneously depolarizing large portions of the atria or ventricles, thereby causing the re-entry circuits to extinguish (Chapters 61, 64, and 65).

A nonsynchronized shock that is delivered coincident with the T wave during supraventricular tachycardia (SVT) or ventricular tachycardia (VT) may precipitate ventricular fibrillation (VF). *Cardioversion* refers to the termination of SVT or VT by delivery of a shock in synchrony with the QRS complex. When shocks are delivered to terminate VF, synchronization to the QRS complex is not necessary, and this process is referred to as *defibrillation.*

Technique

Whenever cardioversion or defibrillation is performed on an elective basis, the patient should be in a fasting state. Intravenous access to a peripheral vein should be established, and oxygen, suction, and equipment needed for airway management should be readily available. Transthoracic shocks are painful, and drugs commonly used for anesthesia or amnesia include short-acting barbiturates such as methohexital or a short-acting amnestic agent such as midazolam. In the anteroapical configuration, one electrode is positioned to the right of the sternum at the level of the second intercostal space, and the second electrode is positioned at the midaxillary line, lateral to the apical impulse. In the anteroposterior configuration, an electrode is placed to the left of the sternum at the fourth intercostal space, and the second electrode is positioned posteriorly, to the left of the spine, at the same level as the anterior electrode. These two-electrode configurations result in similar success rates of cardioversion and defibrillation.

Important variables affecting the success of cardioversion or defibrillation are the shock waveform and shock strength. Defibrillators that deliver biphasic shocks are now clinically available and have a significantly higher success rate than conventional defibrillators. Other technique-dependent variables that maximize delivery of energy to the heart include firm paddle pressure, delivery of the shock during expiration, and repetitive shocks. Patient-related variables that may decrease the probability of successful cardioversion and defibrillation include metabolic disturbances, long arrhythmia duration, some antiarrhythmic drugs such as amiodarone, and body weight in excess of 80 kg.

Because cardioversion of atrial fibrillation (Chapter 64) may be complicated by thromboembolism, anticoagulation with warfarin is generally necessary for 3 weeks before cardioversion and for 1 month after cardioversion whenever atrial fibrillation has been present for 48 hours or longer. The 3-week period of anticoagulation before cardioversion can be eliminated if no atrial thrombi are seen on a transesophageal echocardiogram, but anticoagulation for 1 month after cardioversion is still necessary to prevent thrombus formation secondary to transient, postconversion atrial stunning.

Indications

The most common arrhythmias treated by cardioversion and defibrillation are VF, VT, atrial fibrillation, and atrial flutter (Chapters 63, 64, and 65). Treatment of VF is always an emergency, and a 200-J shock should be delivered as quickly as possible, followed by one or more 360-J shocks if necessary. Depending on the patient's hemodynamic status, cardioversion of VT may be performed electively or on an emergency basis; if elective, an initial shock strength of 50 J is appropriate, followed by higher energy levels if additional shocks are needed. An initial energy level of 50 J is appropriate for cardioversion of atrial flutter. In atrial fibrillation, in which cardioversion is generally performed on an elective basis, an initial shock of 100 to 200 J is appropriate, depending on the patient's body weight. Shocks of 300 to 360 J are then used if necessary. If atrial fibrillation must be treated on an urgent basis, for example, in a patient with Wolff-Parkinson-White syndrome who has a very rapid ventricular rate and hemodynamic compromise, an initial shock of 200 J should be followed by 360-J shocks, as needed. Because the defibrillation energy requirement is a probability function and not a discrete value, subsequent shocks may be effective for cardioversion and defibrillation even when the first 360-J shock is ineffective.

Complications

Asynchronous shocks may precipitate VF. Rarely, VF may occur even when shocks are synchronized to the QRS complex. The risk for post-shock ventricular arrhythmias is increased in the presence of a supratherapeutic plasma concentration of digitalis, so cardioversion in patients with digitalis toxicity should be avoided.

Transient ST segment elevation may occur after cardioversion and is usually of no clinical consequence. Mild myocardial necrosis may occasionally occur if a total energy exceeding 425 J is delivered in a short period. Another rare complication of cardioversion is pulmonary edema, which may be due to transient left ventricular dysfunction.

Post-shock bradycardia or asystole may occur because of vagal discharge or an underlying sick sinus syndrome. At times, atropine or emergency transcutaneous pacing may be necessary. In patients who have a pacemaker or implantable cardioverter-defibrillator (ICD), the shocking electrodes should be positioned as far away from the generator as possible, and the generator and pacing threshold should be checked afterward.

IMPLANTABLE CARDIOVERTER-DEFIBRILLATORS

ICD Pulse Generators and Leads

ICDs now weigh as little as 60 g, are multiprogrammable, have improved detection algorithms, are capable of antitachycardia and antibradycardia (including dual-chamber) pacing, can deliver biphasic shocks at strengths of less than 1 to 42 J, and provide a record of the electrograms recorded during arrhythmic episodes. With the development of pulse generators small enough to implant in the infraclavicular area and endocardial leads that are inserted transvenously, the implantation procedure has been greatly simplified and is now very similar to that for permanent pacemakers.

ICDs that deliver shocks to terminate atrial fibrillation, as well as VT and VF, are clinically available. Biventricular ICDs are available for patients who need an ICD and have advanced (class III or IV) heart failure and a bundle branch block.

A single lead that contains a pacing-sensing electrode and two defibrillating coils can be used. If adequate defibrillation is not achieved with a single-lead configuration, a subcutaneous patch electrode or subcutaneous array can be added. In another commonly used configuration, the pulse generator itself functions as an electrode, and a lead that has a pacing-sensing electrode at its tip and a distal defibrillating coil electrode is positioned at the right ventricular apex. Multiple other combinations of a chest wall patch electrode and defibrillating electrodes in the right ventricular apex, superior vena cava, or coronary sinus can also be used. When a biventricular ICD is implanted, a lead is inserted into a branch of the coronary sinus for left ventricular pacing.

Indications

ICDs have become first-line therapy in patients who have survived an episode of VF not associated with acute myocardial infarction or who have had an episode of hemodynamically significant, sustained VT (Chapter 65).[I] ICDs are also implanted in individuals at high risk for cardiac arrest, including patients with idiopathic, dilated cardiomyopathy and unexplained syncope or patients with coronary artery disease (CAD), an ejection fraction of less than 35%, spontaneous episodes of nonsustained VT, and inducible sustained VT in the electrophysiology laboratory (Chapter 65).[I] Based on the results of large-scale clinical trials, the indications for implantation of an ICD include patients with a previous myocardial infarction and an ejection fraction of 30% or less, as well as patients with dilated cardiomyopathy (ischemic or nonischemic), an ejection fraction of 35% or less, and class II or III heart failure.[I,B]

Programming of ICDs

Testing is performed at the time of implantation to determine the energy requirement for defibrillation. A safety margin of at least 10 J should be present; for example, if the maximum output of the pulse generator is 32 J, successful defibrillation should be achieved with shocks of 22 J or less in strength. If the patient has had episodes of VT, antitachycardia pacing can be evaluated and programmed as needed to terminate the VT. Appropriate programming of the device is performed during predischarge testing.

With ICDs that are tiered-therapy devices, as many as two VT zones and one VF zone are available to provide individualized therapy for ventricular arrhythmias that have different rates. The rate threshold and various sequences of antitachycardia pacing and low- or high-energy shocks can be programmed for each of the two VT zones. The VF zone is a high-rate zone in which high-energy shocks are delivered. Optimal programming is important for many reasons, including minimizing patient discomfort, reducing the chance of

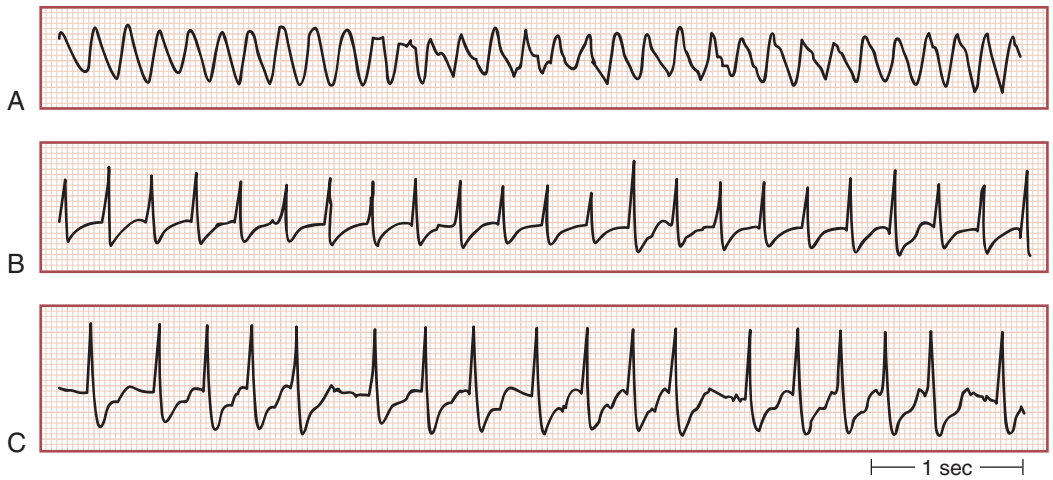

FIGURE 66-3. Examples of stored electrograms obtained several hours after three different patients had experienced a flurry of shocks from an implantable cardioverter-defibrillator and showing the rhythm recorded by the device immediately before a shock was delivered. A, In this patient, the stored electrogram demonstrates ventricular tachycardia at a rate of 300 beats per minute, thus indicating that the shock was appropriate. He was treated with amiodarone to reduce the frequency of episodes of ventricular tachycardia. **B,** This patient received shocks because of paroxysmal supraventricular tachycardia at a rate of 206 beats per minute, which exceeded the programmed rate cutoff of 170 beats per minute. He underwent radio frequency ablation of the paroxysmal supraventricular tachycardia and received no further inappropriate shocks. **C,** The stored electrograms in this patient indicate that the patient received inappropriate shocks that were triggered by atrial fibrillation at a rate of 180 beats per minute. The rate cutoff of the device in this patient was 150 beats per minute. This patient was treated with a β-blocker to keep the ventricular rate less than 150 beats per minute during atrial fibrillation.

syncope with an arrhythmia episode, maximizing the battery life of the pulse generator, and preventing inappropriate shocks.

Complications

Complications related to the implantation procedure include pneumothorax, myocardial perforation, and infection, all of which should have an incidence of less than 1%. Complications associated with the subcutaneous or submuscular pocket into which the device is placed include hematoma formation and erosion of the pocket. The endocardial leads that are used in the ICD system occasionally become dislodged shortly after implantation, thus necessitating a second procedure to reposition the leads. Other lead complications include fracture or breakdown of the insulation, either of which may result in failure to defibrillate. Fracture of a lead may also result in an artifact that mimics VF and triggers inappropriate shocks.

Patients who have an ICD do not require evaluation every time that they experience a device discharge. However, urgent evaluation is necessary if the patient experiences flurries of discharges. Analysis of stored electrograms often reveals the underlying problem (Fig. 66-3). The frequent shocks may be appropriate shocks triggered by flurries of VT or VF; if a correctable cause such as a metabolic defect or proarrhythmic drug cannot be identified, antiarrhythmic drug therapy or catheter ablation, or both, should be used to eliminate these arrhythmia flurries. Flurries of shocks may be triggered by atrial fibrillation with a rapid ventricular response, in which case aggressive management of the atrial fibrillation is indicated. In addition, flurries of shocks may be a manifestation of a lead fracture, in which case lead replacement is necessary.

RADIO FREQUENCY CATHETER ABLATION

Tissue Effects of Radio Frequency Energy

Radio frequency ablation is a percutaneous catheter technique that can permanently eliminate a variety of SVTs and VTs that previously required either chronic pharmacologic treatment for suppression or surgery for cure. Radio frequency energy is delivered through an electrode catheter whose tip is in contact with tissue that is critical to maintenance of the tachycardia. The radio frequency energy results in resistive heating of the tissue and irreversible tissue destruction when the tissue temperature exceeds 50° C. Depending on the type of catheter and the power settings, the lesions that are created are up to 7 to 8 mm in diameter and up to 6 to 8 mm deep. Chronic lesions demonstrate coagulation necrosis and are well demarcated.

Procedural Aspects

Diagnostic electrophysiologic testing (Chapter 62) and radio frequency ablation are often performed during the same procedure, sometimes on an outpatient basis, such as in patients with paroxysmal SVT. Various pacing techniques or infusions of isoproterenol (or both) are used to induce the patient's arrhythmia and allow the specific mechanism of the tachycardia to be determined. Depending on the type of tachycardia, the sites in the heart targeted for ablation are determined by the results of mapping or as guided by specific anatomic landmarks. Radio frequency energy is delivered, typically in applications of 1 minute, at a power setting sufficient to result in adequate tissue heating of 60° to 70° C.

Radio Frequency Ablation of Supraventricular Arrhythmias

AV nodal re-entrant tachycardia (Chapter 64), the most common type of paroxysmal SVT, is eliminated by radio frequency ablation of the "slow" limb of the re-entry circuit. Target sites for ablation are located in the posteroseptal aspect of the right atrium, near the ostium of the coronary sinus. In experienced hands, slow-pathway ablation has a success rate of 98% and is associated with a less than 1% risk of high-degree AV block.

Cryoablation, which is an alternative to radio frequency ablation, is associated with a lower risk for AV block but a lower long-term success rate. Cryoablation is useful in patients at higher risk for AV block, such as small children.

Left-sided accessory pathways are ablated by using either a retrograde aortic or a transseptal approach, and those that are right sided or septal are ablated with a venous approach. Detailed mapping of the accessory pathway is essential for identification of an appropriate ablation site, and the ablation catheter is positioned on either the atrial or the ventricular aspect of the mitral or tricuspid annulus. The success rate of accessory pathway ablation is 90 to 98%, and the complication rate is 2 to 3%. A fatal complication occurs in less than 0.1% of patients. The most common nonfatal but serious complications are cardiac tamponade as a result of mechanical perforation of the heart by an electrode catheter and high-degree AV block in patients with a septal accessory pathway. Cryoablation is associated with a lower risk for AV block and is useful for ablation of accessory pathways located near the AV node.

Detailed mapping is also needed to identify sites for ablation of atrial tachycardias. Most atrial tachycardias arise in the right atrium and are mapped by using a venous approach, but left atrial tachycardias are mapped via a transseptal approach. Assuming that the atrial tachycardia is arising only at one site, the success rate of ablation is approximately 90%, and complications are rare.

Type I atrial flutter (Chapter 64) arises in the right atrium and can be eliminated by radio frequency ablation directed at a critical isthmus in the low right atrium, between the tricuspid annulus and the inferior vena cava. The success rate of this type of ablation is greater than 90%, and the risk for a serious complication is less than 1%.

Catheter ablation aimed at the elimination of atrial fibrillation is useful in patients with symptomatic, drug-refractory atrial fibrillation. The 1-year efficacy of catheter ablation appears to be in the range of 75 to 85% for paroxysmal atrial fibrillation and 65 to 75% for chronic atrial fibrillation. The most serious complications are myocardial perforation, thromboembolism, and atrioesophageal fistula, with an overall risk of 1 to 2%. Pulmonary vein

stenosis is a potentially serious complication that can be avoided by not delivering radio frequency energy applications within the tubular portion of the pulmonary veins.

In patients with refractory atrial fibrillation (Chapter 64) associated with an uncontrolled ventricular rate, radio frequency ablation of the AV node can improve symptoms, functional capacity, and left ventricular function. In AV node ablation, a third-degree AV block is intentionally induced; the success rate is 100%, and all patients require a permanent pacemaker.

Inappropriate sinus tachycardia can also be managed with radio frequency ablation, but this approach should be recommended only as a last resort. The sinus node, located in the high lateral portion of the right atrium, is targeted for ablation. The success rate is 80%, and 10% of patients require a pacemaker because of an inadequate atrial escape rate.

Because of a very favorable risk-benefit ratio, radio frequency ablation is appropriate first-line therapy for any patient with paroxysmal SVT, Wolff-Parkinson-White syndrome, or type I atrial flutter that is symptomatic enough to warrant therapy (Chapter 64). For atrial flutter other than type I and inappropriate sinus tachycardia, an ablation procedure is appropriate only in patients with severe symptoms who are refractory to medication.

Ablation techniques and new technologies for ablation of atrial fibrillation are still evolving, and their long-term efficacy is not yet established. After 1 year, rates of recurrent atrial fibrillation have been reduced by catheter ablation, but rates of stroke and mortality have not.[10]

Radio Frequency Ablation of Ventricular Tachycardia

Radio frequency ablation has been used as first-line treatment of idiopathic VT. The most common type of idiopathic VT arises in the outflow tract of the right ventricle and has a left bundle branch block configuration and superior axis. Another type of idiopathic VT has a right bundle branch block configuration and a superior axis and arises in the inferoapical aspect of the left ventricle (Chapter 65). The success rate of radio frequency ablation of these types of VT has been 85 to 100%, and complications have been rare.

In patients with CAD, VT usually arises in diseased tissue adjacent to an area of previous infarction in the left ventricle. Because the disease process is diffuse instead of focal and because VT may originate at multiple sites, radio frequency ablation of VT is not usually curative in patients with CAD. More often, radio frequency ablation is used as adjunctive therapy with an ICD or with antiarrhythmic drug therapy. In the setting of CAD, the success rate of radio frequency ablation of VT has been 65 to 95%, with serious complications occurring in approximately 5% of patients.

ARRHYTHMIA SURGERY

Wolff-Parkinson-White Syndrome

At present, surgical ablation of an accessory pathway may be indicated for the rare patient with Wolff-Parkinson-White syndrome who has potentially dangerous arrhythmias and in whom catheter ablation is unsuccessful. When performed by an experienced surgeon, the success rate of surgical ablation of an accessory pathway approaches 100%, and the risk for a serious complication is low. Intraoperative mapping is necessary to establish the location of the accessory pathway, which then can be ablated either cryosurgically using an epicardial approach or by direct dissection using an endocardial approach.

Ventricular Tachycardia in Patients with Coronary Artery Disease

The substrate for monomorphic VT in patients with CAD usually lies within visually apparent scar tissue surrounding an area of previous myocardial infarction (Chapter 65). Subendocardial resection has been successful in eliminating VT when performed either on a visual basis, with resection or cryoablation of all visually apparent scar tissue, or on a map-guided basis, with resection or cryoablation limited to the areas found to be participating in generation of the VT. At centers experienced in this type of surgery, the success rate of subendocardial resection has been 85 to 90%, and the operative mortality rate has been in the range of 5 to 10%. Although subendocardial resection has the potential advantage of preventing recurrences of VT, the relatively high operative mortality rate and the widespread availability of ICDs have discouraged its use.

Atrial Fibrillation

In the maze procedure, a series of incisions or linear lesions or both (created by cryoablation or radio frequency ablation) are made in specific regions of the left and right atria to subdivide the atria into parts too small to sustain atrial fibrillation. The operative mortality rate associated with the maze procedure is less than 2%, and more than 90% of patients have had no recurrences of atrial fibrillation during long-term follow-up. However, because it requires extensive surgery, the maze procedure is performed by only a small number of surgeons.

A variety of simpler operative procedures for atrial fibrillation have been developed, some of which can be performed with minimally invasive surgery. The long-term efficacy of these simpler "mini-maze" procedures is lower than that of the maze procedure, but because of their ease and low risk, their use has become widespread, mostly as an adjunct to valve or coronary bypass surgery.

ARTERIAL HYPERTENSION

RONALD G. VICTOR

DEFINITION

Hypertension has been defined as a usual blood pressure of 140/90 mm Hg or higher (Table 67-1), blood pressure levels for which the benefits of drug treatment have been shown in randomized controlled trials. This conservative definition has been called into question by epidemiologic data showing continuous positive relationships between the risk for death from coronary artery disease (CAD) and stroke with systolic or diastolic blood pressure values as low as 115/75 mm Hg (Fig. 67-1). Thus, an artificial dichotomy between "hypertension" and "normotension" may delay medical treatment until vascular health has been irreversibly compromised by elevated blood pressure values previously considered normal. For certain high-risk patients, such as those with CAD, the recommended medical treatment threshold recently has been lowered to 130/80 mm Hg.

EPIDEMIOLOGY

Affecting one fourth of the adult population (70 million people in the United States and 1 billion people worldwide), arterial hypertension is the leading cause of death in the world and the most common cause for an outpatient visit to a physician; it is the most easily recognized treatable risk factor for

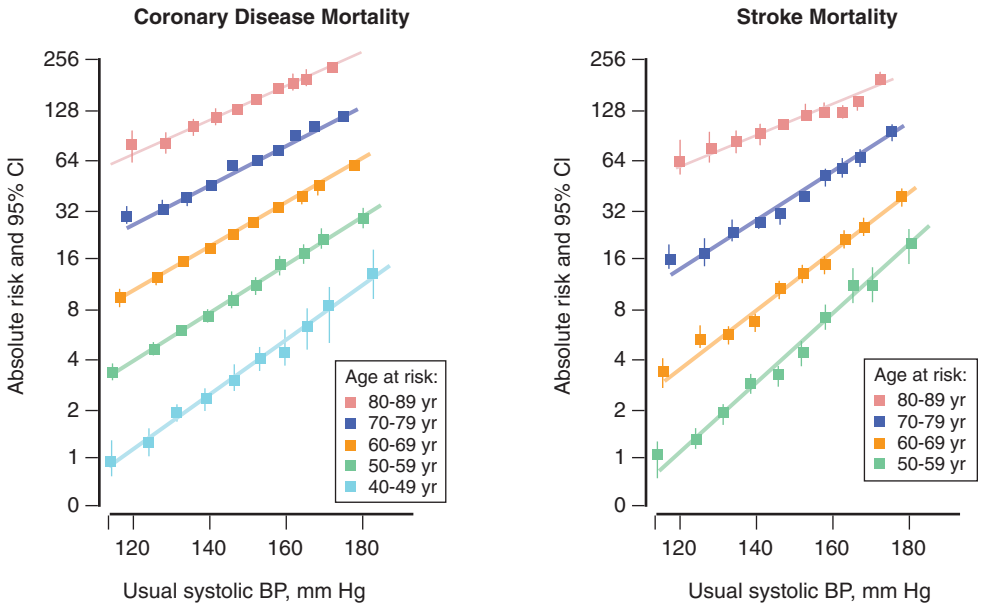

FIGURE 67-1. Absolute risk of coronary artery disease and stroke mortality by usual systolic blood pressure (BP) levels. (From Lewington S, Clarke R, Qizilbash N, et al, for the Prospective Studies Collaboration. Age-specific relevance of usual blood pressure to vascular mortality: a meta-analysis of individual data for one million adults in 61 prospective studies. *Lancet.* 2002;360:1903-1913.)

TABLE 67-1 STAGING OF OFFICE BLOOD PRESSURE*

BLOOD PRESSURE STAGE	SYSTOLIC BLOOD PRESSURE (mm Hg)	DIASTOLIC BLOOD PRESSURE (mm Hg)
Normal	<120	<80
Prehypertension	120-139	80-89
Stage 1 hypertension	140-159	90-99
Stage 2 hypertension	≥160	≥100

*Calculation of seated blood pressure is based on the mean of two or more readings on two separate office visits.

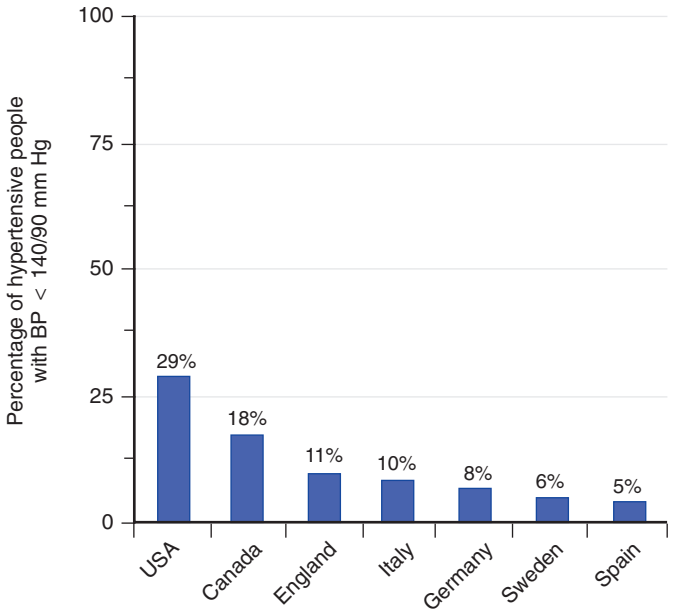

FIGURE 67-2. Hypertension control rates in North America and Europe. (From Wolf-Maier K, Cooper RS, Kramer H, et al. Hypertension treatment and control in five European countries, Canada, and the United States. *Hypertension.* 2004;43:10-17.)

stroke (Chapters 413, 414, and 415), myocardial infarction (Chapters 72 and 73), heart failure (Chapters 58 and 59), peripheral vascular disease (Chapter 79), aortic dissection (Chapter 78), atrial fibrillation (Chapter 64), and end-stage kidney disease (Chapter 132). Because of increasing rates of obesity and aging of the population, hypertension is projected to affect 1.5 billion persons, one third of the world's population, by the year 2025. Presently, about 54% of strokes and 47% of ischemic heart disease worldwide is attributable to high blood pressure. Half of this disease burden is in people who meet the definition of hypertension, and the remainder is in people with lesser degrees of high blood pressure (*prehypertension*).

The asymptomatic nature of most cases of hypertension and the inherent variability in blood pressure can delay diagnosis and treatment. Most cases of hypertension are multifactorial. Blood pressure control typically requires empirical treatment with several classes of prescription medication. Pill burden, prescription drug costs, medication side effects, and insufficient time for patient education contribute to nonadherence to medications. Physicians can be too slow to initiate and intensify blood pressure medication. Lifestyle modification (particularly diet and exercise) can lower blood pressure somewhat, but the reduction rarely is enough to eliminate the need for medication. For all these reasons, blood pressure is controlled to a value below 140/90 mm Hg in less than one third of affected individuals, even in higher-income countries with the most advanced systems of health care (Fig. 67-2). Effective management requires continuity of care by a knowledgeable physician and continued active involvement by an educated patient.

Aging and Pulse Pressure

Patients often ask: Is systolic or diastolic blood pressure more important? Both are (Fig. 67-3). In industrialized societies, systolic pressure rises progressively with age; if individuals live long enough, almost all (>90%) will develop hypertension. This age-dependent rise in blood pressure is not an essential part of human biology. In less developed countries where consumption of calories and salt is low, blood pressures remain low and do not rise with age. In developed countries, diastolic pressure rises until the age of 50 years and decreases thereafter, producing a progressive rise in pulse pressure (systolic pressure minus diastolic pressure) (Fig. 67-4).

Different hemodynamic faults underlie hypertension in younger and older persons. Patients who develop hypertension before the age of 50 years typically have *combined systolic and diastolic hypertension:* systolic pressure above 140 mm Hg *and* diastolic pressure above 90 mm Hg. The main hemodynamic fault is vasoconstriction at the level of the resistance arterioles. In contrast, most patients who develop hypertension after the age of 50 years have *isolated systolic hypertension:* systolic pressure above 140 mm Hg but diastolic pressure below 90 mm Hg (often below 80 mm Hg). In isolated systolic hypertension, the primary hemodynamic fault is decreased distensibility of the large conduit arteries. Collagen replaces elastin in the elastic lamina of the aorta, a process that is accelerated by both aging and hypertension. When pulse wave velocity increases sufficiently, the rapid return of the arterial pulse wave from the periphery augments central systolic (rather than diastolic) pressure. The augmented systolic load on the left ventricle increases myocardial oxygen demands, whereas the rapid diastolic runoff compromises

myocardial perfusion. As the population ages, most uncontrolled hypertension occurs in older patients with isolated systolic hypertension.

Gender and Race/Ethnicity

Before the age of 50 years, hypertension is less common in women than men, suggesting a protective effect of estrogen. After menopause, hypertension is more common in women than men.

One in three African American individuals has hypertension, compared with one in four or five white and Mexican American individuals. In African Americans, hypertension also starts at a younger age, is more severe, and causes more target organ damage, leading to premature disability and death. In the Bogalusa Heart Study, African American children already had higher blood pressures than white children by grade school. However, hypertension is more prevalent in the white populations of several European countries (e.g., Finland, Germany, Spain) than in African Americans and is rare among Africans living in Africa (Fig. 67-5). These international data emphasize the importance of environmental factors.

PATHOBIOLOGY

In 90 to 95% of hypertensive patients, a single reversible cause of the elevated blood pressure cannot be identified, hence the term *primary hypertension.* However, in most patients with primary hypertension, readily identifiable behaviors—habitually excessive consumption of calories, salt, or alcohol—contribute to the elevated blood pressure. In the remaining 5 to 10%, a more discrete mechanism can be identified, and the condition is termed *secondary or identifiable hypertension.* At the organ-system level, hypertension results from a gain in function of pathways that promote vasoconstriction and renal sodium retention or a loss in function of pathways that promote vasodilation and renal sodium excretion. Neural, hormonal, renal, and vascular mechanisms are involved. There is increasing evidence that neurohormonal activation contributes to the early pathogenesis by compromising vascular function (e.g., endothelium-dependent vasodilation) and structure (e.g., inward remodeling) that precede hypertension.

Behavioral Determinants of Human Blood Pressure Variation

The most important behavioral determinants of blood pressure are related to dietary consumption of calories and salt. Across populations, the prevalence of hypertension increases linearly with average body mass index. With the unrelenting obesity epidemic in both developed and developing societies, increasing attention is being paid to the *metabolic syndrome* (Chapter 237) that often accompanies hypertension. The metabolic syndrome refers to the frequent clustering of elevated blood pressure with abdominal ("male pattern") adiposity, insulin resistance with glucose intolerance, and a dyslipidemic pattern consisting typically of elevated plasma triglyceride and low high-density lipoprotein cholesterol levels. In the Framingham Heart Study, obesity has been estimated to account for as much as 60% of the new cases of hypertension. The underlying mechanisms by which weight gain leads to hypertension are incompletely understood, but there is mounting evidence for an expanded plasma volume plus sympathetic overactivity. The sympathetic overactivity is thought to be a compensatory attempt to burn fat but at the expense of peripheral vasoconstriction, renal salt and water retention, and hypertension. In some obese individuals, sleep apnea (Chapter 100) is an important cause of hypertension. Repeated arterial desaturation sensitizes the carotid body chemoreceptors, causing sustained sympathetic overactivity even during waking hours.

Dietary sodium intake is another key behavioral determinant of human hypertension. In the INTERSALT study of 52 locations around the world, the risk for development of hypertension during three decades of adult life was linearly and tightly related to dietary sodium intake. Interindividual variability in blood pressure responses to dietary sodium loading and sodium restriction indicates an important genetic underpinning.

Genetic Determinants of Human Blood Pressure Variation

Concordance of blood pressures is greater within families than in unrelated individuals, greater between monozygotic twins than between dizygotic twins, and greater between biologic siblings than between adoptive siblings living in the same household. As much as 70% of the familial aggregation of blood pressure is attributed to shared genes rather than to shared environment.

The complex regulation of blood pressure has thwarted the genetic dissection of primary human hypertension, with the first positive genome-wide association studies suggesting multiple risk alleles, each having very small effects. Mutations in 20 salt-handling genes cause ultra-rare syndromes of severe, early-onset hypotension (salt-wasting syndromes) or hypertension (all inherited as mendelian traits). The clinical relevance of these mutations to common primary hypertension has been limited, although recent data indicate that heterozygous mutations in genes underlying the pediatric salt-wasting syndromes (Bartter's and Gitelman's) are present in 1 to 2% of the general adult population and confer resistance against primary hypertension.

CLINICAL MANIFESTATIONS

Hypertension has been called the silent killer, an asymptomatic chronic disorder that silently damages the blood vessels, heart, brain, and kidneys if it is undetected and untreated. Although headaches (Chapter 405) are common in patients with mild to moderate hypertension, episodes of headaches do not correlate with fluctuations in blood pressure. Rather, they correlate with a person's awareness of his or her diagnosis.

DIAGNOSIS

Initial Evaluation for Hypertension

The initial evaluation for hypertension should accomplish three goals: (1) stage the blood pressure, (2) assess the patient's overall cardiovascular risk, and (3) detect clues of secondary hypertension that require further evaluation.

Goal 1: Accurate Assessment of Blood Pressure

Office Blood Pressure

Traditionally, blood pressure has been staged as normal, prehypertension, or hypertension based on the average of two or more readings taken at two or more office visits (see Table 67-1). The blood pressure should be measured at least twice after 5 minutes of rest with the patient seated, the back supported, and the arm bare and at heart level. A large adult-sized cuff should be used to measure blood pressure in overweight adults because the standard-sized cuff will cause falsely elevated readings. Tobacco and caffeine should be avoided for at least 30 minutes. Blood pressure should be measured in both arms, to exclude coarctation of the aorta, and after 5 minutes of standing, to exclude a significant postural fall, particularly in older persons and persons with diabetes or other conditions (e.g., Parkinson's disease) that predispose to autonomic insufficiency.

Home and Ambulatory Blood Pressure Monitoring

A person's blood pressure varies so much throughout a 24-hour period that it is impossible to characterize it accurately except by repeated measurements under various conditions. Out-of-office readings are the only way to obtain a clear picture of a person's usual blood pressure for accurate diagnosis and management. These readings are more predictive of cardiovascular events than office readings and overcome many of the pitfalls of office measurement, including physician errors and "white coat" reactions. Home blood pressure monitoring also improves medication adherence by actively involving patients in their own medical care.

New recommendations include the following: (1) home blood pressure monitoring should become a routine part of the clinical management of patients with known or suspected hypertension the same way that home blood glucose monitoring is essential to the management of patients with diabetes; (2) two (or three) readings should be taken in the morning and at night for 1 week, with a total of at least 12 readings being averaged before making clinical decisions; and (3) the target treatment goal is an average home blood pressure of less than 135/85 mm Hg for most patients and less than 130/80 mm Hg for high-risk patients, such as those with CAD, heart failure, diabetes, or chronic kidney disease.

A validated electronic oscillometric monitor with an arm cuff should be chosen from the dabl Educational Web site (*www.dableducational.org*). Each patient's monitor should be checked in the physician's office for its accuracy and appropriate cuff size. Patients must be taught correct measurement techniques and to avoid reporting bias. Wrist monitors are inaccurate and thus not recommended. The oscillometric method may not work well in patients with atrial fibrillation or frequent extrasystoles, for whom manual sphygmomanometry is required. Rare patients become obsessed about taking their blood pressure and need to stop.

Ambulatory blood pressure monitoring (Table 67-2) provides automated measurements of blood pressure during a 24-hour period while patients are engaged in their usual activities, including sleep (Fig. 67-6). Ambulatory blood pressure measurement is superior to standard office measurement in predicting fatal and nonfatal myocardial infarction and stroke. Recommended normal values are an average daytime blood pressure below 135/85 mm Hg, nighttime blood pressure below 120/70 mm Hg, and 24-hour blood pressure below 130/80 mm Hg. Some experts have recommended a lower cutoff value of 130/80 mm Hg as a more stringent definition of normal daytime blood pressure.

About 20% of patients with elevated office blood pressures have normal home or ambulatory blood pressures. If the daytime blood pressure is below 135/85 mm Hg (or preferably below 130/80 mm Hg) and there is no target organ damage despite consistently elevated office readings, the patient has

TABLE 67-2 RECOMMENDED INDICATIONS FOR AMBULATORY BLOOD PRESSURE MONITORING

Suspected "white coat hypertension" (high office blood pressure readings in patients with otherwise low total cardiovascular risk)*
Considerable variability of clinic blood pressure readings
Marked discrepancy between home and office blood pressure readings (e.g., suspected masked hypertension)
Suspected nocturnal hypertension
Suspected resistance to drug treatment
Suspected orthostatic hypotension or autonomic failure, particularly in elderly or diabetic patients
Elevated office blood pressure in pregnant women or suspected preeclampsia

*Medicare currently reimburses for ambulatory monitoring only to confirm the diagnosis of white coat hypertension that is suspected on the basis of three normal home readings in patients with no evidence of target organ damage despite repeatedly elevated office blood pressure readings (ICD 796.2).

Modified from Mancia G, DeBacker G, Dominickak A, et al. 2007 Guidelines for the management of arterial hypertension of the European Society of Hypertension (ESH) and the European Society of Cardiology (ESC). *Eur Heart J.* 2007;23:1462-1536.

"office-only" or "white coat" hypertension, caused by a transient adrenergic response to the measurement of blood pressure in the physician's office. The cardiovascular risk is intermediate to that in persons with consistently normal blood pressure and those with consistently high blood pressure. Many patients do not have pure white coat hypertension but rather white coat aggravation, a white coat reaction superimposed on a milder level of out-of-office hypertension that nevertheless needs treatment. For example, up to 30% of treated patients who have persistently elevated office blood pressure readings will be shown by ambulatory monitoring to have adequate or even excessive control of their hypertension, thereby eliminating overtreatment (see Fig. 67-6). In other patients, office readings underestimate ambulatory blood pressures, presumably because of sympathetic overactivity (e.g., owing to job stress, home stress, or tobacco smoke) that dissipates when the patient comes to the office. Such "masked hypertension," present in up to 10% of patients, increases cardiovascular risk.

Ambulatory monitoring is the only way to detect hypertension during sleep. Blood pressure normally dips during sleep and increases sharply when a person awakens and becomes active (see Fig. 67-6). Nocturnal hypertension increases the aggregate blood pressure burden on the cardiovascular system and is a stronger predictor of cardiovascular outcomes than daytime ambulatory blood pressure or office measurements. Nocturnal hypertension is particularly common in patients with chronic kidney disease (Chapter 132), presumably because of their sustained sympathetic overactivity, which does not shut down during sleep, and centralization of blood volume with nocturnal recumbence.

Goal 2: Cardiovascular Risk Stratification

Although cardiovascular risk increases with increasing blood pressure, it also increases if the patient has hypertensive target organ damage or additional cardiovascular risk factors. More than 75% of hypertensive patients meet current U.S. criteria for initiation of lipid-lowering medication (low-density lipoprotein cholesterol more than 130 mm Hg), and 25% have diabetes. Thus, the minimal laboratory testing required for the initial evaluation of hypertension is determination of blood electrolyte, fasting glucose, and serum creatinine levels (with calculated glomerular filtration rate [GFR]), a fasting lipid panel, hematocrit, spot urinalysis (including urine albumin-to-creatinine ratio), and a resting 12-lead electrocardiogram (ECG).

The gradient of increasing levels of blood pressure with cardiovascular risk steepens as additional risk factors are added (Fig. 67-7). As the overall risks multiply, blood pressure control becomes more important. Current U.S. guidelines recommended a usual blood pressure of 140/90 mm Hg as the threshold for initiating antihypertensive medication in most patients, with a lower threshold of 130/80 mm Hg for high-risk patients with diabetes or chronic kidney disease. Based on more recent data, the operational definition of high-risk patients has been expanded to include most patients with established CAD, carotid artery disease, peripheral artery disease, abdominal aortic aneurysm, heart failure, or high risk for CAD (10-year Framingham risk score of >10%) (Table 67-3). Because cardiovascular risk increases so steeply with age (see Fig. 67-1), most hypertensive men older than 55 years and most hypertensive women older than 65 years will have a Framingham risk score higher than 10% (*http://hp2010.nhlbihin.net/atpiii/calculator.asp*).

Goal 3: Identification and Treatment of Secondary (Identifiable) Causes of Hypertension

The third goal of the initial evaluation is to screen for identifiable causes of hypertension (Table 67-4), in the hope of finding a cure. A thorough search for secondary causes, which is not cost-effective in most patients with hypertension, becomes critically important in two circumstances: (1) when there is a compelling finding on the initial evaluation and (2) when the hypertensive process is so severe that it either is refractory to intensive multiple-drug therapy or requires hospitalization.

Renal Parenchymal Hypertension

Chronic kidney disease (Chapter 132) is the most common cause of secondary hypertension. Hypertension is present in more than 85% of patients with

TABLE 67-3 RECOMMENDED (TARGET) BLOOD PRESSURE VALUES*

BP < 150/80 mm Hg
Very elderly persons (80+ years of age)
BP < 140/90 mm Hg
Uncomplicated hypertension
BP < 130/80 mm Hg
Diabetes mellitus
Chronic kidney disease
GFR <60 mL/min/1.73 m^2
Urine albumin-to-creatinine ratio ≥30 mg/g (consider <120/80 mm Hg if >1 g of proteinuria per day)
Other patients at high risk for coronary artery disease (primary prevention)
Coronary artery disease risk equivalents
Carotid artery disease
Peripheral arterial disease
Abdominal aortic aneurysm
10-year Framingham risk score > 10% (most men over age 55, most women over age 65)
Established coronary artery disease: stable or unstable (secondary prevention)
Secondary prevention of stroke or TIA
Heart failure or left ventricular systolic dysfunction (consider BP < 120/80 mm Hg)

*Values are for office readings; target values for home or daytime ambulatory monitoring are generally set 5 mm Hg lower.
BP = blood pressure; GFR = glomerular filtration rate; TIA = transient ischemic attack.
Adapted from Rosendorff C, Black HR, Cannon CP, et al. Treatment of hypertension in the prevention and management of ischemic heart disease: a scientific statement from the American Heart Association Council for High Blood Pressure Research and the Councils on Clinical Cardiology and Epidemiology and Prevention. *Circulation.* 2007;115:2761-2788.

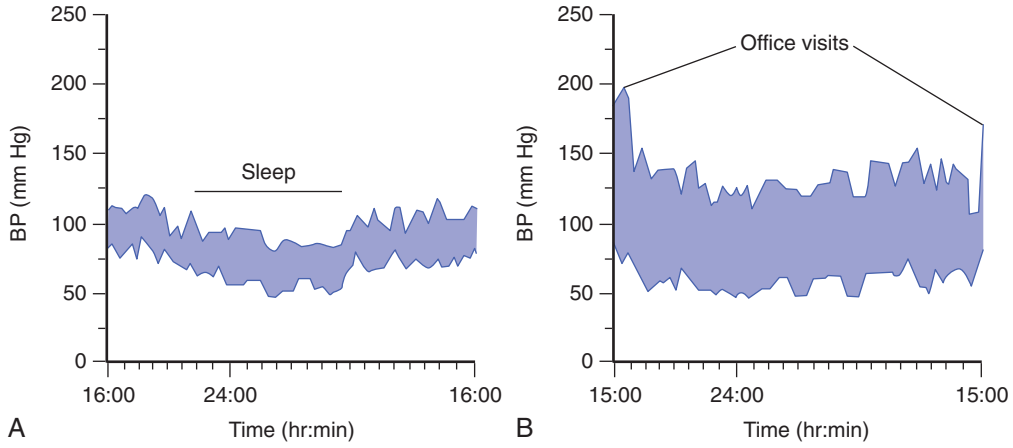

FIGURE 67-6. The 24-hour ambulatory blood pressure (BP) monitor tracings of two different patients. A, Optimal blood pressure in a healthy 37-year-old woman. Note the normal variability in blood pressure, the nocturnal dip in blood pressure during sleep, and the sharp increase in blood pressure on awakening. **B,** Pronounced white coat effect in an 80-year-old woman referred for evaluation of medically refractory hypertension. Documentation of the white coat effect prevented overtreatment of the patient's isolated systolic hypertension. (**A,** Courtesy of Ronald G. Victor, MD, Hypertension Division, Department of Internal Medicine, University of Texas Southwestern Medical Center, Dallas, Texas; **B,** Courtesy of Wanpen Vongpatanasin, MD, Hypertension Division, Department of Internal Medicine, University of Texas Southwestern Medical Center, Dallas, Texas.)

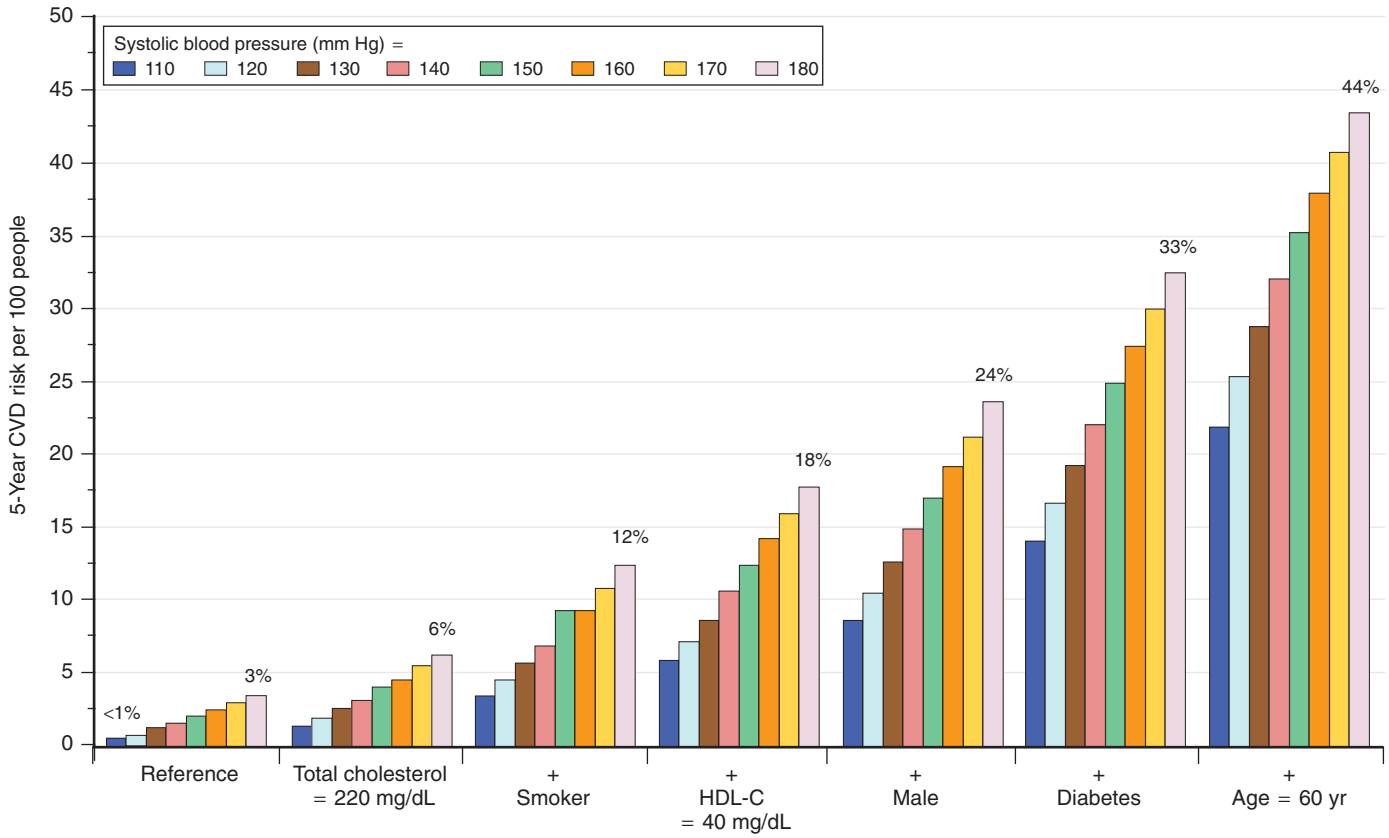

FIGURE 67-7. Absolute risk of cardiovascular disease (CVD) during 5 years in patients by systolic blood pressure at specified levels of other risk factors. The reference category is a nondiabetic, nonsmoking woman aged 50 years with a total cholesterol value of 190 mg/dL and a high-density lipoprotein cholesterol (HDL-C) value of 60 mg/dL. Risks are given for systolic pressures of 110, 120, 130, 140, 150, 160, 170, and 180 mm Hg. In the other categories, additional risk factors are added consecutively. (From Jackson R, Lawes CMM, Benett DA, et al. Treatment with drugs to lower blood pressure and blood cholesterol based on an individual's absolute cardiovascular risk. *Lancet.* 2005;365:434-441.)

TABLE 67-4 GUIDE TO EVALUATION OF IDENTIFIABLE CAUSES OF HYPERTENSION

SUSPECTED DIAGNOSIS	CLINICAL CLUES	DIAGNOSTIC TESTING
Chronic kidney disease	Estimated GFR <60 mL/min/1.73 m^2 Urine albumin-to-creatinine ratio ≥30 mg/g	Renal sonography
Renovascular disease	New elevation in serum creatinine, marked elevation in serum creatinine with ACEI or ARB, drug-resistant hypertension, flash pulmonary edema, abdominal or flank bruit	Renal sonography (atrophic kidney), CT or MR angiography, invasive angiography
Coarctation of the aorta	Arm pulses > leg pulses, arm BP > leg BP, chest bruits, rib notching on chest radiography	MR angiography, TEE, invasive angiography
Primary aldosteronism	Hypokalemia, drug-resistant hypertension	Plasma renin and aldosterone, 24-hour urine aldosterone and potassium after oral salt loading, adrenal vein sampling
Cushing's syndrome	Truncal obesity, wide and blanching purple striae, muscle weakness	1 mg dexamethasone-suppression test, urinary cortisol after dexamethasone, adrenal CT
Pheochromocytoma	Paroxysms of hypertension, palpitations, perspiration, and pallor; diabetes	Plasma metanephrines, 24-hour urinary metanephrines and catecholamines, abdominal CT or MR imaging
Obstructive sleep apnea	Loud snoring, large neck, obesity, somnolence	Polysonography

ACEI = angiotensin-converting enzyme inhibitor; ARB = angiotensin receptor blocker; BP = blood pressure; CT = computed tomography; GFR = glomerular filtration rate; MR, magnetic resonance; TEE = transesophageal echocardiography.

chronic kidney disease and is a major factor causing their increased cardiovascular morbidity and mortality. The mechanisms causing the hypertension include an expanded plasma volume and peripheral vasoconstriction; the peripheral vasoconstriction is caused by both activation of vasoconstrictor pathways (renin-angiotensin and sympathetic nervous systems) and inhibition of vasodilator pathways (nitric oxide).

Measurement of serum creatinine alone is an inadequate screening test for renal insufficiency. A spot urine specimen should be obtained to screen for microalbuminuria, which is defined as a urine albumin-to-urine creatinine ratio of 30 to 300 mg/g (equivalent to excretion of 30 to 300 mg of albumin per 24 hours); higher levels of albuminuria indicate more advanced kidney disease. Using the spot urine specimen, creatinine clearance should be calculated (*www.nephron.com*; *www.newtech.kidney.org*) (Chapter 116) to screen for an estimated GFR below 60 mL/min/1.73 m^2.

In patients with mild (stage 2: GFR of 60 to 90 mL/min/1.73 m^2) or moderate (stage 3: GFR of 30 to 60 mL/min/1.73 m^2) proteinuric chronic kidney disease, stringent blood pressure control is imperative both to slow the progression to end-stage renal disease and to reduce the excessive cardiovascular risk. In patients with severe chronic kidney disease, hypertension often becomes difficult to treat and may require either (1) intensive medical treatment with loop diuretics, potent vasodilators (e.g., minoxidil), high-dose β-adrenergic blockers, and central sympatholytics; or (2) initiation of chronic hemodialysis as the only effective way to reduce plasma volume. In chronic hemodialysis patients, the challenge is to control interdialytic hypertension

without exacerbating dialysis-induced hypotension. The annual mortality rate in the hemodialysis population is 25%; half of this excessive mortality is caused by cardiovascular events that are related, at least in part, to hypertension.

Renovascular Hypertension

PATHOBIOLOGY AND CLINICAL MANIFESTATIONS

The two main causes of renal artery stenosis (Chapter 127) are atherosclerosis (85% of cases), typically in older persons with other clinical manifestations of systemic atherosclerosis, and fibromuscular dysplasia (15% of cases), typically in young women who are otherwise healthy. Although renal artery stenosis and hypertension frequently coexist, the presence of a renal artery stenosis does not prove that the patient's hypertension is renovascular in origin or that revascularization will improve renal perfusion and blood pressure.

Unilateral renal artery stenosis can lead to underperfusion of the juxtaglomerular cells, thereby causing renin-dependent hypertension even though the contralateral kidney is able to maintain normal blood volume. In contrast, bilateral renal artery stenosis (or unilateral stenosis with a solitary kidney) constitutes a potentially reversible cause of progressive renal failure and volume-dependent hypertension. The following clinical clues increase the suspicion of renovascular hypertension: any hospitalization for urgent or emergent hypertension; recurrent "flash" pulmonary edema; recent worsening of long-standing, previously well-controlled hypertension; severe hypertension in a young adult or after the age of 50 years; precipitous and progressive worsening of renal function in response to angiotensin-converting enzyme (ACE) inhibition or angiotensin II receptor blockade; unilateral small kidney by any radiographic study; extensive peripheral arteriosclerosis; and a flank bruit.

DIAGNOSIS

Contrast-enhanced computed tomography (CT) and magnetic resonance angiography are the preferred screening tests for renal artery stenosis, but gadolinium-enhanced magnetic resonance imaging (MRI) is contraindicated in patients with advanced chronic kidney disease to avoid potentially fatal gadolinium-induced nephrogenic systemic fibrosis (Chapter 275). Fibromuscular dysplasia classically causes a "string of beads" lesion in the midportion of a renal artery (Fig. 67-8A), whereas atherosclerotic renal artery lesions are proximal and discrete (see Fig. 67-8B). Invasive renal angiography is the "gold standard" for confirming the diagnosis of renal artery stenosis.

TREATMENT

Rx

Balloon angioplasty is the treatment of choice for fibromuscular dysplasia, with overall favorable outcomes. In contrast, medical management of hypertension and the associated atherosclerotic risk factors is first-line treatment for atherosclerotic renal artery stenosis. Truly drug-resistant hypertension and a progressive decline in renal function (ischemic nephropathy) currently are the only two firm indications for balloon angioplasty. Most atherosclerotic renal artery lesions do not cause hypertension or progressive renal failure, and most patients will not benefit from revascularization (balloon angioplasty or stenting), which carries substantial risks of serious complications. About 15% of patients undergoing cardiac catheterization will have a renal artery lesion when coronary angiography is followed by routine ("drive-by") renal angiography, but evidence does not support this diagnostic practice or therapy based on it.

Mineralocorticoid-Induced Hypertension Due to Primary Aldosteronism

PATHOBIOLOGY

The most common causes of primary aldosteronism (Chapter 234) are a unilateral aldosterone-producing adenoma and bilateral adrenal hyperplasia. Because aldosterone is the principal ligand for the mineralocorticoid receptor in the distal nephron, excessive aldosterone production causes excessive renal Na^+-K^+ exchange, often resulting in hypokalemia.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The diagnosis should always be suspected when hypertension is accompanied by either unprovoked hypokalemia (serum potassium concentration below 3.5 mmol/L in the absence of diuretic therapy) or a tendency to develop excessive hypokalemia during diuretic therapy (serum potassium concentration below 3.0 mmol/L). However, more than one third of patients do not have hypokalemia on initial presentation, and the diagnosis should also be considered in any patient with resistant hypertension.

Screening for hyperaldosteronism should be restricted to the small fraction of hypertensive patients with hypokalemia or severe drug-resistant hypertension. If such patients have a positive screening test—a high serum aldosterone level and a suppressed plasma renin activity level— and want to consider laparoscopic adrenalectomy, the patient should be referred to an experienced center for further evaluation: salt-loading to test for nonsuppressible aldosteronism and, if present, adrenal vein sampling to test for lateralization.

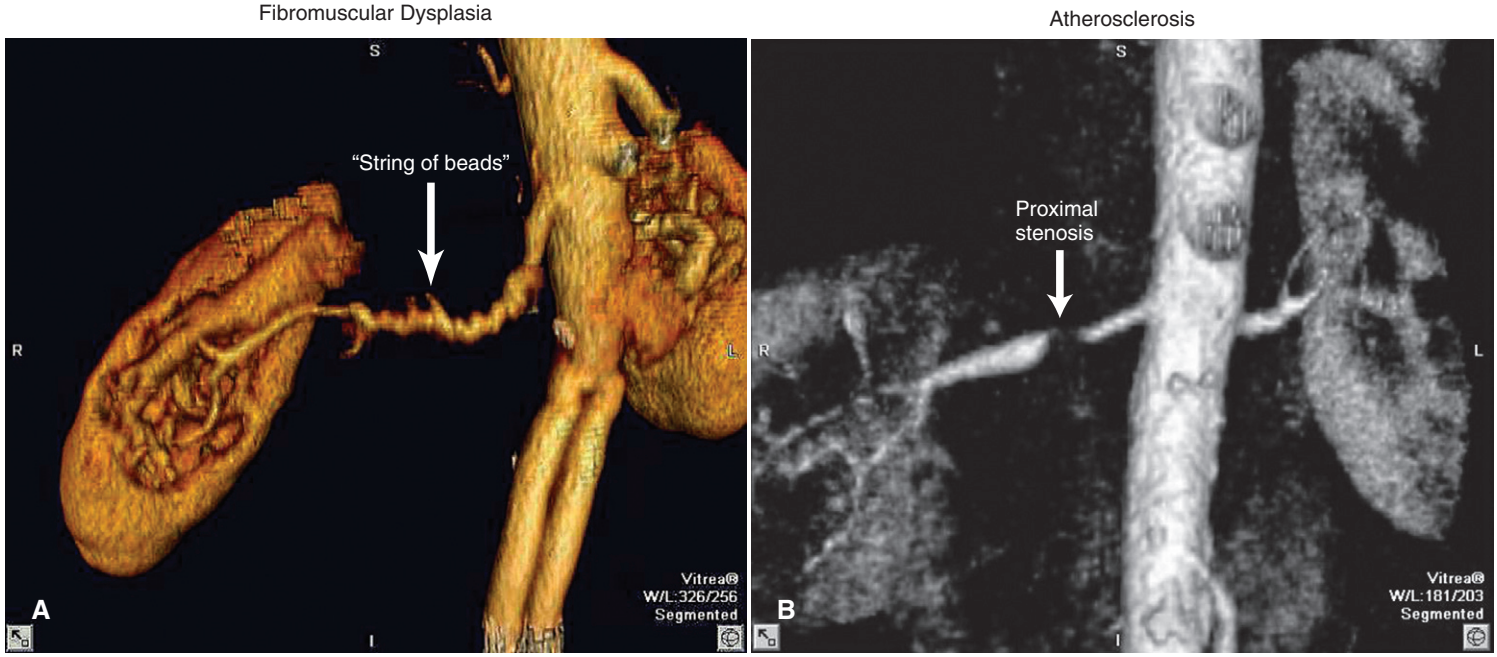

FIGURE 67-8. Computed tomographic angiogram with three-dimensional reconstruction. A, The classic "string of beads" lesion of fibromuscular dysplasia (bilateral in this patient). **B,** A severe proximal atherosclerotic stenosis of the right renal artery and mild stenosis of the left renal artery. (Images courtesy of Bart Domatch, MD, Radiology Department, University of Texas Southwestern Medical Center, Dallas, Texas.)

TREATMENT

CT has too many false-positive and false-negative results to be used as a noninvasive alternative to invasive adrenal vein sampling. Laparoscopic adrenalectomy and mineralocorticoid receptor blockade with eplerenone (50 to 100 mg per day) constitute highly effective therapeutic options that target the disease-causing mechanism with a favorable risk-to-benefit ratio.

Mendelian Forms of Mineralocorticoid-Induced Hypertension

Almost all the rare mendelian forms of hypertension are mineralocorticoid induced and involve excessive activation of the epithelial Na^+ channel (ENaC), the final common pathway for reabsorption of sodium from the distal nephron (Fig. 67-9). Thus, salt-dependent hypertension can be caused both by gain-of-function mutations of ENaC or the mineralocorticoid receptor and by increased production or decreased clearance of mineralocorticoid receptor ligands, which are aldosterone, deoxycorticosterone, and cortisol.

Pheochromocytomas and Paragangliomas

Pheochromocytomas are rare catecholamine-producing tumors of the adrenal chromaffin cells, whereas paragangliomas are even rarer tumors of the extra-adrenal chromaffin cells (Chapter 235). The diagnosis should be suspected when hypertension is drug resistant or paroxysmal, particularly when accompanied by paroxysms of headache, palpitations, pallor, or diaphoresis. In some patients, pheochromocytoma is misdiagnosed as panic disorder. A family history of early-onset hypertension may suggest pheochromocytoma as part of the multiple endocrine neoplasia syndromes (Chapter 239). An increasing number of pheochromocytomas are being detected incidentally on abdominal imaging studies for nonadrenal indications. If the diagnosis is missed, outpouring of catecholamines from the tumor can cause unsuspected hypertensive crisis during unrelated surgical procedures, in which case mortality rates exceed 80%.

Other Neurogenic Causes

Other causes of neurogenic hypertension that can be confused with pheochromocytoma include sympathomimetic agents (cocaine, methamphetamine; Chapter 33), baroreflex failure, and obstructive sleep apnea (Chapter 100). A history of surgery and radiation therapy for head and neck tumors (Chapter 196) raises suspicion of baroreceptor damage. Snoring and somnolence suggest sleep apnea, but continuous positive airway pressure to treat the sleep apnea rarely improves blood pressure substantially (Chapter 100).

Other Causes of Secondary Hypertension

Coarctation of the aorta typically occurs just distal to the origin of the left subclavian artery, so the blood pressure is lower in the legs than in the arms (opposite of the normal situation) (see Fig. 69-7 in Chapter 69). The clue is that the pulses are weaker in the lower than in the upper extremities, indicating the need to measure blood pressure in the legs as well as in both arms. Intercostal collaterals can produce bruits on examination and rib notching on the chest radiograph. Coarctations can be cured with surgery or angioplasty.

Hyperthyroidism tends to cause systolic hypertension with a wide pulse pressure, whereas hypothyroidism tends to cause mainly diastolic hypertension. Treatment is for the underlying disease. Hyperparathyroidism (Chapter 253) also has been associated with hypertension. Cyclosporine and tacrolimus are important causes of secondary hypertension in transplant recipients, apparently by inhibition of calcineurin, the calcium-dependent phosphatase that is expressed not only in lymphoid tissue but also in neural, vascular, and renal tissue. In the absence of outcomes data, nondihydropyridine calcium-channel blockers (CCBs) have become the drugs of first choice, but they increase cyclosporine blood levels. Combination therapy with diuretics, CCBs, and central sympatholytics often is required.

PREVENTION AND TREATMENT OF HYPERTENSION

At the population level, the primary prevention of hypertension requires large-scale societal changes, including further efforts to influence the food industry to reduce salt in processed foods, efforts to increase exercise, and the availability of fresh fruits and vegetables. Once a person's blood pressure rises to prehypertensive levels, lifestyle modifications alone are almost never enough to return blood pressure to normal, and recidivism is almost universal.

Although short-term pharmacologic therapy with a low-dose angiotensin receptor blocker (ARB) has been advocated to prevent conversion from prehypertension to full-blown hypertension, blood pressure quickly rises again once the ARB is discontinued.[2] Thus, lifelong prescription medication is the cornerstone of effective therapy for primary hypertension, with lifestyle modification serving as an adjunct but not as an alternative. The objective is to reduce the blood pressure and associated metabolic abnormalities sufficiently to reduce the risk for cardiovascular events and end-stage renal disease without compromising the patient's quality of life.

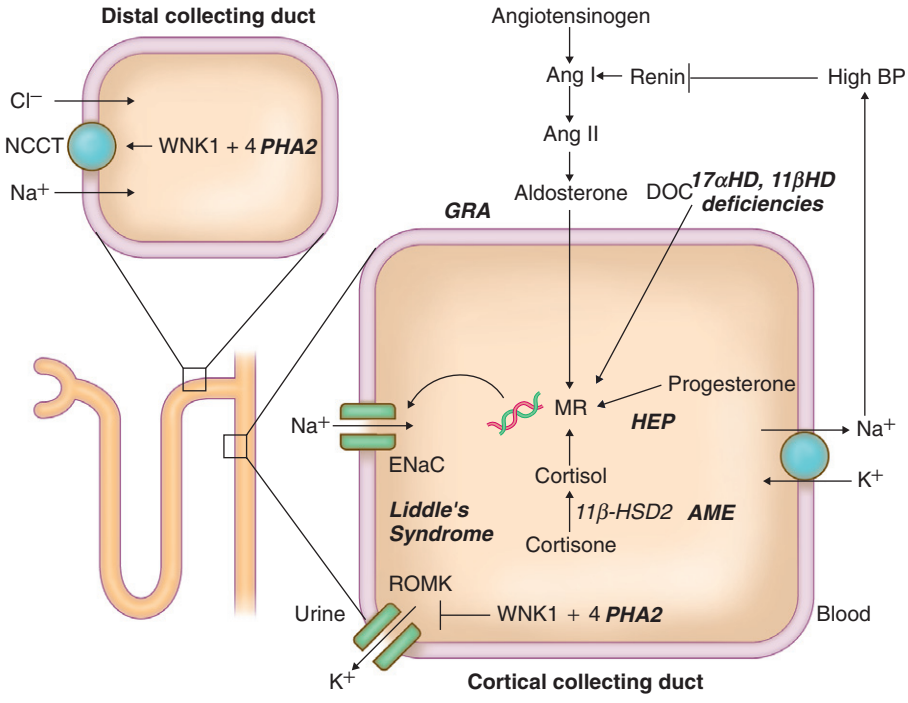

FIGURE 67-9. Mendelian forms of hypertension that cause mineralocorticoid-induced hypertension. AME = apparent mineralocorticoid excess; Ang = angiotensin; BP = blood pressure; GRA = glucocorticoid-remediable aldosteronism; 17αHD and 11βHD = 17α- and 11β-hydroxylase deficiency; 11β-HSD2 = 11β-hydroxysteroid dehydrogenase type 2; DOC = deoxycorticosterone; ENaC = epithelial Na^+ channel; HEP = hypertension exacerbated by pregnancy; MR = mineralocorticoid receptor; NCCT = sodium-chloride cotransporter; PHA2 = pseudohypoaldosteronism type 2; ROMK = rectifying outer medullary K^+ channel; WNK = with no lysine kinases. See text for explanation. (Modified from Lifton RP, Gharavi AG, Geller DS. Molecular mechanisms of human hypertension. *Cell.* 2001;104:545-556.)

Randomized trials have proved beyond any doubt that antihypertensive drug therapy reduces cardiovascular risk, with benefits that are proportional to the reduction in blood pressure achieved.[1] However, in practice, most treated patients do not achieve the same low risk levels of truly normotensive persons because their blood pressures remain higher than optimal owing to the threshold levels of guidelines, the hesitation of practicing physicians to start and intensify drug treatment, the costs of medications, and nonadherence despite the generally declining costs of medications as they become generic.

Multidrug regimens with two, three, or even more medications of different drug classes are almost always required to achieve currently recommended blood pressure goals, particularly for high-risk patients. Low-dose drug combinations exert synergistic effects on blood pressure while minimizing dose-dependent side effects. For most patients with hypertension, lipid-lowering therapy and antiplatelet therapy are indicated as part of a comprehensive cardiovascular risk-reduction strategy (Chapter 51).

Lifestyle Modification

Every antihypertensive regimen should include lifestyle modification. The Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC 7) recommended a trial of lifestyle modification alone for an unspecified time (6 to 12 months in prior guidelines) before antihypertensive medication is prescribed, even for high-risk patients. This is wishful thinking and may be a cause of therapeutic inertia. More recent data, however, support greater urgency in achieving pharmacologic control of high blood pressure to reduce cardiovascular risk, at least in patients with multiple risk factors. In sufficiently motivated individuals, lifestyle modification can decrease medication requirements, have a favorable impact on associated cardiovascular risk factors, and emphasize the active role patients can play in controlling their blood pressure.

Moderate dietary sodium reduction (Chapter 220) reduces renal potassium wasting during diuretic therapy and lowers blood pressure by 2/2 mm Hg on average. Most dietary sodium comes from processed foods rather than from the salt shaker. Without draconian measures, daily salt consumption can be reduced from 10 to 6 g by teaching patients to read food labels (6 g of NaCl = 2.4 g of sodium = 100 mmol of sodium). The Dietary Approaches to Stop Hypertension (DASH) study showed that individuals with prehypertension or stage 1 hypertension can lower their blood pressures, at least over the short term, by as much as 11/6 mm Hg even without restricting calorie or sodium intake if they adhere to a diet rich in fresh fruits and vegetables (for high potassium content) and low-fat dairy products.[2] This diet (*www.nhlbi.nih.gov/health/public/heart/hbp/dash/*) is strongly recommended because the blood pressure–lowering effects can approach the magnitude of drug monotherapy, can be enhanced by an additional 2/1 mm Hg by dietary sodium restriction, and are seen in all ethnic groups, especially African Americans.

Smokers should be counseled to quit because tobacco (Chapter 31) is such a potent risk factor for coronary heart disease, stroke, and progression of hypertensive nephrosclerosis to end-stage renal disease. Because blood pressure increases transiently by 10 to 15 mm Hg after each cigarette, smokers of more than 20 cigarettes per day often have higher blood pressures out of the office than in the smoke-free medical office. Blood pressure increases similarly with the first morning cup of coffee, but the pressor response to caffeine usually (but not always) habituates throughout the day. Thus, caffeine consumption need not be eliminated.

Moderate alcohol (Chapter 32) consumption (one or two drinks per day) does not increase the risk for hypertension in Western populations; but in Japanese populations, hypertension is more common in men who are moderate drinkers than in men who cannot drink because of a loss-of-function mutation in the alcohol dehydrogenase gene. In all populations, heavy drinking (three or more standard-sized drinks per day) and especially binge drinking activate the sympathetic nervous system the next day during withdrawal and are associated with an increased incidence and severity of hypertension, which is reversible if alcohol consumption decreases.

After a bout of aerobic exercise (Chapter 15), a small reduction in blood pressure can persist for several hours. Relaxation techniques (e.g., meditation, biofeedback, breathing exercises) can decrease blood pressure transiently but generally produce little if any demonstrable effect on ambulatory blood pressure (Chapter 38). However, in some individuals in whom overwhelming home or job strain or anger is a major determinant of high blood pressure, cognitive behavior therapy and anxiolytics (Chapter 404) may be beneficial. Patients often associate hypertension directly with life stress, but stress management alone rarely is sufficient to control their hypertension.

Pharmacologic Therapy

More than 100 antihypertensive medications are marketed (Table 67-5). Lowering blood pressure with medication reduces but does not eliminate cardiorenal risks.

Classes of Oral Antihypertensive Drugs

The various classes of oral antihypertensive drugs have different mechanisms of actions, which explain the therapeutic principles of their use as well as their major contraindications and side effects (Table 67-6).

Diuretics

Mechanism of Action. With initiation of diuretic therapy, contraction of blood volume causes the initial fall in blood pressure. With continued therapy, blood volume is partially restored, and vasodilator mechanisms (e.g., opening of adenosine triphosphate [ATP]-sensitive K^+ channels) sustain the antihypertensive action. Loop diuretics block Na^+-K^+-$2Cl^-$ transport in the thick ascending loop of Henle, where a large portion of the filtered sodium is reabsorbed. Thiazide diuretics and the indoline derivative indapamide block Na^+-Cl^- cotransporter in the distal convoluted tubule, where a smaller portion of the filtered sodium is reabsorbed. Spironolactone and eplerenone prevent aldosterone from activating the mineralocorticoid receptor, thereby inhibiting the downstream activation of ENaC, whereas triamterene and amiloride block ENaC directly; because less sodium is presented to the Na^+,K^+-ATPase on the vascular side of the collecting duct cells, less potassium is excreted in the urine.

Therapeutic Principles. Diuretics are the oldest, least expensive, and still among the most effective antihypertensive medications. In the Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT), the thiazide-type diuretic chlorthalidone was at least as effective as (and in some instances more effective than) newer and more expensive agents (the ACE inhibitor lisinopril or the dihydropyridine CCB amlodipine) in lowering blood pressure and preventing the attendant cardiovascular complications in all subgroups of patients.[3] Combined with other classes of antihypertensive medications, diuretics exert a synergistic effect on blood pressure. The most common cause of apparently drug-resistant hypertension is the failure to include a diuretic in the therapeutic regimen or to dose it correctly.

Because of their long half-lives, thiazides are more effective than short-acting loop diuretics for most patients with hypertension. Chlorthalidone, the thiazide-type diuretic used in the ALLHAT and many other trials, is more potent and has a much longer duration of action than hydrochlorothiazide, which for decades has replaced chlorthalidone as the main thiazide-type diuretic in clinical practice. Low-dose hydrochlorothiazide (12.5 mg/day), often in fixed-dose combination with an ACE inhibitor or ARB, is recommended for mild uncomplicated hypertension, whereas chlorthalidone (typically 25 mg/day, which has a potency equivalent to about 40 mg of hydrochlorothiazide [HCTZ]) is recommended for more severe or more difficult hypertension.

When the GFR falls below 50 mL/min/1.73 m^2, standard doses of hydrochlorothiazide become ineffective, although chlorthalidone or much higher doses of HCTZ can be effective. Loop diuretics are the diuretics of choice for treating hypertension in patients with chronic kidney disease or heart failure. Because the duration of action of furosemide is less than 6 hours, torsemide is a better choice owing to its longer half-life. The addition of chlorthalidone to a loop diuretic can sometimes restore blood pressure responsiveness in patients with resistant hypertension due to volume expansion in the setting of advanced chronic kidney disease.

Thiazides can aggravate glucose intolerance (especially when used in combination with a β-blocker), cause hypokalemia and hyponatremia (especially in older persons), precipitate gout, elevate serum lipids, and rarely cause severe photosensitive dermatitis. They are more likely than any other antihypertensive drugs to cause erectile dysfunction.

With its more favorable side-effect profile, eplerenone (50-100 mg/day) has replaced spironolactone as the drug of choice for primary aldosteronism. Low-dose eplerenone (12.5 to 50 mg/day) and low-dose spironolactone (6.25 to 50 mg/day) have been understudied and underused in primary hypertension. Both drugs are powerful antihypertensives and avoid hypokalemia. Either drug can be remarkably effective as add-on therapy for otherwise drug-resistant hypertension. Hyperkalemia must be avoided when using these agents in patients with kidney disease.

Angiotensin-Converting Enzyme Inhibitors and Angiotensin Receptor Blockers

Mechanism of Action. The renin-angiotensin-aldosterone system is one of the most important targets for antihypertensive drugs. The interaction of angiotensin II with G protein–coupled receptors, termed *AT_1 receptors*, accelerates numerous cellular processes that contribute not only to hypertension but also to its end-organ damage. The ACE inhibitors block the conversion of angiotensin I to angiotensin II, initially leading to a dramatic fall in plasma angiotensin II levels; with continued treatment, however, plasma angiotensin II levels return to normal (the phenomenon of "ACE escape") because ACE inhibitors do not block alternative pathways that generate angiotensin II. The sustained antihypertensive action of ACE inhibitors is explained in part by their ability to block the metabolism of bradykinin, a potent endothelium-dependent vasodilator. These agents slow the deterioration of renal function in patients with chronic kidney disease by causing greater dilation of the efferent renal arteriole, thereby reducing intraglomerular pressure.

By comparison, ARBs lower blood pressure specifically by blocking the interaction of angiotensin II on the AT_1 receptors. Thus, ARBs do not increase bradykinin, which has been implicated in both the therapeutic benefits and the side effects of ACE inhibitors (i.e., cough, angioedema).

Therapeutic Principles. Because of their favorable side-effect profiles and putative ancillary benefits on vascular health, ACE inhibitors and ARBs have gained popularity for the general treatment of hypertension. As monotherapy,

TABLE 67-5 ORAL ANTIHYPERTENSIVE AGENTS

DRUG	DOSE RANGE, TOTAL, MG/DAY (DOSES PER DAY)	USUAL STARTING DOSE, MG/DAY (DOSES PER DAY)
DIURETICS		
Thiazide Diuretics

HCTZ = hydrochlorothiazide.

TABLE 67-6 MAJOR CONTRAINDICATIONS AND SIDE EFFECTS OF ANTIHYPERTENSIVE DRUGS

DRUG CLASS	MAJOR CONTRAINDICATIONS	SIDE EFFECTS
Diuretics		
Thiazides	Gout	Insulin resistance, new-onset type 2 diabetes Hypokalemia, hyponatremia Hypertriglyceridemia Hyperuricemia, precipitation of gout Erectile dysfunction (more than other drug classes) Potentiate nondepolarizing muscle relaxants Photosensitivity dermatitis
Loop diuretics	Hepatic coma	Interstitial nephritis Hypokalemia Potentiate succinylcholine Potentiate aminoglycoside ototoxicity
Potassium-sparing diuretics	Serum potassium concentration > 5.5 mEq/L GFR < 30 mg/mL/1.73 m^2	Hyperkalemia
ACEIs	Pregnancy Bilateral renal artery stenosis Hyperkalemia	Cough Hyperkalemia Angioedema Leukopenia Fetal toxicity Cholestatic jaundice (rare fulminant hepatic necrosis if the drug is not discontinued)
Dihydropyridine CCBs	As monotherapy in chronic kidney disease with proteinuria	Headaches Flushing Ankle edema CHF Gingival hyperplasia Esophageal reflux
Nondihydropyridine CCBs	Heart block Systolic heart failure	Bradycardia, AV block (especially with verapamil) Constipation (often severe with verapamil) Worsening of systolic function, CHF Gingival edema or hypertrophy Increase cyclosporine blood levels Esophageal reflux
ARBs, DRI	Pregnancy Bilateral renal artery stenosis Hyperkalemia	Hyperkalemia Angioedema (very rare) Fetal toxicity
β-Adrenergic blockers	Heart block Asthma Depression Cocaine and methamphetamine abuse	New-onset type 2 diabetes (especially in combination with a thiazide) Heart block, acute decompensated CHF Bronchospasm Depression, nightmares, fatigue Cold extremities, claudication (β_2 effect) Stevens-Johnson syndrome Agranulocytosis
α-Adrenergic blockers	Orthostatic hypotension Systolic heart failure Left ventricular dysfunction	Orthostatic hypotension Drug tolerance (in the absence of diuretic therapy) Ankle edema CHF First-dose effect (acute hypotension) Potentiate hypotension with PDE-5 inhibitors (e.g., sildenafil)
Central sympatholytics	Orthostatic hypotension	Depression, dry mouth, lethargy Erectile dysfunction (dose dependent) Rebound hypertension with clonidine withdrawal Coombs' test–positive hemolytic anemia and elevated liver enzymes with α-methyldopa
Direct vasodilators	Orthostatic hypotension	Reflex tachycardia Fluid retention Hirsutism, pericardial effusion with minoxidil Lupus with hydralazine

ACE = angiotensin-converting enzyme; ARBs = angiotensin receptor blockers; AV = atrioventricular; CCBs = calcium-channel blockers; CHF = congestive heart failure; DRI = direct renin inhibitor; GFR = glomerular filtration rate; NSAIDs = nonsteroidal anti-inflammatory drugs; PDE-5 = phosphodiesterase-5.

they generally are less potent than diuretics or CCBs, particularly in African Americans, but they amplify the effects of these other drug classes when they are used in combination. An ACE inhibitor or an ARB is considered the basis for antihypertensive drug therapy in mild or moderate chronic kidney disease (Chapter 116) because they rarely precipitate hyperkalemia or acute renal failure and appear to provide renoprotection. Serum creatinine and potassium concentrations must be monitored in all patients receiving an ACE inhibitor or ARB. In patients with chronic kidney disease, initiation of an ACE inhibitor or ARB often causes small and transient increases in serum creatinine concentration that do not necessitate discontinuation. ACE inhibitors and ARBs can precipitate acute renal failure in patients with bilateral renal artery stenosis (Chapter 127) or hypovolemia. After correction of hypovolemia, the ACE inhibitor or ARB usually can be restarted safely at a lower dose.

The most common side effect of ACE inhibitors is a dry cough. Patients may complain not of a cough but rather of having to clear the throat or loss of voice later in the day. These symptoms occur in 3 to 39% of patients, resolve in a few days after the drug is discontinued, and can be eliminated by switching the patient to an ARB. The incidence is higher in African Americans than in whites and is highest in Asians.

The ARBs are less effective than dihydropyridine CCBs in controlling hypertension but are increasingly popular because they have a more favorable side-effect profile than ACE inhibitors. Their efficacy is enhanced by addition

of low-dose HCTZ or a dihydropyridine CCB. An increasing number of fixed-dose combinations are available (see Table 67-5). Losartan, the prototype, differs from the other ARBs in two ways: a shorter duration of action, requiring twice-daily dosing if it is used as monotherapy; and a uricosuric effect, which may be beneficial in patients with hyperuricemia. Newer ARBs vary in potency and duration of action. The putative special metabolic benefit of telmisartan, which shares structural homology with the insulin sensitizer pioglitazone, remains unproved.

Direct Renin Inhibitors

Aliskiren is the first in a new class of orally effective, nonpeptide, low-molecular-weight renin inhibitors. Direct renin inhibitors block the renin-angiotensin-aldosterone system at its origin without increasing bradykinin. By eliminating the reactive rise in plasma renin activity seen with ACE inhibitors and ARBs, direct renin inhibition may prevent more hypertensive complications, particularly renal complications. Short-term studies in patients with mild or moderate hypertension suggest that once-daily low-dose (150 mg) or high-dose (300 mg) aliskiren is equivalent to an ARB in terms of both blood pressure–lowering effect and favorable side-effect profile. The contraindications are the same. Randomized trials of cardiovascular outcomes compared with other drugs are pending.

Calcium-Channel Blockers

Mechanism of Action. The CCBs are antiarrhythmic, antianginal, and antihypertensive because they block the opening of voltage-gated (L-type) Ca^{2+} channels in cardiac myocytes and vascular smooth muscle cells. The resultant decrease in the cytosolic Ca^{2+} signal decreases heart rate and ventricular contractility and relaxes vascular smooth muscle. Blood pressure lowering is related mainly to peripheral arterial vasodilation, with the rank order of potency being dihydropyridines > diltiazem >> verapamil. In contrast, for negative chronotropic and inotropic effects, the rank order of potency is verapamil >> diltiazem > dihydropyridines.

Therapeutic Principles. *Short-acting dihydropyridines should not be used to treat hypertension.* By triggering an abrupt fall in blood pressure with reflex sympathetic activation, these rapidly acting arterial vasodilators can precipitate myocardial ischemia, infarction, stroke, and death. By comparison, the safety and efficacy of long-acting dihydropyridine CCBs was confirmed by ALLHAT and the VALUE (Valsartan Antihypertensive Long-term Use Evaluation) trial. For most hypertensive patients, these are among the most potent, best tolerated, and safest antihypertensive medications available, but there are some caveats. For comparable degrees of blood pressure lowering, dihydropyridine CCBs exert protection against myocardial infarction and stroke equivalent to that of diuretics, but their use is associated with a greater risk for heart failure. For patients with renal insufficiency and proteinuria, dihydropyridine CCB-based therapy is less renoprotective than ARB- or ACE inhibitor–based therapy. However, in most patients with renal disease, multiple classes of medications, including dihydropyridines, are required to achieve blood pressure goals. Thus, dihydropyridine CCBs should not be used as first-line therapy for hypertension in patients with proteinuria, but they may be used as adjunctive therapy once the dose of the ACE inhibitor or ARB has been maximized in combination with an appropriate diuretic.

Verapamil is a weak antihypertensive and of limited utility because of dose-dependent constipation. Diltiazem is intermediate in potency between verapamil and the dihydropyridines; it is usually well tolerated. Verapamil and diltiazem can cause heart block, especially in older patients and in patients taking digoxin.

Adrenergic Receptor Blockers and Central Sympatholytics

Sympathetic drive to the sinus node increases heart rate and cardiac output through β-adrenergic receptors, whereas sympathetic drive to the peripheral vasculature causes neurogenic vasoconstriction through α-adrenergic receptors. Sustained activation of the sympathetic nervous system is thought to contribute to chronic hypertension by vascular remodeling, renin release, and attenuation of renal sodium excretion by an action on the distal tubules.

β-Adrenergic Blockers

Mechanism of Action. Interaction of epinephrine or norepinephrine with β_1-adrenoreceptors in the heart causes G protein–linked activation of adenylate cyclase, resulting in positive chronotropic and inotropic effects. Interaction of catecholamines with β_2-adrenoreceptors relaxes bronchiolar and arteriolar smooth muscle. With the initiation of β-blocker therapy, blood pressure at first is little affected because the fall in cardiac output is offset by a compensatory increase in peripheral resistance. Over time, blood pressure falls progressively as the peripheral vasculature relaxes. Thus, the antihypertensive effect of β-blockade involves decreases in cardiac output (β_1-receptors), renin release (β_1-receptors), and norepinephrine release (prejunctional β_2-receptors).

The prototype β-blocker, propranolol, nonselectively blocks both β_1- and β_2-receptors. Other standard β-blockers (metoprolol, atenolol, acebutolol, and bisoprolol) are *relatively* cardioselective. In low doses, they exert a greater inhibitory effect on β_1- than on β_2-receptors, but selectivity is lost at high doses. In contrast, combined α- and β-blockers (labetalol, carvedilol, nebivolol) cause vasodilation by blocking α_1-adrenoreceptors on vascular smooth muscle and possibly by increasing the bioavailability of nitric oxide.

Therapeutic Principles. Although standard β-blockers are first-line medical therapy for ischemic heart disease (Chapters 72 and 73) and heart failure (Chapter 59), they are no longer first-line or even second-line agents for uncomplicated hypertension. They predispose to diabetes, particularly when combined with a thiazide, and offer less stroke protection than other antihypertensive drugs. In addition to being rather weak antihypertensives, they are less effective than other agents in lowering central aortic blood pressure because bradycardia allows more time for wave reflection and thus central pressure augmentation. β-blockers can cause fatigue, limit exercise tolerance, and worsen depression.

Compared with standard β-blockers, combined α-/β-blockers are better antihypertensives. They lower blood pressure more and have a more favorable metabolic profile. Generic carvedilol is now widely affordable ($10 for a 90-day supply), but its patent has expired, and no outcomes trials have been performed. Labetalol, which rarely causes severe hepatotoxicity, should be reserved for hypertensive urgencies, perioperative management, or very difficult hypertension. All β-blockers can precipitate heart block, and they can aggravate preexisting asthma.

α-Adrenergic Blockers

Mechanism of Action. By blocking the interaction of norepinephrine on vascular α-adrenergic receptors, these drugs cause peripheral vasodilation, thereby lowering blood pressure. By increasing skeletal muscle blood flow, they increase insulin sensitivity. By dilating urethral smooth muscle, they improve symptoms of prostatism. Prazosin, doxazosin, terazosin, and intravenous phentolamine selectively block α_1-adrenoreceptors; phenoxybenzamine blocks both α_1- and α_2-receptors.

Therapeutic Principles. Phenoxybenzamine remains the drug of choice for preoperative management of pheochromocytoma (Chapter 235); after α-blockade is achieved, a β-blocker should be added to block an otherwise excessive reflex tachycardia. The selective α_1-blockers are not first-line agents and should not be used as monotherapy because their propensity to cause fluid retention can lead to tachyphylaxis and unmask or exacerbate heart failure. However, when they are prescribed as part of a combination regimen that includes a diuretic, they are effective fourth- or fifth-line therapy for difficult hypertension and are particularly useful in older men with prostatism. Although marketed specifically for prostatism and not as an antihypertensive agent, the selective α_{1A}-blocker tamsulosin lowers blood pressure in some men.

Central Sympatholytics

Mechanism of Action. Stimulation of postsynaptic α_2-adrenergic receptors and imidazoline receptors in the central nervous system lowers central sympathetic outflow, whereas stimulation of presynaptic α_2-receptors causes feedback inhibition of norepinephrine release from peripheral sympathetic nerve terminals. The combined effect is reduced sympathetic drive to the heart and peripheral circulation, thereby leading to decreased heart rate, cardiac output, and peripheral vascular resistance.

Therapeutic Principles. The central sympatholytics are best reserved for short-term oral treatment of severe uncontrolled hypertension. They are potent antihypertensive agents that may be needed as fourth- or fifth-line therapy for very difficult hypertension, but their troublesome central nervous system side effects often reduce quality of life. To avoid rebound hypertension between doses, short-acting clonidine must be given every 6 to 8 hours or, whenever possible, discontinued using a gradual tapering schedule. Rebound hypertension is less of a problem with longer-acting preparations (guanfacine, clonidine patch). α-Methyldopa remains the drug of choice for chronic hypertension in pregnancy (Chapter 247).

Direct Vasodilators

Mechanism of Action. Minoxidil and hydralazine are potent hyperpolarizing arterial vasodilators that work by opening vascular ATP-sensitive K^+ channels.

Therapeutic Principles. By causing selective and rapid arterial dilation, both drugs cause profound reflex sympathetic activation and tachycardia as well as ankle edema. For this reason, hydralazine has largely been replaced by the longer-acting dihydropyridine CCBs. However, hydralazine remains the treatment of choice for acute severe hypertension in pregnancy (Chapter 247). A combination of hydralazine plus nitroglycerin now is recommended for the treatment of heart failure specifically in African Americans, in whom hypertensive heart disease is the most common cause of heart failure (Chapter 58). Severe hypertension accompanying advanced chronic kidney disease (Chapter 132) is the main indication for minoxidil, which must be combined with a β-blocker to prevent excessive reflex tachycardia and with a loop diuretic to prevent excessive fluid retention. Institution of hemodialysis is usually a more effective means of controlling hypertension.

Antihypertensive Drug Interactions

By inhibiting the kidney's ability to excrete sodium, nonsteroidal anti-inflammatory drugs (including aspirin in daily doses above 81 mg), can negate

the antihypertensive action of diuretics and renin-angiotensin system inhibitors, but they do not interfere with CCBs. However, even a single glass of grapefruit juice increases the bioavailability of dihydropyridine CCBs by inhibiting the intestinal cytochrome P-450 3A4 system, which is responsible for the first-pass metabolism of many oral medications. Acetaminophen per se does not appear to cause salt retention, but in Great Britain, and not in the United States, each acetaminophen tablet contains 1000 mg of sodium. A high-fat meal will impair aliskiren absorption. Verapamil and diltiazem will increase blood levels of cyclosporine and digoxin.

Which Drugs for Which Patients?

Choosing the best drugs to treat hypertension in a given patient is based primarily on effective lowering of blood pressure and prevention of hypertensive complications with minimal side effects (see Table 67-6) and cost. A secondary consideration is concomitant treatment of comorbid cardiovascular diseases (e.g., angina, heart failure). According to a strict evidence-based approach, a "compelling indication" is defined as a comorbid condition for which the use of a specific antihypertensive drug has been shown to improve disease outcomes in a randomized controlled trial (Table 67-7).

Choice of Therapy for the Patient with "Uncomplicated" Primary Hypertension

To date, a few DNA sequence variations have been proposed to identify individual patients whose blood pressure is particularly sensitive to a specific drug class. However, pharmacogenetic research has yet to affect the clinical treatment of hypertension.

In the absence of such ideal scientific information, the now outdated 2003 JNC 7 guidelines recommended a thiazide-type diuretic as cost-effective first-line therapy for most patients with hypertension. They also recommended initiation of therapy with two drugs (one being a thiazide) for stage 2 hypertension. In contrast, the European Society of Hypertension–European Society of Cardiology makes no specific drug class recommendation, arguing that the most effective drugs are those that the patient will tolerate and take. The revised guidelines of the British Hypertension Society previously advocated initiation of therapy with an ACE inhibitor or ARB ("A" drug) for young white patients (<55 years), who often have high-renin hypertension, but a CCB or diuretic ("C" or "D" drug) for older and black patients, who often have low-renin hypertension.

In contrast, there is growing evidence and consensus about the overriding importance of lowering blood pressure with combinations of drugs with different mechanisms of action (see Table 67-5), rather than belaboring the choice of the single best initial agent, to reach currently recommended blood pressure treatment targets (see Table 67-3). For example, tight control (goal systolic pressure of <130 mm Hg) of systolic blood pressure in nondiabetic patients is significantly more effective than usual control (goal systolic pressure of <140 mm Hg) in reducing subsequent left ventricular hypertrophy by electrocardiography, and it can reduce important cardiovascular events by 50%.[8] Systolic blood pressure targets are achieved in only 50 to 60% of hypertensive patients, even when they receive an average of three drugs in the idealized setting of a randomized trial.

Low-dose combination drug therapy is not only the best way to control blood pressure but also the best way to minimize side effects because the dose-response relationship for blood pressure is rather flat, occurring at the lower end of the dose range for most medications, whereas many of the side effects are steeply dose dependent. Synergistic combinations achieve blood pressure control at lower doses.

The question is: Which drug combinations are best?

Dual therapy with an ACE inhibitor plus amlodipine (the longest-acting, best studied, and now generic dihydropyridine CCB) was found in recent trials to offer more cardiovascular protection, particularly against stroke, than dual therapy with either a β-blocker plus a thiazide[9] or an ACE inhibitor plus thiazide.[10] Other recent data indicate that ACE inhibitors or ARBs offer similar cardiovascular protection[11] and thus are interchangeable, except for higher cost of ARBs and almost no cough. All the ACE inhibitors and ARBs are available as fixed-dose combinations with a low dose of hydrochlorothiazide (see Table 67-5). Lotrel is the prototype ACE inhibitor–amlodipine fixed-dose combination, and several new (branded) ARB-CCB combinations recently have been marketed (see Table 67-5).

Amlodipine and other dihydropyridine CCBs cause dose-dependent ankle edema because they preferentially dilate arteries rather than veins, thereby elevating hydrostatic pressure; the resulting ankle edema often can be relieved by the addition of an ACE inhibitor, ARB, or aliskiren, which dilate the veins as well as the arteries. Standard β-blockers are no longer recommended to treat uncomplicated hypertension. In contrast, generic carvedilol is being used increasingly as third- or fourth-line therapy. Central sympatholytic agents should be reserved as fifth-line therapy for patients with difficult hypertension.

Despite much compelling basic research on ancillary (pleiotropic) benefits of ACE inhibitors or ARBs to block multiple adverse effects of angiotensin II, in clinical trials most of the cardiovascular benefit derived from these and all other classes of antihypertensive agents comes directly from lowering blood pressure (Fig. 67-10). Dual therapy with an ACE inhibitor and ARB provides no more cardiovascular protection than either alone and is associated with more hypotension and renal failure.[11]

Along with antihypertensive medication and lifestyle modification, additional cardiovascular risk reduction with low-dose aspirin (81 mg) (Chapter 37) and lipid-lowering medication (Chapter 213) should be strongly considered as an integral part of cardiovascular risk reduction. In treated hypertensive

TABLE 67-7 "COMPELLING" INDICATIONS AND PUBLISHED EVIDENCE

COMPELLING INDICATION	DRUG CLASS (RELEVANT CLINICAL TRIALS*)
Systolic heart failure	ACEI (CONSENSUS, SAVE) ARB (Val-HeFT, CHARM) β-Blocker (MERIT-HFCOMET) Aldosterone antagonist (RALES)
Recent MI	β-Blockers (ISIS)
Reduced left ventricular function after MI	ACEI (SAVE, TRACE) Aldosterone antagonist (EPHESUS) β-Blocker (CAPRICORN)
Type 1 diabetes	ACEI (CCSG)
Type 2 diabetes	ACEI (MICRO-HOPE)
Type 2 diabetic nephropathy	ARB (IDNT, RENAAL, IRMA-2, MOSES, ONTARGET)
Nondiabetic chronic kidney disease	ACEI (REIN, AIPRI, AASK, ONTARGET)
CV disease	ACEI (HOPE, EUROPA) ARB (ONTARGET)
Prior stroke or TIA	ACEI + thiazide (PROGRESS)
Isolated systolic hypertension in older persons	DHP-CCB (Syst-Eur, Syst-China, STOP-2) Thiazide (SHEP) ACEI (STOP-2) ARB (SCOPE, second-line)
Hypertension in the very elderly	ACEI + thiazide (HYVET)
Left ventricular hypertrophy by electrocardiography	ARB plus thiazide (LIFE)

ACE = angiotensin-converting enzyme; ACEI = angiotensin-converting enzyme inhibitor; ARB = angiotensin receptor blocker; CHF = congestive heart failure; CV = cardiovascular; DHP-CCB = dihydropyridine calcium-channel blocker; MI = myocardial infarction; TIA = transient ischemic attack.
Modified and updated from Elliott WJ. *Compelling Indications for Antihypertensive Drugs.* ASH Clinical Hypertension Review Course. New York: American Society of Hypertension; 2005:333-351.

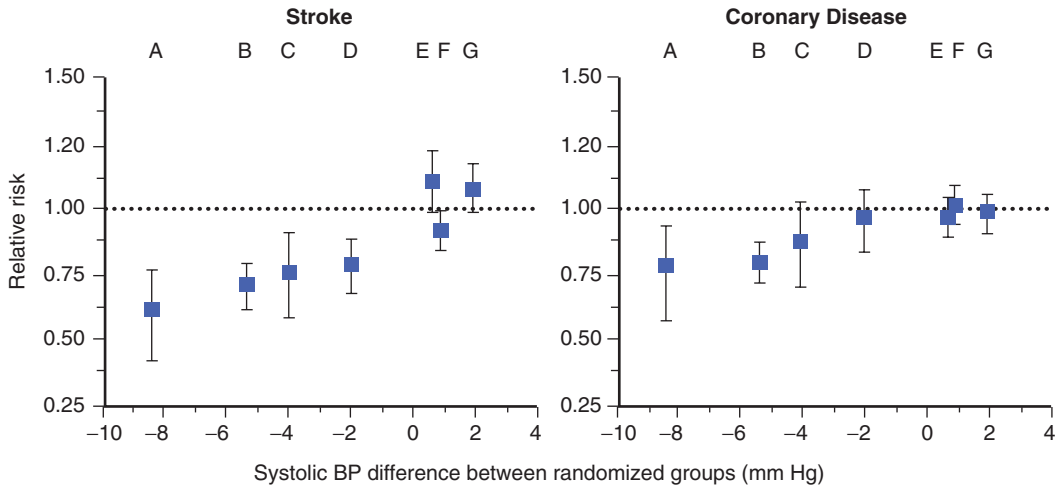

FIGURE 67-10. Meta regression analysis of randomized controlled intervention trials. (12 trials, *N* = 94,338 patients with hypertension, coronary artery disease, or diabetic nephropathy who were assigned to treatment with amlodipine or an angiotensin receptor blocker.) Systolic blood pressure (BP) differences were obtained by subtracting the mean change in the amlodipine or ARB group from the corresponding mean change in the reference group. Regardless of drug class, most of the protection against stroke and myocardial infarction was related to lowering of systolic BP. (From Wang J-G, Li Y, Franklin SS, et al. Prevention of stroke and myocardial infarction by amlodipine and angiotensin receptor blockers: a quantitative review. *Hypertension.* 2007;50:181-188.)

patients, low-dose aspirin reduces the risk for myocardial infarction by 36% without increasing the risk for intracerebral hemorrhage. In patients with moderate hypertension, additional cardiovascular risk factors, and an average low-density lipoprotein cholesterol level of 130 mg/dL, the addition of 10 mg of atorvastatin to the antihypertensive regimen results in a 36% reduction in fatal and nonfatal myocardial infarction and a 27% reduction in fatal and nonfatal stroke.[12] Thus, statin therapy should be used in such patients with the goal of reducing the low-density lipoprotein cholesterol level to below 100 mg/dL or even lower (Chapter 213).

Hypertension in Minority Populations

Mexican Americans have the lowest rate of control of hypertension of all U.S. race/ethnic groups but also have the highest risk for diabetes. Thus, antihypertensive regimens should be tailored to avoid causing more new cases of diabetes. In African Americans, hypertension not only is more prevalent than in the general population but also starts at a younger age, is less well controlled, and causes disproportionate and premature disability and death. African Americans commonly have lower plasma renin levels and have less response to monotherapy with an ACE inhibitor, ARB, or β-blocker than do white hypertensive patients. In one randomized trial, African American participants in the ALLHAT had a 40% higher risk for fatal stroke when taking an ACE inhibitor than when taking a diuretic, probably because blood pressure remained higher on the ACE inhibitor. However, when high doses of an ACE inhibitor or ARB are used in combination with a diuretic, antihypertensive efficacy is amplified, and racial/ethnic differences disappear. ACE inhibitors or ARBs can help achieve excellent control of hypertension in African American patients when used as part of an appropriate multidrug regimen.

Hypertensive Nephrosclerosis: A Misnomer?

Second only to diabetes, hypertension is thought to be the next most common cause of end-stage renal disease (ESRD; Chapter 132). Because African Americans are at increased risk for both hypertension and chronic kidney disease, most cases of nondiabetic kidney disease in African Americans have been attributed to *hypertensive nephrosclerosis*—small shrunken kidneys caused by chronic glomerular ischemia owing to severe constriction of the afferent renal arteriole. However, most cases of presumed hypertensive nephrosclerosis are due primarily to a West African ancestral gene locus on chromosome 21 (ApoL1), which both confers resistance against trypanosomiasis and is a powerful risk factor for non-diabetic chronic kidney disease. This risk allele, which is present in 30% of African Americans, may explain why intensive lowering of blood pressure failed to prevent ESRD in the African American Study of Kidney Disease trial.[13]

Mild to moderate nondiabetic chronic kidney disease has been considered a compelling indication for ACE inhibitors, but the renal benefit of an ACE inhibitor–based regimen in nondiabetic chronic kidney disease has been confined to short-term trials and was not demonstrated during long-term follow-up.[13] A recommended multidrug regimen for hypertension in patients with stage II or stage III chronic kidney disease is a loop diuretic (for effective control of obligatory sodium retention), a low-dose ACE inhibitor or ARB (to reduce intraglomerular hypertension), and a central sympatholytic (to reduce sympathetic overactivity from a pressor reflex arising in the failing kidneys). If proteinuria is present, the blood pressure should be lowered gradually to 130/80 mm Hg, if possible, without causing a progressive rise in serum creatinine levels. The ACE inhibitor and loop diuretic will need to be held temporarily if the rise in serum creatinine concentration exceeds 30% of the baseline value or the serum potassium concentration increases to more than 5.6 mmol/L; they often can be restarted at lower doses once the acute deterioration in renal function has resolved.

Hypertension in Patients with Diabetes

Compared with its 25% prevalence in the general adult population, hypertension is present in 75% of diabetic patients and is a major factor contributing to an excessive risk for myocardial infarction, stroke, heart failure, microvascular complications, and diabetic nephropathy progressing to ESRD (Chapter 237). Compared with less intensive treatment, more intensive reduction of blood pressure has been proved to reduce stroke and microvascular end points dramatically in patients with diabetes. To reduce these risks, blood pressures should be lowered to 130/80 mm Hg, a goal that typically requires three to five drugs.[14] On the basis of data from randomized trials, type 1 diabetes (Chapter 236) with renal insufficiency is a compelling indication for ACE inhibitor–based antihypertensive therapy, whereas type 2 diabetes (Chapter 237) with renal insufficiency is now considered to be a compelling indication for ARB-based antihypertensive therapy because similar data do not exist for ACE inhibitor–based regimens in type 2 diabetic patients (see Table 67-7). However, an ACE inhibitor or ARB alone rarely achieves the stringent blood pressure goals; a loop diuretic is usually needed to shrink the expanded plasma volume, and a dihydropyridine CCB is usually needed for antihypertensive synergy. To optimize renal protection, the CCB should not be started until antihypertensive therapy has been initiated with an ACE inhibitor or ARB. A β-blocker should be added if the patient has coronary disease, which is prevalent in diabetes or heart failure. The α- and β-blocker carvedilol has a better metabolic profile than the pure β-blockers.

Systolic Hypertension in Older Persons

In older persons with isolated systolic hypertension, lowering systolic pressure from above 160 to below 150 mm Hg has been shown to reduce the risk for stroke by 30%, myocardial infarction by 23%, and overall cardiovascular mortality by 18%; it also reduces heart failure admissions and slows the progression of dementia. Even hypertensive patients older than 80 years have benefited from treatment with an ACE inhibitor and thiazide regimen (perindopril plus indapamide) compared with placebo.[15]

However, because of slower drug metabolism and reduced postural autonomic reflexes in older persons, it is important to start with low doses of antihypertensive medication and titrate slowly. If orthostatic hypotension is present, medication should be titrated to standing blood pressure. The same triple combination therapy for systolic and diastolic hypertension should be used for isolated systolic hypertension: an ACE inhibitor (or ARB), a dihydropyridine CCB, and thiazide. In some older patients, even low-dose thiazides cause unacceptable degrees of hyponatremia. β-blockers should be restricted to patients with coronary disease or heart failure and should be used with caution because they are more likely to precipitate heart block, to impair exercise tolerance, and to cause depression.

Blood Pressure Lowering for Secondary Prevention of Stroke

Most neurologists recommend minimal or no blood pressure reduction during an acute ischemic stroke unless the patient is a candidate for thrombolytic therapy (Chapters 414 and 415). Once the patient's condition has stabilized, however, lowering blood pressure by 12/5 mm Hg with a combination

of the thiazide diuretic indapamide plus the ACE inhibitor perindopril reduces the risk for recurrent stroke by 43%.[16]

Hypertension in Patients with Ischemic Heart Disease

In patients with stable coronary disease, 130/80 mm Hg is an appropriate threshold for starting an antihypertensive regimen. Blood pressure should be lowered slowly, and caution is advised in lowering diastolic blood pressure below 60 mm Hg to avoid the potential risk for subendocardial ischemia. To lower myocardial oxygen demands in patients with coronary disease, the antihypertensive regimen should reduce blood pressure without causing reflex tachycardia. Thus, a β-blocker is often prescribed in conjunction with a dihydropyridine CCB. β-Blockers are indicated for hypertensive patients who have sustained a myocardial infarction (Chapters 72 and 73) and for most patients with chronic heart failure (Chapter 59), and they are typically first-line therapy in patients with angina (Chapter 71). ACE inhibitors are indicated for almost all patients with left ventricular systolic dysfunction (Chapters 59 and 60) and may be considered for post–myocardial infarction patients even in the absence of ventricular dysfunction (Chapters 72 and 73). In patients with very high cardiovascular risk profiles but without known left ventricular dysfunction, the ACE inhibitor ramipril (10 mg/day) reduces cardiovascular events, an effect that may or may not be beyond what can be explained by blood pressure reduction alone. In normotensive patients with stable coronary artery disease, data are conflicting as to whether the addition of an ACE inhibitor reduces the risk for subsequent cardiovascular events.

The CCBs, including amlodipine, and the α-blockers have a greater propensity than other antihypertensive drugs to precipitate heart failure and should be avoided in hypertensive patients with known heart failure and those with asymptomatic left ventricular systolic dysfunction. Optimal control of hypertension is perhaps the best way to prevent diastolic heart failure.

Hypertension Associated with Oral Contraceptives and Estrogen Replacement

Oral contraceptives, particularly current low-dose estrogen preparations, cause a small increase in blood pressure in most women but rarely cause a large increase into the hypertensive range. The mechanism is unknown, but women older than 35 years and those who smoke or are overweight appear to be at increased risk. Drospirenone, a progestin with structural homology to spironolactone, is claimed to have neutral or beneficial effects on blood pressure from mineralocorticoid reception antagonism. If hypertension develops, oral contraceptive therapy should be discontinued in favor of other methods of contraception. Oral estrogen replacement therapy after menopause appears to cause a small increase in blood pressure, whereas transdermal estrogen (which bypasses first-pass hepatic metabolism) appears to cause a small decrease in blood pressure.

Hypertension in Pregnancy

Hypertension, the most common nonobstetric complication of pregnancy, is present in about 10% of all pregnancies (Chapter 247). About one third is caused by chronic hypertension and two thirds by preeclampsia, defined as an increase in blood pressure to 140/90 mm Hg or more after the 20th week of gestation, accompanied by proteinuria (>300 mg/24 hours) and pathologic edema. Preeclampsia sometimes also is accompanied by seizures (eclampsia) and the multisystem HELLP syndrome (Chapters 153 and 247) of hemolysis, elevated liver enzymes, and low platelets. Preeclampsia is the most common cause of maternal mortality and perinatal mortality. Given the current trend of childbearing in women older than 35 years, the prevalence of chronic hypertension in pregnancy is rising. In the absence of randomized trials, α-methyldopa remains the drug of choice for chronic hypertension in pregnancy, and hydralazine (plus bedrest) for preeclampsia. In preeclampsia, magnesium sulfate is predictably effective in preventing seizures but, despite being a vasodilator, has inconsistent effects on blood pressure.

Resistant Hypertension

One in five hypertensive patients has drug-resistant hypertension, in which blood pressure remains above goal values despite concurrent treatment with three antihypertensive drugs of different classes. Most such patients actually have *pseudoresistance* from (1) improper blood pressure measurement technique, (2) white coat reactions, (3) medication nonadherence, (4) ingestion of pressor substances (e.g., nonsteroidal anti-inflammatory drugs, excessive alcohol, psychiatric drugs), or (5) an inadequate blood pressure regimen. Common correctable issues are clonidine rebound (especially with as-needed dosing), inadequate diuretic therapy, inappropriate use of a loop diuretic in a patient with normal renal function, infrequent dosing with a short-acting loop diuretic (e.g., once-a-day furosemide), and low-dose thiazide in a patient with impaired renal function. Significant impairment in renal function can be present with serum creatinine concentrations in the range of 1.2 to 1.4 mg/dL or even lower, particularly in older patients with little muscle mass. GFR should be estimated by standard equations (Chapter 116), and urinary albumin-to-creatinine ratio from a spot urine specimen should be obtained.

Truly drug-resistant patients should be screened for secondary hypertension, especially unrecognized chronic kidney disease, obstructive sleep apnea, and primary aldosteronism. In the absence of an identifiable cause for the hypertension, a mineralocorticoid receptor antagonist and an α-/β-blocker are recommended as highly effective fourth- and fifth-line therapy. Low-dose eplerenone or spironolactone can be remarkably effective for resistant hypertension—even when serum aldosterone is within the normal range. An implantable carotid baroreceptor pacemaker and radio frequency ablation of the renal nerves are potentially useful device-based treatments currently undergoing evaluation for drug-resistant hypertension.

Acute Severe Hypertension

Twenty-five percent of all emergency department patients present with an elevated blood pressure (Chapter 7). *Hypertensive emergencies* are acute, often severe, elevations in blood pressure, accompanied by rapidly progressive target organ dysfunction, such as myocardial or cerebral ischemia or infarction, pulmonary edema, or renal failure. *Hypertensive urgencies* are severe elevations in blood pressure without severe symptoms and without evidence of acute or progressive target organ dysfunction. The key distinction depends on the state of the patient and the assessment of target organ damage, not just the absolute level of blood pressure.

The full-blown clinical picture of a hypertensive emergency is a critically ill patient who presents with a blood pressure above 220/140 mm Hg, headaches, confusion, blurred vision, nausea and vomiting, seizures, pulmonary edema, oliguria, and grade 3 or grade 4 hypertensive retinopathy (Fig. 67-11). Hypertensive emergencies require immediate intensive care unit (ICU) admission for intravenous therapy and continuous blood pressure monitoring. Hypertensive emergencies often can be managed with oral medications and appropriate outpatient follow-up in 24 to 72 hours. The most common hypertensive cardiac emergencies include acute aortic dissection (Chapter 78), hypertension after cardiac surgery (Chapter 74), acute myocardial infarction (Chapter 73), and unstable angina (Chapter 72). Other hypertensive emergencies include cocaine-induced sympathetic crisis, eclampsia (Chapter 247), head trauma (Chapter 406), severe body burns (Chapter 112), postoperative bleeding from vascular suture lines, and epistaxis that cannot be controlled with anterior and posterior nasal packing. Neurologic emergencies—acute ischemic stroke, hemorrhagic stroke, subarachnoid hemorrhage, and hypertensive encephalopathy—can be difficult to distinguish from one another (Chapters 413 to 415). Hypertensive encephalopathy (Chapter 415) is characterized by severe hypertensive retinopathy (retinal hemorrhages and exudates, with or without papilledema) and a posterior leukoencephalopathy (affecting mainly the white matter of the parieto-occipital regions) seen on cerebral MRI or CT. A new focal neurologic deficit suggests a stroke in

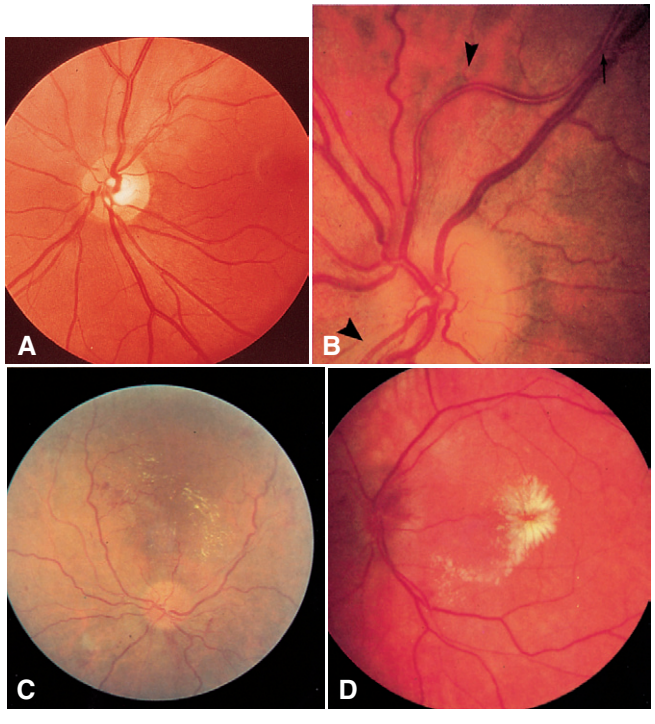

FIGURE 67-11. Hypertensive retinopathy is traditionally divided into four grades. **A,** Grade 1 shows early and minor changes in a young patient. Increased tortuosity of a retinal vessel and increased reflectiveness (silver wiring) of a retinal artery are seen at 1 o'clock in this view. Otherwise, the fundus is completely normal. **B,** Grade 2 also shows increased tortuosity and silver wiring *(arrowheads)*. In addition, there is "nipping" of the venules at arteriovenous crossings. **C,** Grade 3 shows the same changes as grade 2 plus flame-shaped retinal hemorrhages and soft "cotton-wool" exudates. **D,** In grade 4, there is swelling of the optic disc (papilledema), retinal edema is present, and hard exudates may collect around the fovea, producing a typical "macular star." (From Forbes CD, Jackson WF. *Color Atlas and Text of Clinical Medicine,* 3rd ed. London: Mosby; 2003.)

evolution, which demands a much more conservative approach to the elevated blood pressure (Chapter 414).

In most other hypertensive emergencies, the goal of parenteral therapy is to achieve a controlled and gradual lowering of blood pressure. A good rule of thumb is to lower the initially elevated arterial pressure by 10% in the first hour and by an additional 15% during the next 3 to 12 hours to a blood pressure of no less than 160/110 mm Hg. Blood pressure can be reduced further during the next 48 hours. Exceptions to this rule are aortic dissection (Chapter 78) and postoperative bleeding from vascular suture lines, two situations that demand much more rapid normalization of blood pressure. In most other cases, unnecessarily rapid correction of the elevated blood pressure to completely normal values places the patient at high risk for worsening cerebral, cardiac, and renal ischemia. In chronic hypertension, cerebral autoregulation is reset to higher than normal blood pressures. This compensatory adjustment prevents tissue overperfusion (increased intracranial pressure) at very high blood pressures, but it also predisposes to tissue underperfusion (cerebral ischemia) when an elevated blood pressure is lowered too quickly (Chapter 414). In patients with coronary disease, overly rapid or excessive reduction in diastolic blood pressure in the ICU can precipitate an acute myocardial ischemia or infarction.

Intravenous Drugs for Hypertensive Emergencies. Among parenteral agents for hypertensive emergencies (Table 67-8), no definitive comparisons of efficacy and safety exist. Sodium nitroprusside, which is a nitric oxide donor that causes both venous and arterial dilation, has been the most widely used agent for hypertensive emergencies because it can be titrated rapidly to control blood pressure. Disadvantages are reflex tachycardia, rebound hypertension after discontinuation, and thiocyanate toxicity in patients with renal insufficiency. Intravenous nitroglycerin, another nitric oxide donor, is a potent coronary vasodilator and therefore the drug of choice for hypertension in the setting of acute coronary syndromes, when it typically is combined with intravenous β-blockade (metoprolol) to reduce the double product (systolic blood pressure times heart rate) and thus myocardial oxygen demands. Nitroglycerin also is a potent venodilator that lowers preload in patients with hypertension in the setting of exacerbated heart failure. However, nitroprusside may be necessary if pulmonary edema results from severe hypertension (increased afterload). Compared with nitroprusside, the fall in blood pressure is less predictable with nitroglycerin. Intravenous labetalol is an effective treatment of hypertensive crisis, particularly in the setting of myocardial ischemia with preserved ventricular function. Nicardipine is a parenteral dihydropyridine CCB that is used most often in the postoperative cardiac surgery patient. Clevidipine, a new dihydropyridine CCB with an ultrafast onset and offset of action of 1 minute, is a pure arterial vasodilator that does not depress cardiac output and appears safe for patients with heart failure. Fenoldopam mesylate is a selective dopamine-1 receptor agonist that causes both systemic and renal vasodilation as well as increased glomerular filtration, natriuresis, and diuresis; it is a good choice for hypertensive emergencies in the setting of acute renal failure. Hydralazine (intravenous or intramuscular) is recommended only for hypertension during pregnancy because of the marked reflex tachycardia it precipitates.

After the blood pressure has been brought under acute control, oral labetalol and dihydropyridine CCBs are particularly useful agents in weaning patients from parenteral therapy so they can be transferred from the ICU. A few doses of intravenous furosemide are often needed to overcome drug resistance due to secondary volume expansion resulting from parenteral vasodilator therapy.

Secondary hypertension should be suspected in patients admitted to the ICU with hypertensive crisis. Normal 24-hour urinary catecholamine values or normal plasma normetanephrine and metanephrine values collected when the blood pressure is the highest (first 24 hours in ICU) effectively rule out pheochromocytoma (Chapter 235). Bilateral renal artery stenosis (Chapter 127) and other secondary causes should be excluded after the patient has been transferred out of the ICU but before discharge from the hospital.

Oral Medications for Hypertensive Urgencies. Most patients who present to the emergency department with hypertensive urgencies either are not adhering to their medical regimen or are being treated with an inadequate regimen. To expedite medication changes, outpatient follow-up should be arranged within 72 hours. Uncontrolled severe chronic hypertension may not require acute treatment in the emergency department if the patient clearly has adequate outpatient follow-up. Otherwise, for management of the patient during the short interim period, labetalol is effective in a dose of 200 to 300 mg, which can be repeated in 2 to 3 hours and then prescribed in twice-daily dosing. If a β-blocker is contraindicated, clonidine is effective in an initial dose of 0.1 or 0.2 mg followed by additional hourly doses of 0.1 mg. Captopril, a short-acting ACE inhibitor, lowers blood pressure within 15 to 30 minutes of oral dosing. A small test dose of 6.25 mg should be used to avoid an excessive fall in blood pressure in hypovolemic patients; then, the full oral dose is 25 mg, which can be repeated in 1 to 2 hours and prescribed as 25 to 75 mg twice daily.

Incidental Blood Pressure Elevation in the Emergency Department

Blood pressures above 160/110 mm Hg are a common incidental finding among patients who present to emergency departments and other acute care settings for urgent medical or surgical care of symptoms that are unrelated to blood pressure (e.g., musculoskeletal pain, orthopedic injury). The elevated blood pressure more often is the first indication of chronic hypertension than a simple physiologic stress reaction, so there is an important opportunity to initiate primary care referral for formal evaluation of possible chronic hypertension. Home or ambulatory blood pressure monitoring is indicated to determine whether the patient's blood pressure normalizes completely once the acute illness has resolved.

PROGNOSIS

An important prognostic factor in hypertension is electrocardiographic or echocardiographic left ventricular hypertrophy (LVH), with the latter already present in as many as 30% of patients with newly diagnosed hypertension and

TABLE 67-8 PARENTERAL AGENTS FOR MANAGEMENT OF HYPERTENSIVE EMERGENCIES

AGENT	DOSE	ONSET OF ACTION	PRECAUTIONS
PARENTERAL VASODILATORS			
Sodium nitroprusside	0.25-10 μg/kg/min IV infusion	Immediate	Thiocyanate toxicity, rebound hypertension
Nitroglycerin	5-100 μg/min IV infusion	2-5 min	Headache, tachycardia, tolerance
Nicardipine	5-15 mg/hr IV infusion	5-10 min	Protracted hypotension after prolonged use
Clevidipine	1-2 mg as rapid IV infusion, rapidly increase dose to 16 mg	2-4 min	Minimal
Fenoldopam mesylate	0.1-0.3 μg/kg/min IV infusion	1-5 min	Headache, tachycardia, increased intraocular pressure
Hydralazine	5-10 mg as IV bolus or 10-40 mg IM; repeat q4-6h	10 min IV; 20 min IM	Unpredictable and excessive falls in pressure; reflex tachycardia, angina exacerbation
Enalaprilat	0.625-1.25 mg q6h IV bolus	15-60 min	Unpredictable and excessive falls in pressure; acute renal failure (in bilateral renal stenosis)
PARENTERAL ADRENERGIC INHIBITORS			
Labetalol	20-80 mg as slow IV injection q10min, or 0.5-2 mg/min IV as infusion hypotension	5-10 min	Bronchospasm, heart block, orthostatic hypotension
Metoprolol	5 mg IV q10min × 3 doses	5-10 min	Bronchospasm, heart block, heart failure, exacerbation of cocaine-induced MI
Esmolol	500 μg/kg IV during 3 min, then 25-100 mg/kg/min as IV infusion	1-5 min	Bronchospasm, heart block, heart failure
Phentolamine	5-10 mg IV bolus q5-15min	1-2 min	Tachycardia, orthostatic hypotension

90% of patients with severe hypertension. LVH is associated with an increased risk for heart failure, stroke, and kidney failure. All drugs that lower blood pressure will reduce left ventricular mass, but the reduction averages only 12% or less and is less with β-blockers. With regression of LVH, the associated risks are reduced but not eliminated.

Because of their relatively short duration (typically <5 years), randomized trials may underestimate the lifetime protection against disability and death afforded by several decades of antihypertensive therapy in clinical practice. In the Framingham Heart Study, treatment of hypertension for 20 years in middle-aged adults reduced total cardiovascular mortality by 60%, which is considerably greater than the results of most randomized controlled trials despite the less intense treatment guidelines when therapy was initiated in the 1950s to 1970s. Further benefits may be seen with lower blood pressure treatment thresholds and goals than those presently endorsed, along with better control of associated cardiovascular risk factors.

PULMONARY HYPERTENSION

VALLERIE MCLAUGHLIN

DEFINITION

The normal pulmonary vasculature is a low-pressure system, with less than one tenth the resistance to flow observed in the systemic vasculature. Pulmonary hypertension refers to the hemodynamic state in which the pressure in the pulmonary artery is elevated above a mean of 25 mm Hg. A specific type of pulmonary hypertension, pulmonary arterial hypertension, also requires that the left heart filling pressure (pulmonary capillary wedge pressure, left ventricular end-diastolic pressure, or left atrial pressure) be 15 mm Hg or less. The syndrome of pulmonary arterial hypertension results when blood flow through the pulmonary circulation is restricted, thereby leading to pathologic increases in pulmonary vascular resistance and, ultimately, to right ventricular failure. Pulmonary hypertension may also be a consequence of many other chronic diseases, including left heart failure (Chapter 58), a variety of parenchymal lung diseases, and thromboembolic disease (Chapter 98) (Table 68-1).

EPIDEMIOLOGY

Normal pulmonary blood pressure is 20/10 (mean 15) mm Hg at rest at sea level, rising to 30/13 (mean 20) mm Hg with mild exercise. Pressures rise with altitude, and at an altitude of about 15,000 feet, normal resting pulmonary artery pressures are about 38/14 (mean 20) mm Hg. Pulmonary arterial systolic pressure rises gradually with age, and each 10-mm Hg increase is associated with a 2.7-fold greater risk for mortality.

Idiopathic pulmonary arterial hypertension, formerly called primary pulmonary hypertension, is the prototype of group 1 pulmonary arterial hypertension. This disease affects women more than men in a 2 : 1 ratio. It may present at any age, with a mean age of onset of 37 years. The prevalence of pulmonary arterial hypertension is between 15 and 26 per million persons. Heritable pulmonary arterial hypertension occurs in a familial context, most often (70%) owing to a mutation in the bone morphogenic protein receptor type 2. Less commonly, mutations in activin receptor–like kinase type 1, or endoglin, have been identified in patients with pulmonary arterial hypertension, predominately with coexistent hereditary hemorrhagic telangiectasia (Chapter 176). Drug- and toxin-induced pulmonary arterial hypertension has been most clearly linked to anorexigens, including aminorex, fenfluramine, and dexfenfluramine. Although these agents are no longer used, observational studies suggest that amphetamines, methamphetamines, and L-tryptophan are likely related to the development of pulmonary arterial hypertension.

One of the most common types of group 1 pulmonary arterial hypertension occurs in the setting of connective tissue diseases. For example, the prevalence of pulmonary arterial hypertension in patients with scleroderma (Chapter 275) is in the range of 7 to 12%. It is less common in systemic lupus erythematosus (Chapter 274), rheumatoid arthritis (Chapter 272), and other systemic vasculitides (Chapter 278). Pulmonary arterial hypertension is a rare but well established complication of human immunodeficiency virus (HIV) infection, with a prevalence of 0.5%. Prospective hemodynamic studies show that 2 to 6% of patients with portal hypertension (Chapter 148) develop pulmonary arterial hypertension, although the reason for the association is not clear.

A significant proportion of patients with untreated systemic-to-pulmonary shunts, commonly owing to congenital heart disease (Chapter 69), develop pulmonary arterial hypertension. Persistent exposure of the pulmonary vasculature to increased blood flow and pressure leads to an elevated pulmonary vascular resistance. In some cases, Eisenmenger's syndrome (Chapter 69), with a reversal of flow across the defect, results in right-to-left shunting. Pulmonary veno-occlusive (Chapter 98) disease and pulmonary capillary hemangiomatosis are rare disorders that directly affect the pulmonary vasculature. The presentation of each is often similar to pulmonary arterial hypertension, but the prognosis is particularly poor.

Pulmonary hypertension owing to left heart disease probably represents the most frequent cause of pulmonary hypertension seen in practice (group 2 patients). Left-sided ventricular (Chapter 58) or valvular disease

TABLE 68-1 UPDATED CLINICAL CLASSIFICATION OF PULMONARY HYPERTENSION

GROUP 1
Pulmonary arterial hypertension (PAH)
Idiopathic PAH
Heritable
BMPR2
ALK1, endoglin (with or without hereditary hemorrhagic telangiectasia)
Unknown
Drug and toxin induced
Associated with
Connective tissue diseases
HIV infection
Portal hypertension
Congenital heart diseases
Schistosomiasis
Chronic hemolytic anemia
Persistent pulmonary hypertension of the newborn
Pulmonary veno-occlusive disease with left to right shunts and/or pulmonary capillary hemangiomatosis
GROUP 2
Pulmonary hypertension owing to left heart disease
Systolic dysfunction
Diastolic dysfunction
Valvular disease
GROUP 3
Pulmonary hypertension owing to lung diseases and/or hypoxia
Chronic obstructive pulmonary disease
Interstitial lung disease
Other pulmonary diseases with mixed restrictive and obstructive pattern
Sleep-disordered breathing
Alveolar hypoventilation disorders
Chronic exposure to high altitude
Developmental abnormalities
GROUP 4
Chronic thromboembolic pulmonary hypertension
GROUP 5
Pulmonary hypertension with unclear multifactorial mechanisms
Hematologic disorders: myeloproliferative disorders, splenectomy
Systemic disorders: sarcoidosis, pulmonary Langerhans cell histiocytosis: lymphangioleiomyomatosis, neurofibromatosis, vasculitis
Metabolic disorders: glycogen storage disease, Gaucher's disease, thyroid disorders
Others: tumoral obstruction, fibrosing mediastinitis, chronic renal failure on dialysis

ALK1 = activin receptor-like kinase type 1; BMPR2 = bone morphogenetic protein receptor type 2; HIV = human immunodeficiency virus.
Reprinted from Simonneau G, Robbins IM, Beghetti M, et al. Updated clinical classification of pulmonary hypertension. *J Am Coll Cardiol.* 2009;54:S43-S54.

(Chapter 75) may increase left atrial pressure, which then is transmitted back to the pulmonary vasculature. Often, the transpulmonary gradient and pulmonary vascular resistance are normal. In such cases, optimal treatment of the left heart disease results in reduction of the left heart filling pressures and, consequently, a reduction in the pulmonary artery pressures. On occasion, patients with left heart disease have an elevation of pulmonary artery pressure greater than expected based on the elevation of left heart filling pressures, with a transpulmonary gradient of more than 12 mm Hg and a pulmonary vascular resistance of more than 3 Wood units (Wood units = [pulmonary artery pressure minus mean pulmonary capillary wedge pressure] divided by cardiac output). This difference may be due to an increase in pulmonary artery vasomotor tone or pulmonary vascular remodeling in the setting of persistently elevated left heart filling pressures.

Group 3 patients have pulmonary hypertension owing to lung diseases or hypoxia. Any disorder that results in hypoxemia (e.g., chronic obstructive lung disease [Chapter 88], interstitial lung disease [Chapter 92], sleep-disordered breathing [Chapter 100]) may result in pulmonary hypertension, although the pressure elevation tends to be modest, with a mean pulmonary artery pressure of 25 to 35 mm Hg. Echocardiography-based observations have suggested that up to 80% of patients with chronic obstructive lung disease and idiopathic pulmonary fibrosis have elevated pulmonary artery pressures. In patients who have more advanced parenchymal lung disease and undergo evaluation for lung volume reduction surgery or lung transplantation, 40 to 50% have pulmonary hypertension at the time of right heart catheterization. Most often, the elevations in pulmonary artery pressures are modest, but a small proportion of patients have more substantial elevations.

Group 4 patients have chronic thromboembolic pulmonary hypertension (Chapter 98), which must be differentiated from the other groups because the treatment is quite different. Approximately 4% of patients who have suffered an acute pulmonary embolism progress to develop chronic thromboembolic pulmonary hypertension. Approximately half of those ultimately diagnosed with chronic thromboembolic pulmonary hypertension do not have a known history of an acute pulmonary embolism. Patients with a significant clot burden can be candidates for a pulmonary thromboendarterectomy, which is a potentially curative procedure for this disorder.

Group 5 pulmonary arterial hypertension consists of several forms for which the etiology is unclear or multifactorial. Among these conditions are a number of hematologic, systemic, and metabolic disorders.

PATHOBIOLOGY

The pathobiology of pulmonary arterial hypertension is complex and incompletely elucidated (Fig. 68-1). The pulmonary arterial hypertension phenotype is characterized by endothelial dysfunction, a decreased ratio of apoptosis to proliferation in pulmonary artery smooth muscle cells, and a thickened, disordered adventitia in which adventitial metalloproteases are excessively activated. The evolution of pulmonary vascular disease frequently originates with the interaction of a predisposing state and one or more inciting stimuli, a concept referred to as the "multiple-hit hypothesis."

In group 1 pulmonary arterial hypertension, patients have a panvasculopathy predominantly affecting the small pulmonary arterioles. It is characterized by a variety of arterial abnormalities, including intimal hyperplasia, medial hypertrophy, adventitial proliferation, thrombosis in situ, varying degrees of inflammation, and plexiform lesions. An individual patient may manifest all or some of these lesions, and the distribution of the lesions may be diffuse or focal.

The genetic defect best characterized in heritable pulmonary arterial hypertension is that of the bone morphogenetic protein receptor type 2, a member of the transforming growth factor-β signaling family. This defect accounts for 70% of heritable pulmonary arterial hypertension cases, although it has also been detected in 11 to 40% of patients with apparently idiopathic pulmonary arterial hypertension and no family history. Characteristics of this gene include incomplete penetrance (20%) and genetic anticipation. Less commonly, mutations in activin receptor–like kinase type 1, or endoglin, have been identified, usually in families with coexistent hereditary hemorrhagic telangiectasia.

The imbalance in the production or metabolism of vasoactive mediators in the pulmonary vasculature includes a reduction in prostacyclin and nitric oxide, which have vasodilator and antiproliferative properties, and an increase in thromboxane and endothelin, which are vasoconstrictors as well as mitogens. The reduction in nitric oxide synthase in pulmonary arterial hypertension diminishes nitric oxide and, subsequently, cyclic guanosine monophosphate production. Endothelin-1 is a potent vasoconstrictor and smooth muscle mitogen that may contribute to the development of pulmonary arterial hypertension. Prostacyclin synthase is reduced in pulmonary arterial hypertension, resulting in an inadequate production of prostacyclin I_2, which is a vasodilator with potent antiproliferative effects. Other aberrations include those of the voltage-dependent potassium channels and serotonin pathways. Disorders of inflammatory and coagulation pathways have also been described.

Chronic changes in the pulmonary vasculature also occur as a result of other types of pulmonary hypertension. Chronic elevation of left heart filling pressures causes a backward transmission of pressure to the pulmonary venous system and triggers vasoconstriction in the pulmonary arterial bed. Histologically, the veins thicken abnormally, and a neointima is formed. As secondary features, medial hypertrophy and thickening of the neointima on the arterial side of the pulmonary circulation occur. These changes can be reversed with therapies that result in chronic reduction of left heart filling pressures.

In parenchymal lung disease, changes in the distal pulmonary arterial vessels are related to hypoxia. Hypoxia induces muscularization of the distal

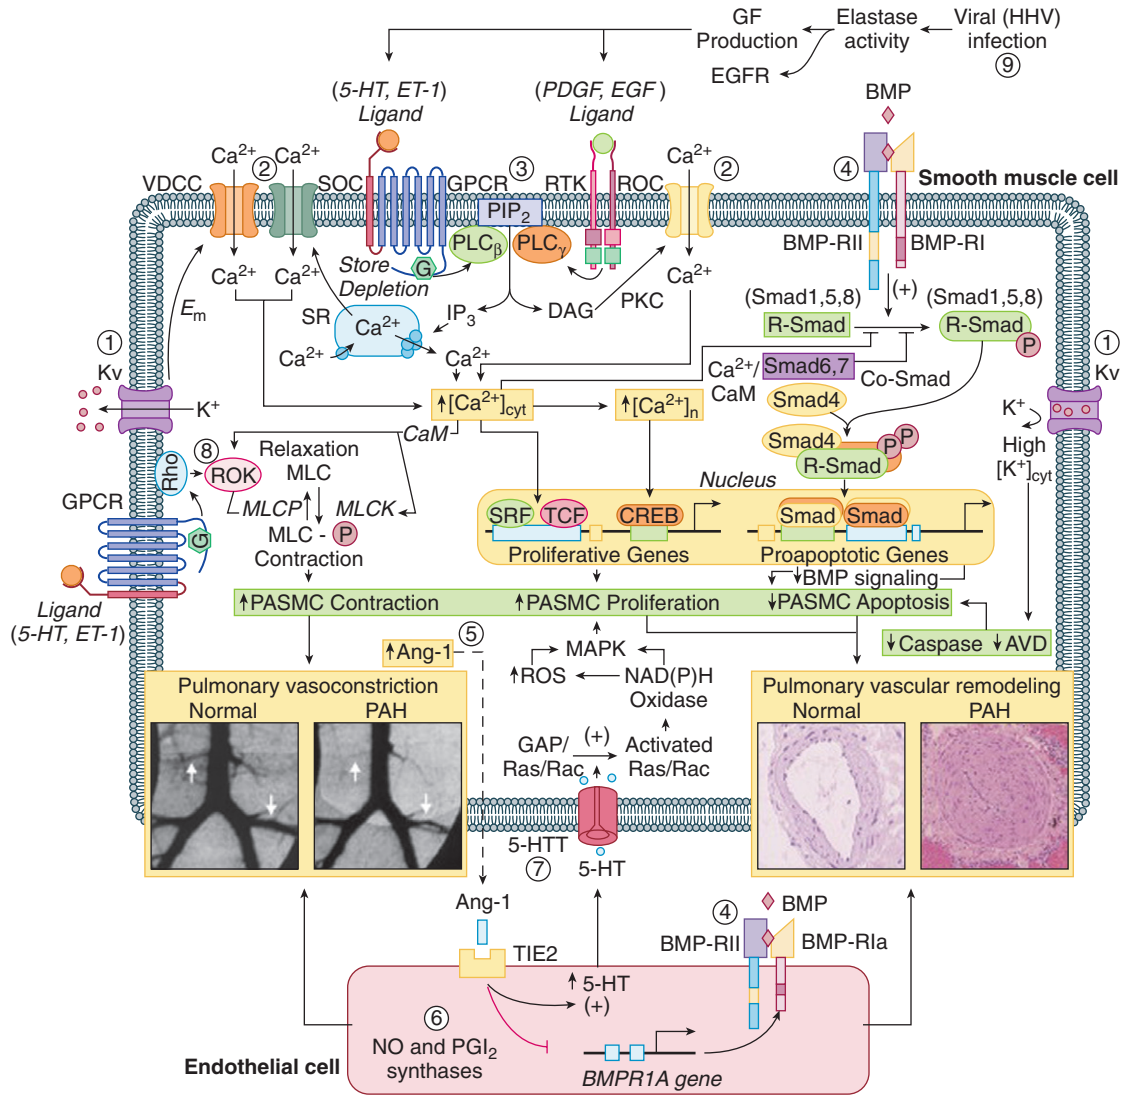

FIGURE 68-1. Potential mechanisms involved in the development of pulmonary arterial hypertension (PAH). vessels and medial hypertrophy of the more proximal vessels. Neither neointima formation nor the development of plexiform lesions is observed.

The pathology of chronic thromboembolic pulmonary hypertension is often distinct from idiopathic pulmonary arterial hypertension. The lesions are frequently more variable, with some arterial pathways that appear relatively unaffected and others that show recanalized vascular thromboses. However, the involvement of distal microvessels, particularly when thromboses have occurred in subsegmental arteries, can resemble idiopathic pulmonary arterial hypertension with the formation of plexiform lesions.

Pathophysiology

The normal pulmonary vasculature bed has a remarkable capacity to dilate and recruit unused vasculature to accommodate increases in pulmonary blood flow. In pulmonary hypertension, the pulmonary artery pressure and pulmonary vascular resistance are increased at rest and further increase with exertion. In response to this increased afterload, the normally very thin right ventricle hypertrophies and eventually dilates. Early on in the process, the right ventricle may be capable of maintaining normal cardiac output at rest, although it may fail to augment cardiac output with exercise, thereby leading to exertional dyspnea. As the disease progresses, the right ventricular dysfunction may progress to the point that resting cardiac output is impaired. Right ventricular function is a major determinant of functional capacity and prognosis in pulmonary arterial hypertension. Although the left ventricle is not affected by pulmonary vascular disease itself, progressive right ventricular dilation can impair left ventricular filling and lead to mildly increased left heart filling pressure. The pathophysiology of pulmonary hypertension related to left heart and lung disease is further complicated by those underlying disorders.

The two most frequent mechanisms of death are progressive right ventricular failure and sudden death. Right ventricular failure, as evidence by elevated jugular venous pressure, lower extremity edema, and occasionally ascites, may also be accompanied by evidence of poor forward flow owing to inadequate filling of the left ventricle. Hypotension, hypoperfusion, and renal insufficiency may result. Other potential causes of death include pneumonia, sepsis, and pulmonary embolism.

CLINICAL MANIFESTATIONS

History

Dyspnea, which is the most common symptom of pulmonary hypertension, initially may be attributed to underlying disorders such as heart failure or obstructive lung disease, but the dyspnea of pulmonary hypertension typically is insidious in progression and reproducible. Dyspnea is classified by the

World Health Organization (WHO) system, which is similar to the New York Heart Association classification system for angina and heart failure (see Table 50-5 in Chapter 50), and may progress to dyspnea at rest.

Other common symptoms of pulmonary hypertension include fatigue, lightheadedness, chest pain (Chapter 50), and palpitations (Chapters 50 and 62). Syncope (Chapter 62), which is an ominous finding, is often exertional in nature; it signifies the inability of the right ventricle to augment cardiac output as needed for physical activity. Symptoms of right heart failure, including edema and ascites, signify advanced disease.

Patients often have symptoms associated with their underlying disease, which typically is far advanced by the time pulmonary arterial hypertension develops. For example, patients with pulmonary hypertension associated with left heart disease often have paroxysmal nocturnal dyspnea and orthopnea. Patients with pulmonary hypertension related to hypoxic lung disease may have cough, sputum production, or wheezing.

Physical Examination

Distention of jugular veins (see Fig. 50-3 in Chapter 50) may signify right ventricular failure, and prominent v ways (see Fig. 50-4 in Chapter 50) may be a result of tricuspid regurgitation. The amplitude of the carotid upstroke may give some insight into the cardiac output. The classic physical examination finding in pulmonary hypertension is a loud pulmonic component to the second heart sound, which reflects high pulmonary pressures that increase the force of the pulmonic valve closure. Palpation of the sternum often reveals a parasternal lift as the hypertrophied, pressure-overloaded right ventricle obliterates the retrosternal air space. A right ventricular fourth heart sound reflects diastolic filling of the hypertrophied, noncompliant right ventricle, akin to the left-sided fourth heart sound in a patient with systemic hypertension and left ventricular hypertrophy. The murmur of tricuspid regurgitation, which is holosystolic, located at the left lower sternal border, and augments with inspiration, is common in patients with moderate to severe pulmonary hypertension. Other findings on auscultation may include an early systolic click and the murmur of pulmonic regurgitation. A right ventricular third heart sound often signifies advanced disease and right heart failure. Other signs consistent with right ventricular failure include hepatomegaly, peripheral edema (see Fig. 50-7 in Chapter 50), ascites, hypotension, diminished pulse pressure, and cool extremities.

Other physical examination findings may give some insight into the etiology of the pulmonary hypertension. For example, central cyanosis and clubbing may suggest an intracardiac shunt and Eisenmenger's physiology. Sclerodactyly, telangiectasias (see Fig. 275-3 in Chapter 275), arthritis, Raynaud's phenomenon (see Fig. 80-5 in Chapter 80), and skin rashes may increase the suspicion of an underlying connective tissue disease. Splenomegaly, spider angioma, palmar erythema (see Fig. 148-2 in Chapter 148), icterus (see Fig. 148-1 in Chapter 148), and caput medusa may suggest portal hypertension as an etiology. Signs of left heart disease, such as pulmonary congestion, a left-sided third heart sound, or findings of mitral or aortic valve disease on auscultation may signify pulmonary hypertension as a result of left heart disease. Fine rales, accessory muscle use, wheezing, protracted expiration, and productive cough may denote group 3 pulmonary hypertension as a result of hypoxic lung disease. Pulmonary vascular bruits suggest chronic thromboembolic pulmonary hypertension.

DIAGNOSIS

Initial assessments include an electrocardiogram (ECG) and chest radiograph. The ECG may show right axis deviation, right ventricular enlargement, right atrial enlargement, and ST and T wave changes across the anterior precordium that reflect right ventricular strain (Fig. 68-2). The chest radiograph may demonstrate enlarged proximal pulmonary arteries (see Fig. 53-6 in Chapter 53) with peripheral tapering or pruning of the pulmonary vasculature (Fig. 68-3A). The lateral may reveal the reduction in retrosternal air space as a result of right ventricular enlargement (see Fig. 68-3B).

If, based on the history, physical examination, ECG, and chest radiograph, there is a reasonable suspicion for pulmonary hypertension, a series of diagnostic evaluations should follow (Fig. 68-4), usually beginning with an echocardiogram, and with further testing guided by the patient subtype (Table 68-2). The echocardiogram gives insight not only into the presence of pulmonary hypertension but also into the presence of common disorders of the left heart that may result in pulmonary hypertension. Two-dimensional echocardiographic findings reflective of elevated pulmonary artery pressures include right atrial enlargement, right ventricular enlargement, flattening of the intraventricular septum, and an underfilled left ventricle (Fig. 68-5). The right ventricular systolic pressure may be estimated based on the velocity of the tricuspid regurgitant jet using the modified Bernoulli equation (Chapter 55) (Fig. 68-6), although a reliable estimate of right ventricular systolic pressure is not always obtainable, and this measurement is prone to error, particularly in patients with parenchymal lung disease, The echocardiogram is also useful to assess for left heart causes of pulmonary hypertension, such

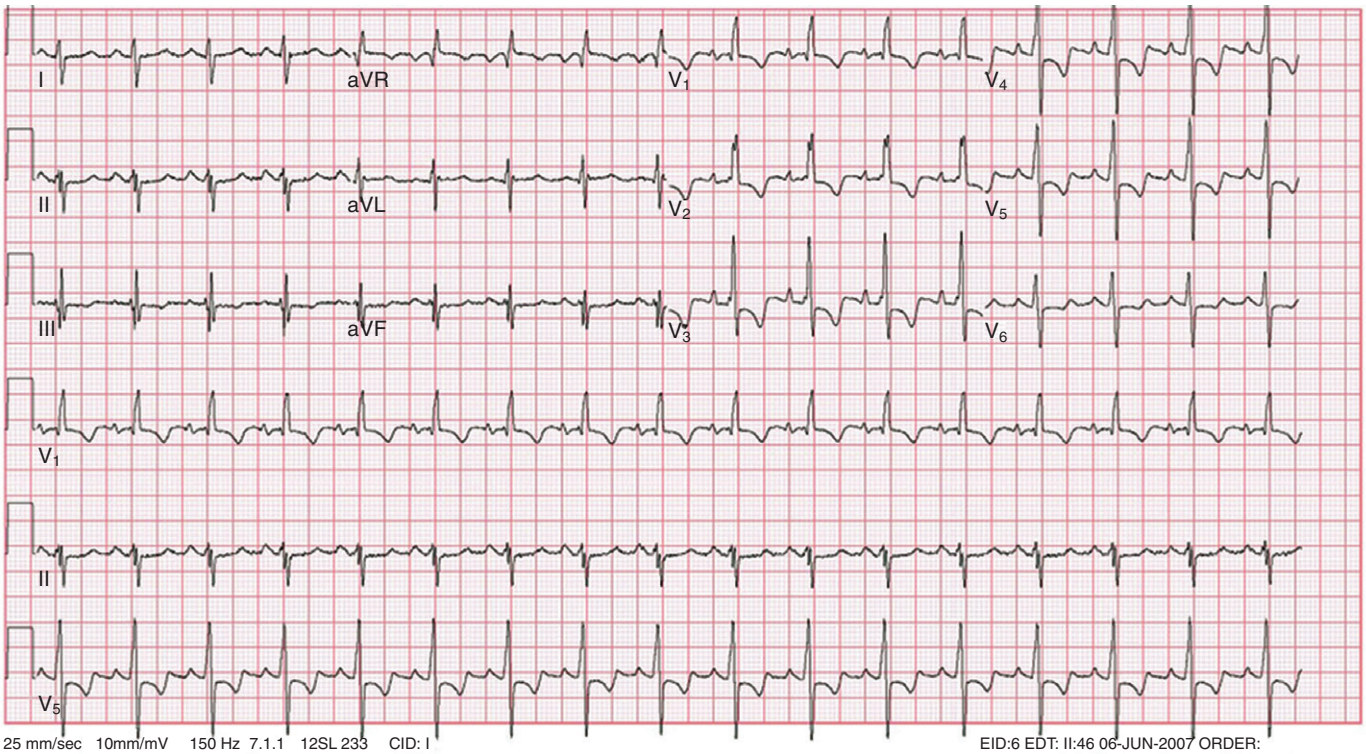

FIGURE 68-2. Electrocardiogram demonstrating sinus rhythm, right axis deviation, and right ventricular hypertrophy with a strain pattern.

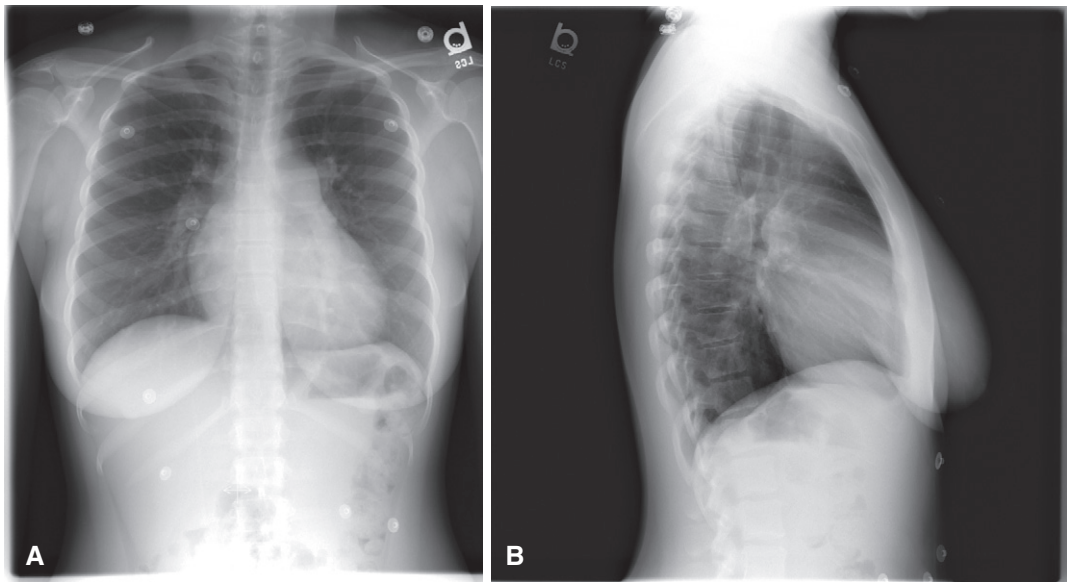

FIGURE 68-3. Posterior-anterior **(A)** and Lateral **(B)** chest radiographs demonstrating enlarged proximal pulmonary arteries and right ventricular enlargement.

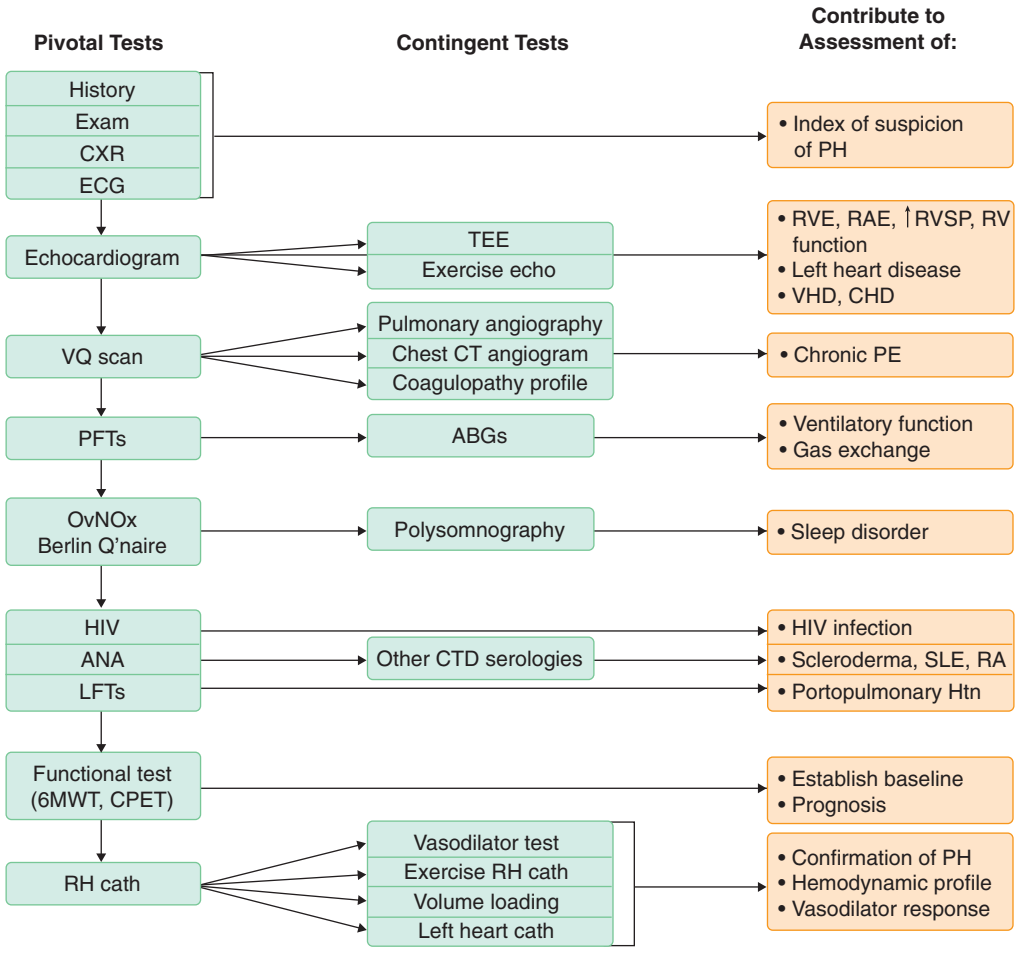

FIGURE 68-4. Diagnostic approach to pulmonary arterial hypertension (PH). Because the suspicion of PH may arise in various ways, the sequence of tests may vary. However, the diagnosis of PH requires that certain data support a specific diagnosis. In addition, the diagnosis of idiopathic pulmonary arterial hypertension (IPAH) is one of excluding all other reasonable possibilities. *Pivotal tests* are those that are essential to establishing a diagnosis of any type of PH by either identification of criteria of associated disease or exclusion of diagnoses other than IPAH. All pivotal tests are required for a definitive diagnosis and baseline characterization. An abnormality of one assessment (such as obstructive pulmonary disease on pulmonary function tests [PFTs]) does not preclude that another abnormality (chronic thromboembolic disease on VQ scan and pulmonary angiogram) is contributing or predominant. *Contingent tests* are recommended to elucidate or confirm results of the pivotal tests and need only be performed in the appropriate clinical context. The *combination* of pivotal and appropriate contingent tests contributes to assessment of the differential diagnoses in the right-hand column. It should be recognized that definitive diagnosis may require additional specific evaluations not necessarily included in this general guideline. 6MWT = 6-minute walk test; ABGs = arterial blood gases; ANA = antinuclear antibody serology; CHD = congenital heart disease; CPET = cardiopulmonary exercise test; CT = computed tomography; CTD = connective tissue disease; CXR = chest X-ray; ECG = electrocardiogram; HIV = human immunodeficiency virus screening; Htn = hypertension; LFTs = liver function tests; PE = pulmonary embolism; RA = rheumatoid arthritis; RAE = right atrial enlargement; RH cath = right heart cath; RVE = right ventricular enlargement; RVSP = right ventricular systolic pressure; SLE = systemic lupus erythematosus; TEE = transesophageal echocardiography; VHD = valvular heart disease; VQ scan = lung ventilation-perfusion scintigram. (From McLaughlin VV, Archer SL, Badesch DB, et al. ACCF/AHA 2009 expert consensus document on pulmonary hypertension: a report of the American College of Cardiology Foundation Task Force on Expert Consensus Documents and the American Heart Association developed in collaboration with the American College of Chest Physicians; American Thoracic Society, Inc.; and the Pulmonary Hypertension Association. *J Am Coll Cardiol.* 2009;53:1573-1619.)

TABLE 68-2 APPROACH TO SPECIFIC PATIENT SUBGROUPS

	FURTHER ASSESSMENT	RATIONALE
BMPR2 mutation	Echocardiogram yearly; RHC if echocardiogram demonstrates evidence of PAH (high right ventricular systolic pressure or right heart chamber enlargement)	Early detection of PAH; 20% chance of developing PAH
First-degree relative of patient with BMPR2 mutation or within pedigree of two or more patients with a diagnosis of PAH	Genetic counseling and recommendation for BMPR2 genotyping; proceed as above if positive	Autosomal dominant transmission
Systemic sclerosis	Echocardiogram yearly; RHC if echocardiogram demonstrates evidence of PAH (high right ventricular systolic pressure or right heart chamber enlargement)	About 8% (by RHC): 27% (by echo screening) prevalence of PAH in systemic sclerosis
HIV infection	Echocardiogram if symptoms or signs suggestive of PAH; RHC if echo demonstrates evidence of PAH (high right ventricular systolic pressure or right heart chamber enlargement)	0.5% prevalence of PAH
Portal hypertension	Echocardiogram if OLT considered; RHC if echocardiogram demonstrates evidence of PAH (high right ventricular systolic pressure or right heart chamber enlargement)	4% prevalence of PAH in candidates for OLT; PAH is predictive of poor OLT outcome
Prior appetite suppressant use (fenfluramine)	Echocardiogram only if symptomatic	Incidence of PAH is approximately 0.005% if agent used >3 mo
Congenital heart disease with shunt	Echocardiogram and RHC at time of diagnosis; consider repair of defect if significant left-to-right shunt present	High probability of PAH developing in unrepaired shunt (Eisenmenger's syndrome)
Recent acute pulmonary embolism	Ventilation-perfusion (V/Q) scintigraphy 3 mo after event if symptomatic; pulmonary angiogram if positive	3% risk of chronic thromboembolic PH; negative V/Q scan excludes chronic thromboembolism
Sickle cell disease	Echocardiogram yearly; RHC if echocardiogram demonstrates evidence of PAH (high right ventricular systolic pressure or right heart chamber enlargement)	Increased mortality if PH present, early detection of PH, 30% develop PH, about 10% develop PAH

BMPR2 = bone morphogenic protein receptor 2; HIV = human immunodeficiency virus; OLT = orthotopic liver transplantation; PAH = pulmonary arterial hypertension; RHC = right heart catheterization.

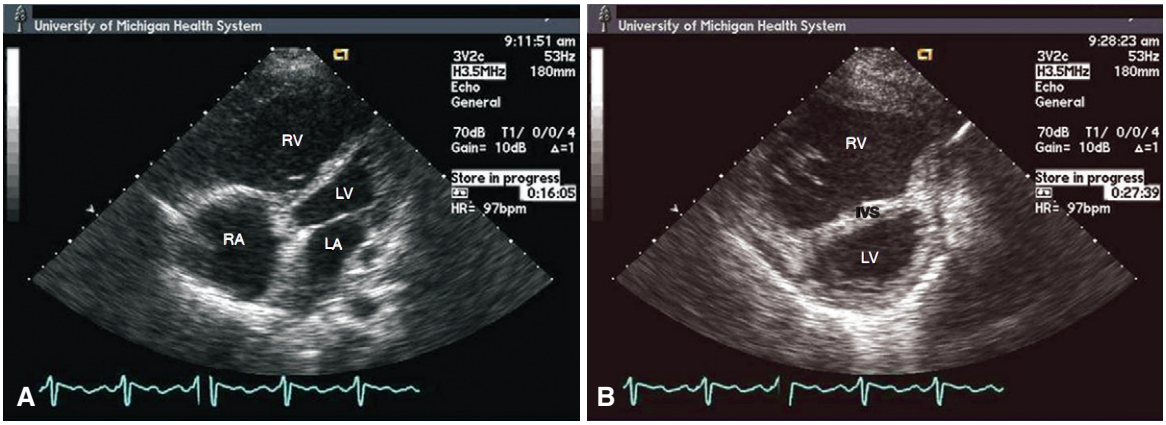

FIGURE 68-5. Echocardiographic images of the heart. A, Four-chamber view. Right atrial (RA) enlargement, right ventricular (RV) enlargement. The left atrium (LA) and left ventricle (LV) are small and underfilled. **B,** Short axis view. RV enlargement is present. Flattening of the intraventricular septum (IVS) results from pressure and volume overload of the RV.

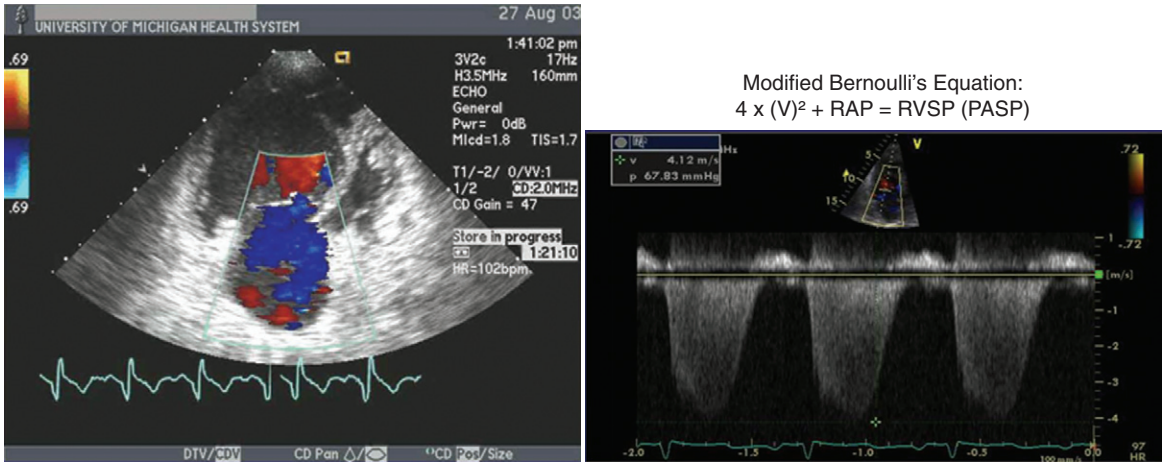

FIGURE 68-6. Calculation of estimated pulmonary artery pressure based on the velocity of the tricuspid regurgitant jet. RAP = right atrial pressure; RVSP = right ventricular systolic pressure; PASP = pulmonary artery systolic pressure; V = tricuspid jet velocity (m/sec).

as systolic dysfunction, diastolic dysfunction, and valvular heart disease. Occasionally, a previously unknown congenital heart defect is discovered during this evaluation. In approximately 25% of patients, a previously trivial patent foramen ovale may shunt blood from the right atrium to the left atrium, owing to the high pulmonary vascular resistance, and thereby worsen systemic oxygenation.

In a patient with unexplained dyspnea and evidence of pulmonary hypertension on echocardiogram, chronic thromboembolic pulmonary hypertension must be excluded. The study of choice for this assessment is the ventilation-perfusion scan (see Fig. 98-4 in Chapter 98), which often shows multiple perfusion defects that are not matched on ventilation. Although spiral computed tomography (CT) is excellent for the assessment of acute pulmonary embolus, it sometimes fails to detect surgically accessible chronic thromboembolic disease. If either of these studies is abnormal, further evaluation with a pulmonary angiogram may be required to determine whether chronic thrombolic disease is the diagnosis and, if so, whether it is surgically accessible.

Pulmonary function tests in patients with pulmonary arterial hypertension may show mild restrictive disease and a mildly reduced diffusing capacity for carbon monoxide. Patients with the scleroderma spectrum of diseases tend to have more substantial reductions in the diffusing capacity for carbon monoxide, which may even precede the development of pulmonary hypertension. Pulmonary function tests may disclose evidence of obstructive or restrictive lung disease; further evaluation with chest CT may be necessary. Overnight oximetry is useful to screen for obstructive sleep apnea (Chapter 100). If indicated, formal polysomnography may be required.

Recommended serologic testing, given the known associations, includes an antinuclear antibody test and HIV serology, in addition to liver function tests to assess for chronic liver disease. A study of functional capacity, most commonly the 6-minute walk test, is useful to assess the severity of disease, to determine the potential need for oxygen, and to establish a baseline against which to assess subsequent changes in exercise capacity as a result of medical interventions.

If pulmonary arterial hypertension is suspected based on the noninvasive evaluation, the diagnosis must be confirmed with a right heart catheterization that measures right atrial pressure, right ventricular pressure, pulmonary artery (systolic, diastolic, and mean) pressures, pulmonary arterial wedge pressure (reflective of left ventricular end-diastolic pressure or left atrial pressure), cardiac output and index, heart rate, systemic blood pressure, and oxygen saturations in the superior vena cava, inferior vena cava, pulmonary artery, and a systemic artery. From this information, pulmonary vascular resistance and systemic vascular resistance may be calculated, right ventricular performance can be assured, and an intracardiac or intrapulmonary shunt can be confirmed or excluded.

In patients with left heart or parenchymal lung disease, however, optimal management of the underlying condition is often undertaken before considering right heart catheterization. Patients with suspected chronic thromboembolic disease often undergo both right heart catheterization and pulmonary angiography (Chapter 98) to assess surgical candidacy and operative risk.

Measurement of the wedge pressure, a surrogate for left atrial pressure in the absence of pulmonary vein obstruction, is useful to exclude pulmonary hypertension caused by left heart disease or, in rare cases, pulmonary venoocclusive disease. If an optimal wedge pressure tracing cannot be obtained, or if there is any question about the accuracy of the wedge pressure tracing, a left ventricular end-diastolic pressure should be obtained.

Acute vasodilator testing is often performed at the time of the initial right heart catheterization, not only for its prognostic implications but also to identify patients who might be candidates for therapy with calcium-channel blockers. Although the data regarding vasodilator testing and treatment with calcium-channel blockers are largely restricted to patients with idiopathic pulmonary arterial hypertension, vasodilator testing is often performed in patients with other types of pulmonary arterial hypertension. However, acute vasodilator testing is not indicated and may be harmful in patients with significantly elevated left heart filling pressures because pulmonary edema may ensue.

The three agents most commonly used for acute vasodilator testing in the cardiac catheterization laboratory are inhaled nitric oxide, intravenous epoprostenol, and intravenous adenosine. A positive response to an acute vasodilator is a decrease in mean pulmonary artery pressure by at least 10 mm Hg, to a mean pulmonary artery pressure of less than 40 mm Hg, without a decrease in cardiac output. If a patient meets these criteria, it is reasonable to administer a trial of oral calcium-channel blockers.

TREATMENT

General Measures

Important goals of therapy in patients with pulmonary arterial hypertension include alleviation of symptoms, particularly dyspnea; improvement of functional capacity, which is often measured by the 6-minute walk test; and improvement of hemodynamics by lowering pulmonary artery pressure and increasing cardiac output. Another important goal of therapy is to reverse, or at least prevent, disease progression, often measured in clinical trials as hospitalization, escalation of therapy, and lung transplantation.

Patients are encouraged to engage in low-level graded aerobic exercise, such as walking, as tolerated. Patients are advised to avoid heavy physical exertion or isometric exercise because this may provoke exertional syncope. Exposure to high altitudes may contribute to hypoxic pulmonary vasoconstriction and may not be well tolerated. A sodium-restricted diet (<2400 mg/day) is advised and is particularly important to manage volume status in patients with right ventricular failure. Routine immunizations, such as those against influenza and pneumococcal pneumonia, are advised. Because hypoxia is a potent pulmonary vasoconstrictor, supplemental oxygen is recommended to maintain saturations above 90% at rest, with exertion, and during sleep. In patients with intracardiac shunting and Eisenmenger's physiology (Chapter 69), this goal may not be possible.

Patients with pulmonary arterial hypertension are advised against pregnancy because the hemodynamic fluctuations of pregnancy, labor, delivery, and the postpartum period are potentially life-threatening, with a 30 to 50% mortality rate in some series. Current guidelines recommend that pregnancy be avoided or terminated early in women with pulmonary arterial hypertension. Women of childbearing potential should be counseled on contraception options at the time of diagnosis.

For patients with idiopathic, heritable, anorexigen-induced, and connective tissue disease–associated pulmonary arterial hypertension (group 1 pulmonary arterial hypertension), clinical trial data can guide effective therapy (Fig. 68-7). For all other types of pulmonary hypertension, the safety and efficacy of pulmonary arterial hypertension–specific therapies have not been demonstrated, so treatment should instead be targeted at the underlying disease.

Treatment of the Underlying Conditions

The initial treatment should be directed at any underlying or associated conditions, especially lung disease, that also directly affect exercise tolerance and systemic diseases that have effective therapies. After these disorders have been optimally treated, specific therapy of the pulmonary arterial hypertension itself should be considered.

Background Therapy

In three uncontrolled observational series in patients with primarily idiopathic pulmonary arterial hypertension, warfarin coagulation improved survival. Consensus recommendations advocate the use of warfarin titrated to an INR of 1.5 to 2.5 in patients with idiopathic pulmonary arterial hypertension. Although no data are available to guide recommendations in patients with other types of pulmonary arterial hypertension, warfarin is generally recommended in patients with advanced disease and severe right heart failure, in the absence of contraindications. Diuretics (e.g., furosemide, initiated at 20 mg and titrated as needed) are indicated to manage right ventricular volume overload; in some patients, intravenous diuretics may be necessary. Serum electrolytes and renal function must be closely monitored. Digoxin, 0.125 to 0.25 mg/day, is sometimes used in patients with right ventricular failure and a low cardiac output and in patients with atrial arrhythmias, despite the paucity of data; if the patient experiences any evidence of digoxin toxicity, the drug should be discontinued because of the unfavorable risk-to-benefit ratio.

Vasodilator Therapy

Calcium-Channel Blockers

Approximately 7% of adult patients with idiopathic pulmonary arterial hypertension have a favorable response to acute vasodilator testing and excellent prognosis with calcium-channel blockers. Long-acting nifedipine, diltiazem, and amlodipine are the most commonly used calcium-channel blockers. Because of its potential negative inotropic effects, verapamil should be avoided. Patients must be followed closely for both the safety and efficacy of this therapy. If a patient who meets the definition of an acute response does not improve to WHO class I or II on calcium-channel blocker therapy, the patient should not be considered a chronic responder; alternative or additional pulmonary arterial hypertension specific therapy should be instituted.

Targeted Therapies

In clinical trials, intravenous epoprostenol improves functional class, exercise endurance, hemodynamics, and survival in patients with idiopathic pulmonary arterial hypertension,■ and it also improves exercise tolerance and hemodynamics in patients with pulmonary arterial hypertension related to

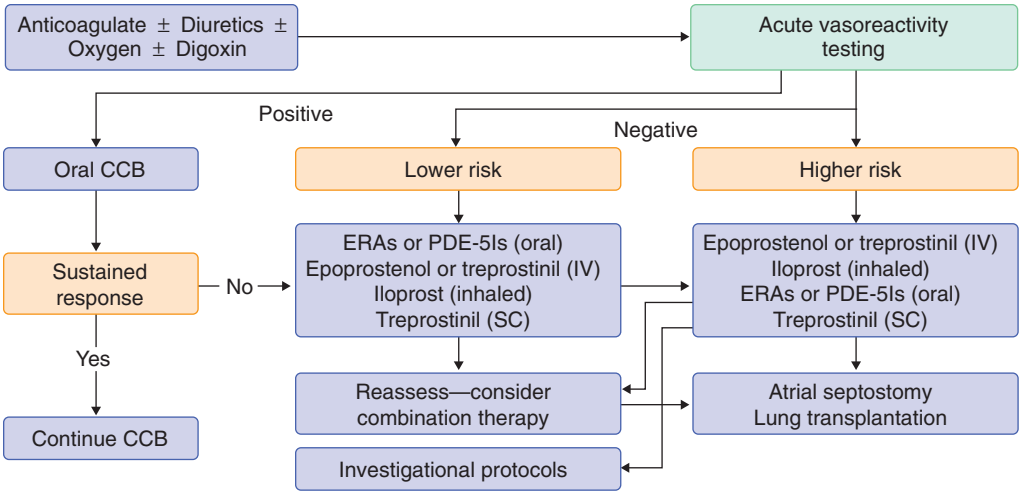

FIGURE 68-7. Pulmonary hypertension treatment algorithm. CCB = calcium-channel blocker; ERA = endothelin receptor antagonist; IV = intravenous; PDE-5I = phosphodiesterase type 5 inhibitor; SC = subcutaneous. (From McLaughlin VV, Archer SL, Badesch DB, et al. ACCF/AHA 2009 expert consensus document on pulmonary hypertension: a report of the American College of Cardiology Foundation Task Force on Expert Consensus Documents and the American Heart Association developed in collaboration with the American College of Chest Physicians; American Thoracic Society, Inc.; and the Pulmonary Hypertension Association. *J Am Coll Cardiol.* 2009; 53:1573-1619.)

the scleroderma spectrum of diseases.[2] Uncontrolled studies have also reported favorable effects with intravenous epoprostenol in patients with numerous forms of associated pulmonary arterial hypertension. Observational series suggest a long-term survival benefit with intravenous epoprostenol compared with historical controls. Epoprostenol must be delivered by continuous intravenous infusion, commonly initiated in the hospital at a dose of 2 ng/kg/minute, with the dose titrated up based on symptoms of pulmonary arterial hypertension and side effects of the therapy. Each patient must learn the techniques of sterile preparation of the medication, operation of the ambulatory infusion pump, and care of the central venous catheter. Although dosing must be highly individualized, maintenance doses in the range of 25 to 40 ng/kg/minute are typically needed for patients on monotherapy. Common side effects include headache, jaw pain, flushing, nausea, diarrhea, skin rash, and musculoskeletal pain. Infections and infusion interruption can be life-threatening.

Subcutaneous treprostinil can provide a modest but statistically significant improvement in exercise tolerance.[3] The main limitation of this therapy is pain and erythema at the site of the subcutaneous infusion, a complication that occurs in 85% of patients. Other prostanoid-type side effects, including headache, diarrhea, rash, and nausea, also occur. Subcutaneous treprostinil is often started in the home, with the dose titrated up based on symptoms of pulmonary arterial hypertension and drug side effects. Treprostinil is less potent than epoprostenol, and higher doses are required to achieve the desired efficacy. Inhaled treprostinil four times daily[4] and inhaled iloprost six to nine times daily[5] also are effective for improving exercise capacity. However, cough is an additional side effect with this method of administration.

The endothelin receptor antagonist bosentan (initiated orally at 62.5 mg twice daily and titrated up to 125 mg twice daily after 1 month) improves hemodynamics and exercise capacity and the clinical course of pulmonary arterial hypertension.[6,7] Ambrisentan (administered orally at doses of either 5 mg or 10 mg once daily) has similar benefits.[8] Liver enzymes must be monitored on a monthly basis; the dose should be reduced if liver enzymes rise to greater than three to five times the upper limits of normal and discontinued if they rise to five times the upper limit of normal. Other side effects include lower extremity edema, headache, and nasal congestion.

The chronic administration of inhaled nitric oxide is cumbersome and not clinically useful. However, the phosphodiesterase type 5 antagonists sildenafil and tadalafil are effective and useful for pulmonary arterial hypertension.[9,10] Sildenafil is approved at a dose of 20 mg three times daily and tadalafil at a dose of 40 mg once daily. The most common side effects of the phosphodiesterase inhibitors are headache, flushing, dyspepsia, and epistaxis.

Given the availability of therapies that target different pathologic processes, combination therapy is an attractive theoretical option in pulmonary arterial hypertension. Emerging data support the incremental benefit of combining more than one targeted therapy[4,11,12] under careful observation, usually in a specialized center.

Invasive Therapies

Despite advances in medical therapies for pulmonary arterial hypertension, many patients experience progressive functional decline, largely related to worsening right heart failure. In carefully selected patients, atrial septostomy may improve symptoms. Atrial septostomy creates a right-to-left interatrial shunt, thereby decreasing right heart filling pressures and improving right heart function and left heart filling. Although the right-to-left shunting decreases systemic arterial oxygen saturation, it is anticipated that the improvement in cardiac output will result in overall augmentation in systemic oxygen delivery. Contraindications to performing atrial septostomy include severe right ventricular failure on cardiorespiratory support, mean right atrial pressure of more than 20 mm Hg, pulmonary vascular resistance index of more than 55 U/m^2, resting oxygen saturation of less than 90% on room air, and left ventricular end-diastolic pressure of more than 18 mm Hg. Because of the high morbidity and mortality associated with this procedure, it should be performed only by experienced operators in specialized centers.

Bilateral lung (Chapter 101) or heart-lung transplantation (Chapter 82) is the final option for selected patients with pulmonary arterial hypertension when medical therapy fails. The 1-, 3-, 5-, and 10-year survival rates are 66%, 57%, 47%, and 27%, respectively, in patients with idiopathic pulmonary arterial hypertension who undergo transplantation. Transplantation as a potential therapeutic option should be discussed with selected patients at the time of diagnosis, although timing of referral is challenging. Patients who are otherwise good transplant candidates should be referred when they have an unacceptable response to medical therapies.

Assessing Response to Therapy

Given the complexity of the disease, the variable response to therapy, and the goal of optimizing and individualizing care, patients with pulmonary arterial hypertension must be followed closely. The usual recommendation is every 3 to 6 months in stable patients and every 1 to 3 months in patients with worsening or unstable symptoms or signs.

PROGNOSIS

Several clinical factors are correlated with prognosis (Table 68-3). The natural history of idiopathic pulmonary arterial hypertension is a median survival of 2.8 years with 1-, 3-, and 5-year survival rates of 68%, 48%, and 34%, respectively. Patients with pulmonary arterial hypertension related to the scleroderma spectrum of diseases tend to have a poorer prognosis than those with idiopathic pulmonary arterial hypertension, whereas patients with pulmonary arterial hypertension related to congenital heart disease tend to have a better prognosis, perhaps because they have better right ventricular function. Observational series suggest survival benefits for modern treatments, including epoprostenol, treprostinil, bosentan, and ambrisentan, but data are limited. Nevertheless, studies have demonstrated the 1-year survival on current medical therapy to be in the 85 to 88% range.

The natural history of patients with groups 2 and 3 pulmonary hypertension are influenced by their left heart and lung disease. In most cases, the presence of pulmonary hypertension in addition to the underlying disease portends a poor prognosis.

TABLE 68-3 PULMONARY ARTERIAL HYPERTENSION: DETERMINANTS OF PROGNOSIS*

DETERMINANTS OF RISK	LOWER RISK (GOOD PROGNOSIS)	HIGHER RISK (POOR PROGNOSIS)
Clinical evidence of RV failure	No	Yes
Progression of symptoms	Gradual	Rapid
WHO class†	II, III	IV
6-MW test‡	Longer (>400 m)	Shorter (<300 m)
CPET	Peak Vo_2 > 10.4 mL/kg/min	Peak Vo_2 < 10.4 mL/kg/min
Echocardiography	Minimal RV dysfunction	Pericardial effusion, significant RV enlargement or dysfunction, right atrial enlargement
Hemodynamics	RAP < 10 mm Hg, CI > 2.5 L/min/m^2	RAP > 20 mm Hg, CI < 2.0 L/min/m^2
BNP§	Minimally elevated	Significantly elevated

*Most data available pertain to idiopathic pulmonary arterial hypertension. Few data are available for other forms of PAH. One should not rely on any single factor to make risk predictions.
†WHO class is the functional classification for PAH and is a modification of the New York Heart Association functional class.
‡6-MW test is also influenced by age, gender, and height.
§Because there are currently limited data regarding the influence of BNP on prognosis, and many factors including renal function, weight, age, and gender may influence BNP, absolute numbers are not given for this variable.
6-MW = 6-minute walk; BNP = brain natriuretic peptide; CI = cardiac index; CPET = cardiopulmonary exercise testing; peak Vo_2 = average peak oxygen uptake during exercise; RAP = right atrial pressure; RV = right ventricle; WHO = World Health Organization.

CONGENITAL HEART DISEASE IN ADULTS

ARIANE J. MARELLI

The convergence of major progress in medicine, pediatrics, and cardiovascular surgery has resulted in the survival of an increasingly large number of adult patients with congenital heart disease. Adult physicians are becoming increasingly responsible for these patients, commonly in concert with a cardiologist and a tertiary care facility.

DEFINITIONS

Patients can be divided into three categories according to the surgical status: unoperated, surgically palliated, or physiologically repaired. Congenital heart lesions can be classified as *acyanotic* or *cyanotic*. *Cyanosis* refers to a blue discoloration of the mucous membranes resulting from an increased amount of reduced hemoglobin. Central cyanosis occurs when the circulation is mixed because of a right-to-left shunt.

A *native lesion* refers to an anatomic lesion present at birth. Acquired lesions, naturally occurring or as a result of surgery, are superimposed on the native anatomy. *Palliative* interventions are performed in patients with cyanotic lesions and are defined as operations that either increase or decrease pulmonary blood flow while allowing a mixed circulation and cyanosis to persist (Table 69-1). *Physiologic* repair applies to procedures that provide total or nearly total anatomic and physiologic separation of the pulmonary and systemic circulations in complex cyanotic lesions and result in patients who are acyanotic.

Eisenmenger's complex refers to flow reversal across a ventricular septal defect (VSD) when pulmonary vascular resistance exceeds systemic levels. *Eisenmenger's physiology* designates the physiologic response in a broader category of shunt lesions in which a right-to-left shunt occurs in response to an elevation in pulmonary vascular resistance. *Eisenmenger's syndrome* is a term applied to common clinical features shared by patients with Eisenmenger's physiology.

Each congenital lesion can influence the course of another. For example, the physiologic consequences of a VSD are different if it occurs in isolation or in combination with pulmonary stenosis. A *simple lesion* is defined as either a shunt lesion or an obstructive lesion of the right or left heart occurring in isolation. A *complex lesion* is a combination of two or more abnormalities.

EPIDEMIOLOGY

Genetic Determinants

In 90% of patients, congenital heart disease is attributable to multifactorial inheritance; only 5 to 10% of malformations are due to primary genetic factors, either chromosomal or related to a single mutant gene. The most common defect observed in patients with chromosomal aberrations is a VSD, which occurs in 90% of patients with trisomy 13 and trisomy 18. Defects of the endocardial cushions and the ventricular septum are found in 50% of patients with Down syndrome (trisomy 21). The most frequently observed defects in patients with Turner's syndrome (45,X) are aortic coarctation, aortic stenosis, and atrial septal defect (ASD). About 15% of patients with tetralogy of Fallot have a deletion on chromosome 22q11; prevalence is higher in those with a right aortic arch. Abnormalities involving the chromosomal band 22q11 can also result in a group of syndromes, the most common of which is DiGeorge syndrome. The shared phenotypic features are designated CATCH-22 syndromes, that is, a combination of *c*ardiac defects, *a*bnormal facies, *t*hymic hypoplasia, *c*left palate, and *h*ypocalcemia. The

TABLE 69-1 PALLIATIVE SURGICAL SHUNTS FOR CONGENITAL HEART LESIONS

PALLIATIVE SHUNT	ANASTOMOSIS
SYSTEMIC ARTERIAL TO PULMONARY ARTERY SHUNTS	
Classic Blalock-Taussig	Subclavian artery to PA
Modified Blalock-Taussig	Subclavian artery to PA (prosthetic graft)
Potts anastomosis	Descending aorta to left PA
Waterston shunt	Ascending aorta to right PA
SYSTEMIC VENOUS TO PULMONARY ARTERY SHUNTS	
Classic Glenn	SVC to right PA
Bidirectional Glenn	SVC to right and left PA
Bilateral Glenn	Right and left SVC to right and left PA

PA = pulmonary artery; SVC = superior vena cava.

recurrence risk for families with a child who carries a congenital cardiac malformation due to a chromosomal anomaly is related to the recurrence risk of the chromosomal anomaly itself.

Typically, single mutant genes are also associated with syndromes of cardiovascular malformations, although not every patient with the syndrome has the characteristic cardiac anomaly. Examples include osteogenesis imperfecta (autosomal recessive), associated with aortic valve disease; Jervell and Lange-Nielsen syndrome (autosomal recessive) and Romano-Ward syndrome (autosomal dominant), associated with a prolonged QT interval and sudden death; and Holt-Oram syndrome (autosomal dominant), in which an ASD occurs with a range of other skeletal anomalies. Osler-Weber-Rendu telangiectasias are associated with pulmonary arteriovenous fistulas. Williams syndrome occurs with supravalvular aortic stenosis in most cases. Noonan's syndrome is associated with pulmonary stenosis, ASD, and hypertrophic cardiomyopathy. Although autosomal dominant inheritance has been implicated for both, most cases are sporadic. Deletion at chromosome 7q11.23 has been identified in patients with Williams syndrome, and a gene defect has been mapped to 12q22-qter in patients with Noonan's syndrome.

The risk for recurrence when the mother carries a sporadically occurring congenital lesion varies from 2.5 to 18%, depending on the lesion. Obstructive lesions of the left ventricular outflow tract have the highest recurrence rates in offspring. When the father carries the lesion, 1.5 to 3% of the offspring are affected. When a sibling has a congenital cardiac anomaly, the risk for recurrence in another sibling varies from 1 to 3%.

Incidence and Prevalence

Cardiac malformations occur at a rate of 8 per 1000 live births, or 32,000 infants with new diagnoses yearly in the United States. The prevalence of congenital heart disease has increased in the general population, with the steepest rise observed in adults with severe or complex lesions. An estimated 20% die in the first year of life—a substantial decrease from the late 1960s. An overall prevalence of 4 per 1000 adults has been documented. The median age of patients with severe lesions has increased from childhood to late adolescence. Currently, more than 1 million patients are thought to be alive in the United States with congenital heart disease.

Bicuspid aortic valve occurs in about 2% of the general population, is the most common congenital cardiac anomaly encountered in adult populations, and accounts for up to half of surgical cases of aortic stenosis in adults (Chapter 75). ASDs constitute 30 to 40% of cases of congenital heart disease in adults, with ostium secundum ASD accounting for 7% of all congenital lesions. A solitary VSD represents 15 to 20% of all congenital lesions and is the most common congenital cardiac lesion observed in children; its high spontaneous closure rates explain the lesser prevalence in adults. Patent ductus arteriosus (PDA) accounts for 5 to 10% of all congenital cardiac lesions in infants with a normal birthweight. Pulmonary stenosis and coarctation of the aorta represent 3 to 10% of all congenital lesions.

Tetralogy of Fallot is the most common cyanotic congenital anomaly observed in adults. Together with complete transposition of the great arteries, these lesions account for 5 to 12% of congenital heart disease in infants. More complex lesions such as tricuspid atresia, univentricular heart, congenitally corrected transposition of the great arteries, Ebstein's anomaly, and double-outlet right ventricle account for 2.5% or less of all congenital heart disease.

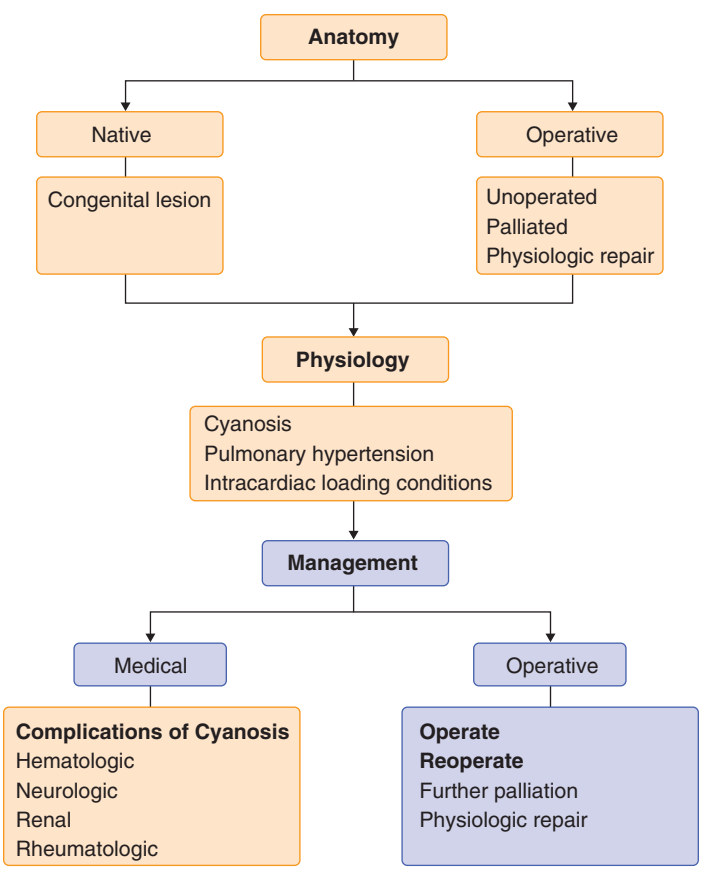

FIGURE 69-1. The goals of complete clinical assessment in congenital heart disease are to define the anatomy and physiology to determine appropriate management.

CLINICAL MANIFESTATIONS

Congenital heart disease is a lifelong condition during which the patient and the lesion evolve concurrently. A patient may have been monitored for many years because of an erroneous diagnosis made in infancy or childhood when diagnostic techniques were more limited. The differential diagnosis of native and surgical anatomy in the adult with an unknown diagnosis depends on whether the patient is cyanotic or acyanotic. On completion of the evaluation, the following questions should be answered (Fig. 69-1): What is the native anatomy? Has this patient undergone surgery for the condition? What is the physiology? What can and should be done for this patient both medically and surgically, and importantly, who should do it?

If the patient has not undergone surgery, the question is, Why not? If the patient is palliated, has the degree of cyanosis progressed as evidenced by a drop in systemic saturation or a rise in hemoglobin? If the patient has undergone a physiologic repair, what procedure was performed? Are residual lesions present, and have new lesions developed as a consequence of surgery? The patient's physiology is determined by the presence or absence of cyanosis, pulmonary hypertension, adequate filling of the cardiac chambers, and any resulting medical complications.

A clinical assessment, 12-lead electrocardiogram (ECG), chest radiograph, and baseline oxygen saturation should be part of every initial assessment. Two-dimensional transthoracic echocardiography (Chapter 55) and Doppler and color flow imaging are used to establish the diagnosis and to monitor the evolution of documented hemodynamic complications. Transesophageal echocardiographic examination is particularly useful in adults and is increasingly important during interventional catheter-guided therapy and surgery. Magnetic resonance imaging (Chapter 56) and computed tomography (Chapter 56) are useful adjuncts. Cardiac catheterization for congenital heart disease has shifted from pure diagnosis to include intervention. Coronary arteriography is recommended for adults older than 40 years in whom surgical intervention is contemplated.

Pulmonary Hypertension and Its Complications

Pulmonary hypertension secondary to structural disease of the heart or circulation can occur with or without an increase in pulmonary vascular resistance. Pulmonary vascular obstructive disease occurs when pulmonary vascular resistance rises and becomes fixed and irreversible. In the most common congenital anomalies, pulmonary hypertension is a result of increased pulmonary blood flow because of a native left-to-right shunt. Examples include ASD, a moderately sized VSD, PDA, and a variety of complex lesions. The rate at which pulmonary hypertension progresses to become pulmonary vascular obstructive disease varies from one lesion to another and depends at least in part on the source of pulmonary blood flow. Pulmonary hypertension typically develops in patients with an ASD after the fourth decade; Eisenmenger's syndrome is a late complication seen in only 5 to 10% of cases. In contrast, in patients with a large VSD or persistent PDA, progressive elevation in pulmonary vascular resistance occurs rapidly because the pulmonary vascular bed is exposed not only to the excess volume of the left-to-right shunt but also to systemic arterial pressures. As a result, Eisenmenger's complex develops in approximately 10% of patients with a large VSD during the first decade. Surgical pulmonary artery banding is a palliative measure aimed at decreasing pulmonary blood flow and protecting the pulmonary vascular bed against the development of early pulmonary vascular obstructive disease.

If forward flow from the right side of the heart is insufficient, native collaterals or surgical shunts provide an alternative source of pulmonary blood flow (see Table 69-1). With large surgical shunts, however, direct exposure of the pulmonary vascular bed to the high pressures of the systemic circulation causes pulmonary vascular obstructive disease. As a result, systemic to pulmonary arterial shunts are currently less favored in neonates and infants, in whom systemic venous to pulmonary arterial shunts are now preferred.

The term *Eisenmenger's syndrome* should be reserved for patients in whom pulmonary vascular obstructive disease is present and pulmonary vascular resistance is fixed and irreversible. These findings, in combination with the absence of left-to-right shunting, render the patient inoperable.

The clinical manifestations of Eisenmenger's syndrome include dyspnea on exertion, syncope, chest pain, congestive heart failure, and symptoms related to erythrocytosis and hyperviscosity. On physical examination, central cyanosis and digital clubbing are hallmark findings. Systemic oxygen saturations typically vary between 75 and 85%. The pulse pressure narrows as the cardiac output falls. Examination of jugular venous pressure can reveal a dominant a wave reflecting a noncompliant right ventricle until tricuspid insufficiency is severe enough to generate a large v wave. A prominent right ventricular impulse is felt in the left parasternal border in end expiration or in the subcostal area in end inspiration. A palpable pulmonary artery is commonly felt. The pulmonary component of the second heart sound is increased and can be felt in most cases. Pulmonary ejection sounds are common when the pulmonary artery is dilated with a structurally normal valve. Right atrial gallop is heard more frequently when the a wave is dominant. A murmur of tricuspid insufficiency is common, but the inspiratory increase in the murmur (Carvallo's sign) disappears when right ventricular failure occurs. In diastole, a pulmonary insufficiency murmur is often heard. The 12-lead ECG shows evidence of right atrial enlargement, right ventricular hypertrophy, and right axis deviation. Chest radiographic findings include a dilated pulmonary artery segment, cardiac enlargement, and diminished pulmonary vascular markings. Echocardiography confirms the right-sided pressure overload and pulmonary artery enlargement as well as the tricuspid and pulmonary insufficiency. Cardiac catheterization is indicated if doubt exists about the potential reversibility of the elevated pulmonary vascular resistance in a patient who might otherwise benefit from surgery.

Cyanosis occurs when persistent venous to arterial mixing results in hypoxemia. Adaptive mechanisms to increase oxygen delivery include an increase in oxygen content, a rightward shift in the oxyhemoglobin dissociation curve, a higher hematocrit, and an increase in cardiac output. When cyanosis is not relieved, chronic hypoxemia and erythrocytosis result in hematologic, neurologic, renal, and rheumatic complications.

Hematologic complications of chronic hypoxemia include erythrocytosis, iron deficiency, and bleeding diathesis. Hemoglobin and hematocrit levels, as well as red blood cell indices, should be checked regularly and correlated with systemic oxygen saturation levels. Symptoms of hyperviscosity include headaches, faintness, dizziness, fatigue, altered mentation, visual disturbances, paresthesias, tinnitus, and myalgia. Symptoms are classified as mild to moderate when they interfere with only some activities, or they can be marked to severe and interfere with most or all activities. Patients with compensated erythrocytosis establish an equilibrium hematocrit at higher levels in an iron-replete state with minimal symptoms. Patients with decompensated erythrocytosis manifest unstable, rising hematocrit levels and experience severe hyperviscosity symptoms.

Hemostatic abnormalities can occur in up to 20% of cyanotic patients with erythrocytosis. Bleeding is usually mild and superficial and leads to easy bruising, skin petechiae, or mucosal bleeding, but epistaxis, hemoptysis, or even life-threatening postoperative bleeding can occur. A variety of clotting factor deficiencies and qualitative and quantitative platelet disorders have been described.

Neurologic complications, including cerebral hemorrhage, can be caused by hemostatic defects and are most often seen after inappropriate use of anticoagulant therapy. Patients with right-to-left shunts may be at risk for paradoxical cerebral emboli. Focal brain injury may provide a nidus for brain abscess if bacteremia supervenes. Attention should be paid to the use of air filters in peripheral intravenous lines to avoid paradoxical emboli through a right-to-left shunt.

Prophylactic phlebotomy has no place in the prevention of cerebral arterial thrombosis. Indications for phlebotomy are the occurrence of symptomatic hyperviscosity in an iron-repleted patient and prevention of excessive bleeding perioperatively.

Pulmonary complications include massive pulmonary hemorrhage and in situ arterial thrombosis. A rapid clinical deterioration associated with progressive hypoxemia often marks the terminal stage of disease. No clear benefits are observed with the use of anticoagulants (systemic or intrapulmonary) because of the risk for prolonged bleeding due to the underlying coagulopathy. The chronic disease process and high mortality prohibit pulmonary endarterectomy.

Renal dysfunction can be manifested as proteinuria, hyperuricemia, or renal failure. Focal interstitial fibrosis, tubular atrophy, and hyalinization of afferent and efferent arterioles can be seen on renal biopsy. Increased blood viscosity and arteriolar vasoconstriction can lead to renal hypoperfusion with progressive glomerulosclerosis. Hyperuricemia is commonly seen in patients with cyanotic congenital heart disease and is thought to be due mainly to the decreased reabsorption of uric acid rather than overproduction from erythrocytosis. Asymptomatic hyperuricemia need not be treated because lowering of uric acid levels has not been shown to prevent renal disease or gout.

Rheumatologic complications include gout and hypertrophic osteoarthropathy, which is thought to be responsible for the arthralgias affecting up to one third of patients with cyanotic congenital heart disease. In patients with right-to-left shunting, megakaryocytes released from the bone marrow bypass the lung and are entrapped in systemic arterioles and capillaries, where they release platelet-derived growth factor, which promotes local cell proliferation. Digital clubbing and new osseous formation with periostitis occur and cause the symptoms of arthralgia. Symptomatic hyperuricemia and gouty arthritis can be treated as necessary with colchicine, probenecid, or allopurinol; nonsteroidal anti-inflammatory drugs are best avoided, given the baseline hemostatic anomalies in these patients.

TREATMENT Rx

In patients with Eisenmenger's syndrome, bosentan (62.5 mg twice daily for 4 weeks, then 125 mg twice daily) improves hemodynamics and exercise capacity for at least 40 weeks.[1] Chronic oxygen therapy is unlikely to benefit hypoxemia secondary to right-to-left shunting in the setting of a fixed pulmonary vascular resistance. Chronic oxygen therapy results in mucosal dehydration with an increased incidence of epistaxis and is therefore not recommended.

In the iron-replete state, moderate to severe hyperviscosity symptoms typically occur when hematocrit levels exceed 65%. If no evidence of dehydration is present, removal of 500 mL of blood during a 30- to 45-minute period should be followed by quantitative volume replacement with normal saline or dextran (Fig. 69-2). The procedure may be repeated every 24 hours until symptomatic improvement occurs.

Treatment of spontaneous bleeding is dictated by its severity and the abnormal hemostatic parameters (Fig. 69-3). For severe bleeding, platelet transfusions, fresh-frozen plasma, vitamin K, cryoprecipitate, and desmopressin have been used. Reduction in erythrocyte mass also improves hemostasis, so cyanotic patients undergoing surgery should have prophylactic phlebotomy if the hematocrit is greater than 65%.

Iron deficiency is common in cyanotic adult patients because of excessive bleeding or phlebotomy. In contrast to normocytic erythrocytosis, which is rarely symptomatic at hematocrit levels less than 65%, iron deficiency may manifest with hyperviscosity symptoms at hematocrit levels well below 65%. The treatment of choice is not phlebotomy but oral iron repletion until a rise in hematocrit is detected, typically within 1 week.

SIMPLE LESIONS

Isolated Shunt Lesions

Hemodynamic complications of significant shunts relate to volume overload and chamber dilation of the primary chamber receiving the excess left-to-right shunt and to secondary complications of valvular dysfunction and damage to the pulmonary vascular bed. The size and duration of the shunt determine the clinical course and therefore the indications for closure. The degree of shunting is a function of both the size of the communication and, depending on its location, biventricular compliance or pulmonary and systemic vascular resistance. Clinically apparent hemodynamic sequelae of shunts are typically apparent or can be expected to occur when pulmonary to systemic flow ratios exceed 1.5:1.

Shunt size can be inferred and measured with cardiac ultrasonography. Secondary enlargement of the cardiac chambers receiving excess shunt flow in diastole occurs as the shunt size becomes hemodynamically significant; in addition, the pulmonary artery becomes enlarged as pulmonary pressure rises. When tricuspid insufficiency occurs primarily from right ventricular dilation or secondary to pulmonary hypertension, the regurgitant jet can be used to estimate the pulmonary pressure as another indicator of shunt significance. When the pulmonary to systemic flow ($\dot{Q}:\dot{Q}$) exceeds 2:1, the volume of blood in both circulations can be estimated by comparing the stroke volume at the pulmonary and aortic valves. Shunt detection and quantification can also be obtained by a first-pass radionuclide study. As a bolus of radioactive substance is injected into the systemic circulation, the rise and fall of radionuclide activity can be measured in the lungs. When a shunt is significant, the rate of persistent activity in the lungs over time can be used to calculate the shunt fraction. For both echocardiographic and radionuclide quantification of shunt size, sources of error are multiple. The most predictable results are obtained only in experienced laboratories. Uncertainty about the physiologic significance of a borderline shunt can be minimized by integrating serial determinations from multiple clinical and relevant diagnostic sources rather than basing management decisions on a single calculated shunt value.

Atrial Septal Defect

Classification of ASDs is based on anatomic location. Most commonly, an ostium secundum ASD occurs in the central portion of the interatrial septum as a result of an enlarged foramen ovale or excessive resorption of the septum primum. The combination of a secundum ASD and acquired mitral stenosis is known as *Lutembacher's syndrome,* the pathophysiology of which is determined by the relative severity of each. Abnormal development of the embryologic endocardial cushions results in a variety of atrioventricular canal defects, the most common of which consists of a defect in the lower part of the atrial septum in the ostium primum location, typically accompanied by a cleft mitral valve and mitral regurgitation. The sinus venosus defect, which accounts for 2 to 3% of all interatrial communications, is located superiorly at the junction of the superior vena cava and right atrium and is generally associated with anomalous drainage of the right-sided pulmonary veins into the superior vena cava or right atrium. Less commonly, interatrial communications can be seen at the site of the coronary sinus, typically associated with an anomalous left superior vena cava.

The pathophysiology is determined by the effects of the shunt on the heart and pulmonary circulation. Right atrial and right ventricular dilation occurs as shunt size increases with pulmonary to systemic flow ratios greater than 1.5:1. Superimposed systemic hypertension and coronary artery disease modify left ventricular compliance and favor left-to-right shunting. Mitral valve disease can occur in up to 15% of patients older than 50 years. Right-sided heart failure, atrial fibrillation, or atrial flutter can occur as a result of chronic right-sided volume overload and progressive ventricular and atrial dilation. Stroke can result from paradoxical emboli, atrial arrhythmias, or both. A rise in pulmonary pressure occurs because of the increased pulmonary blood flow. Pulmonary hypertension is unusual before 20 years of age but is seen in 50% of patients older than 40 years. The overall incidence of pulmonary vascular obstructive disease is 15 to 20% in patients with ASD. Eisenmenger's disease with reverse shunting, a late and rare complication of isolated secundum ASD, is reported in 5 to 10% of patients.

DIAGNOSIS

Although most patients are minimally symptomatic in the first three decades, more than 70% become impaired by the fifth decade. Initial symptoms include exercise intolerance, dyspnea on exertion, and fatigue caused most commonly by right-sided heart failure and pulmonary hypertension. Palpitations, syncope, and stroke can occur with the development of atrial arrhythmias.

On physical examination, most adults have a normal general physical appearance. When Holt-Oram syndrome is present, the thumb may have a third phalanx or may be rudimentary or absent. With an uncomplicated nonrestrictive communication between both atria, the a and v waves are equal in amplitude. Precordial palpation typically discloses a normal left ventricular impulse unless mitral valve disease occurs. Characteristically, if the shunt is significant, a right ventricular impulse can be felt in the left parasternal area in end expiration or in the subxiphoid area in end inspiration. A dilated pulmonary artery can sometimes be felt in the second left intercostal space. On auscultation, the hallmark of an ASD is the wide and fixed splitting of the

second heart sound. Pulmonary valve closure, as reflected by P_2, is delayed because of right ventricular overload and the increased capacitance of the pulmonary vascular bed. The A_2-P_2 interval is fixed because the increase in venous return elevates the right atrial pressure during inspiration, thereby decreasing the degree of left-to-right shunting and offsetting the usual phasic respiratory changes. In addition, compliance of the pulmonary circulation is reduced from the high flow, thus making the vascular compartment less susceptible to any further increase in blood flow. A soft midsystolic murmur generated by the increased flow across the pulmonary valve is usually heard in the second left interspace. In the presence of a high left-to-right shunt volume, increased flow across the tricuspid valve is heard as a mid-diastolic murmur at the lower left sternal border. With advanced right-sided heart failure, evidence of systemic venous congestion is present.

The ECG characteristically shows an incomplete right bundle branch block pattern (Fig. 69-4). Right axis deviation and atrial abnormalities, including a prolonged PR interval, atrial fibrillation, and flutter, are also seen. Typically, the chest radiograph shows pulmonary vascular plethora with increased markings in both lung fields consistent with increased pulmonary blood flow (see Fig. 53-13 in Chapter 53). The main pulmonary artery and both its branches are dilated. Right atrial and right ventricular dilation can be seen. Cardiac ultrasonography is diagnostic and provides important prognostic information (Fig. 69-5). Ostium primum and secundum ASDs are easily identifiable with transthoracic imaging, but a sinus venosus ASD can be missed unless it is specifically sought. For more accurate visualization of the superior interatrial septum and localization of the pulmonary veins, transesophageal echocardiography is useful. With Doppler study, pulmonary artery pressures can be quantified, and the $\dot{Q}:\dot{Q}$ can be measured.

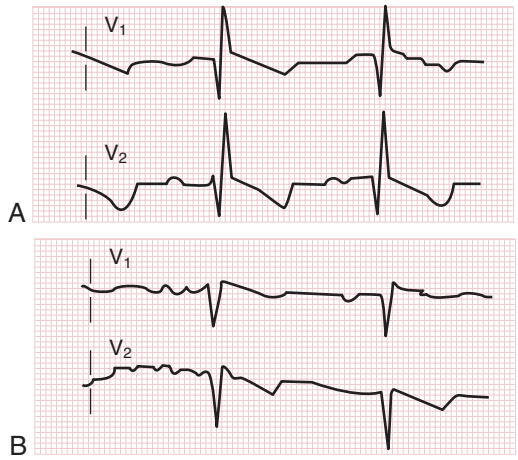

FIGURE 69-4. Electrocardiographic hallmark in atrial septal defect. Right precordial leads V_1 and V_2 illustrate two variants of an incomplete right bundle branch block pattern, the rSrT pattern (**A**) and the rsR′ pattern (**B**).

TREATMENT Rx

Closure of an ASD either percutaneously or surgically is indicated in the presence of right heart enlargement, with or without symptoms. Centrally located defects measuring up to 3.5 cm can be occluded by transcatheter techniques in a cardiac catheterization laboratory. Advantages of this approach include the avoidance of sternotomy and cardiopulmonary bypass. Uncomplicated secundum ASDs may be closed surgically in children and adults with minimal operative mortality, although surgical closure is usually reserved for patients in whom concomitant repair of associated valvular anomalies is required, anomalous pulmonary veins are present, or device closure is not technically feasible.

In patients older than 40 years with symptoms and significant shunts, closure improves functional status and survival.■ In the presence of a significant shunt, closure of an ASD before 25 years of age without evidence of pulmonary hypertension results in a long-term outcome that is similar to that of age- and sex-matched controls. Advanced age (60 years) is not a contraindication to ASD closure in the presence of a significant shunt because a significant number of patients will show evidence of symptomatic improvement. Preoperative pulmonary artery pressure and the presence or absence of pulmonary vascular disease are important predictors of successful interventional outcome.

Patent Foramen Ovale

Integrity of the fetal circulation depends on the patency of the foramen ovale. In most cases, the fall in pulmonary vascular resistance at birth induces the foramen to become sealed. Necropsy studies have revealed that the foramen ovale remains patent beyond the first year of life in about 30% of individuals, and clinical studies have demonstrated that the prevalence of patent foramen ovale is three times greater in patients with cryptogenic stroke (Chapter 414), particularly before the age of 55 years, because of right-to-left shunting and paradoxical embolization of material from the venous circulation. Cardiac investigation of the patient with cryptogenic stroke includes transesophageal echocardiography with agitated saline injection to visualize the presence of a right-to-left shunt (Chapter 55). Patent foramen ovale most likely to result in future paradoxical embolization is found in patients younger than 55 years with a prior cryptogenic stroke, in association with a hypermobile septum with aneurysm formation, and when a significant amount of right-to-left shunting is present at rest without provocative maneuvers. Some data suggest that a patent foramen ovale also may be associated with migraine headaches.

TREATMENT Rx

Currently there are no data to support closure of a patent foramen ovale for primary stroke prevention in a patient in whom it is fortuitously diagnosed on routine echocardiography. Ongoing randomized trials are addressing the benefit of closure versus medical therapy after a stroke; in the meantime, warfarin to an international normalized ratio of 2.0 to 3.0 is usually recommended over aspirin for secondary stroke prevention. Primary closure of a patent foramen ovale is indicated when a patient has contraindications to medical therapy, if medical therapy has failed, or in the presence of a hypercoagulable state not treatable by medical therapy. Device closure in experienced centers is usually preferred to surgical closure, although surgical closure is performed if the patient undergoes cardiac surgery for other reasons. Device closure appears to be associated with a low incidence of yearly recurrence rates. Despite the potential link with migraine headaches, closure of a patent foramen ovale does not result in symptomatic improvement.■

Ventricular Septal Defect

For anatomic classification of VSDs, the interventricular septum can be divided into four regions. Defects of the membranous septum, or infracristal VSDs, are located in a small translucent area beneath the aortic valve and account for up to 80% of VSDs. These VSDs typically show a variable degree of extension into the inlet or outlet septum, hence their designation as perimembranous. Infundibular defects or supracristal outlet VSDs occur in the conal septum above the crista supraventricularis and below the pulmonary valve. Inlet defects are identified at the crux of the heart between the tricuspid

and mitral valves and are usually associated with other anomalies of the atrioventricular canal. Defects of the trabecular or muscular septum can be multiple and occur distal to the septal attachment of the tricuspid valve and toward the apex.

The pathophysiology and clinical course of VSDs depend on the size of the defect, the status of the pulmonary vascular bed, and the effects of shunt size on intracardiac hemodynamics. Unlike ASDs, a VSD may decrease in size with time. Approximately half of all native VSDs are small, and more than half of them close spontaneously; moderate or even large VSDs may also close in 10% or less of cases. The highest closure rates are observed in the first decade of life; spontaneous closure in adult life is unusual.

Patients who have a small defect with trivial or mild shunts are defined as those with a $\dot{Q}:\dot{Q}$ of less than 1.5 and normal pulmonary artery pressure and vascular resistance. Patients with moderate defects have a $\dot{Q}:\dot{Q}$ ratio of greater than 1.2 and elevated pulmonary artery pressure but not elevated pulmonary vascular resistance. Patients with a large and severe defect have an elevated $\dot{Q}:\dot{Q}$ ratio with high pulmonary pressure and elevated pulmonary vascular resistance. Eisenmenger's complex develops in about 10% of patients with VSDs, usually when there is no resistance to flow at the level of the defect, which can be as large as the aorta. When a systolic pressure gradient is present between the ventricles, the physiologic severity may be trivial or mild but can also be moderate or severe.

Minimal or mild defects usually cause no significant hemodynamic or physiologic abnormality. A moderate or severe defect causes left atrial and ventricular dilation consistent with the degree of left-to-right shunting. Shunting across the ventricular septum occurs predominantly during systole when left ventricular pressure exceeds that on the right; diastolic filling abnormalities occur in the left atrium. With moderate or severe defects, the right side of the heart becomes affected as a function of the rise in pulmonary pressure and pulmonary blood flow.

DIAGNOSIS

An adult with a VSD most commonly has a small restrictive lesion that either was small at birth or has undergone some degree of spontaneous closure. A second group of patients consists of those with large, nonrestrictive VSDs that have not been operated on; these patients have had Eisenmenger's complex for most of their lives. Patients with a moderately sized defect are typically symptomatic as children and are therefore more likely to have repair at a young age.

Patients with a trivial or mild shunt across a small, restrictive VSD are usually asymptomatic. Physical examination discloses no evidence of systemic or pulmonary venous congestion, and jugular venous pressure is normal. A thrill may be palpable at the left sternal border. Auscultation reveals normal S_1 and S_2 without gallops. A grade 4 or louder, widely radiating, high-frequency, pansystolic murmur is heard maximally in the third or fourth intercostal space and reflects the high-pressure gradient between the left and right ventricles throughout systole. The striking contrast between a loud murmur and an otherwise normal cardiac examination is an important diagnostic clue. The ECG and chest radiograph are also normal in patients with small VSDs.

At the other end of the spectrum are patients with Eisenmenger's complex (see earlier). Between these two extremes are patients with a moderate defect, whose pathology reflects a combination of pulmonary hypertension and left-sided volume overload resulting from a significant left-to-right shunt. In adults, shortness of breath on exertion can be the result of both pulmonary venous congestion and elevated pulmonary pressure. On physical examination, a diffuse palpable left ventricular impulse occurs with a variable degree of right ventricular hypertrophy and an accentuated second heart sound. A systolic murmur persists as long as pulmonary vascular resistance is below systemic resistance. The ECG commonly shows left atrial enlargement and left ventricular hypertrophy. The chest radiograph shows shunt vascularity with an enlarged left atrium and ventricle. The degree of pulmonary hypertension determines the size of the pulmonary artery trunk.

Echocardiography can identify the defect and determine the significance of the shunt by assessing left atrial and ventricular size, pulmonary artery pressure, and the presence or absence of right ventricular hypertrophy. Cardiac catheterization is reserved for those in whom surgery is considered. Adults with a small defect of no physiologic significance need not be studied invasively. Those with Eisenmenger's complex have severe pulmonary vascular disease and are not surgical candidates. Patients who have a moderately sized shunt that appears hemodynamically significant and in whom pulmonary pressures are elevated are most likely to benefit from direct measurements of pulmonary vascular resistance and reactivity.

TREATMENT Rx

Patients with Eisenmenger's complex have pulmonary vascular resistance that is prohibitive to surgery. For this group of patients, management centers on the medical complications of cyanosis (see earlier). In a few patients with small defects, complications can relate to progressive tricuspid insufficiency caused by septal aneurysm formation or to acquired aortic insufficiency when an aortic cusp becomes engaged in the high-velocity jet flow generated by the defect. The intermediate group of patients with a defect of moderate physiologic significance should have surgical closure unless it is contraindicated by high pulmonary vascular resistance.

Late results after operative closure of isolated VSDs include residual patency in up to 20% of patients, only about 5% of whom need a reoperation. Rhythm disturbances after surgical closure of VSDs include tachyarrhythmias and conduction disturbances. Right bundle branch block occurs in one third to two thirds of patients, whereas first-degree atrioventricular block and complete heart block occur in less than 10%. Sudden cardiac death after surgical repair of VSD occurs in 2% of patients.

Patent Ductus Arteriosus

The ductus arteriosus connects the descending aorta to the main pulmonary trunk near the origin of the left subclavian artery (Fig. 69-6). Normal postnatal closure results in fibrosis and degenerative changes in the ductal lumen, leaving in its place the residual ligamentum arteriosum, which rarely can become part of an abnormal vascular ring. When the duct persists, significant calcification of the aortic ductal end is observed.

The physiologic consequences of a PDA are determined by its size and length as well as by the ratio of pressure and resistance of the pulmonary and aortic circulations on either end of the duct. If systolic and diastolic pressure in the aorta exceeds that in the pulmonary artery, aortic blood flows continuously down a pressure gradient into the pulmonary artery and then returns to the left atrium. The left atrium and subsequently the left ventricle dilate, whereas the right side of the heart becomes progressively affected as pulmonary hypertension develops.

A small PDA has continuous flow throughout the entire cardiac cycle without left-sided heart dilation, pulmonary hypertension, or symptoms. Patients with a small PDA, although protected from hemodynamic complications of a significant left-to-right shunt, remain at risk for infectious endarteritis, which usually develops on the pulmonary side of the duct and occurs at a rate of about 0.45% per year after the second decade. Because endarteritis accounts for up to one third of the total mortality in patients with PDA, ductal closure should be considered even when the PDA is small.

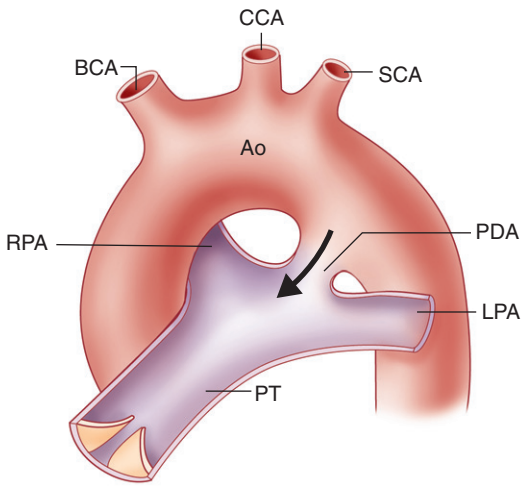

FIGURE 69-6. Anatomy of a patent ductus arteriosus. Note the relationships among the position of the ductus, left subclavian artery, and pulmonary artery bifurcation. Ao = aorta; BCA = brachiocephalic; CCA = common carotid artery; LPA = left pulmonary artery; PDA = patent ductus arteriosus; PT = pulmonary trunk; RPA = right pulmonary artery; SCA = subclavian artery. (From Perloff JK, ed. *Clinical Recognition of Congenital Heart Disease,* 4th ed. Philadelphia: WB Saunders; 1994:510.)

A PDA is of moderate or large size but still restrictive when a left-to-right shunt occurs throughout systole and diastole is of variable duration. Left atrial or ventricular dilation and pulmonary hypertension will vary with the quantity of left-to-right shunting as well as with the secondary effects on the pulmonary vascular bed. Symptoms generally increase by the second and third decades and include dyspnea, palpitations, and exercise intolerance. As heart failure, pulmonary hypertension, or endarteritis develops, mortality rises to 3 to 4% per year by the fourth decade, and two thirds of patients die by 60 years of age. Eisenmenger's physiology with systemic or suprasystemic pulmonary pressure and a right-to-left shunt develops in 5% of patients with an isolated PDA.

DIAGNOSIS

In patients with Eisenmenger's physiology, a right-to-left shunt from the pulmonary artery to the descending aorta results in decreased oxygen saturation in the lower extremities compared with the upper extremities. This difference in cyanosis and clubbing is most prominent in the toes; the left arm is variably affected through the left subclavian artery, and the right arm is typically spared. With a large left-to-right shunt, the pulse pressure widens as diastolic flow into the pulmonary artery lowers systemic diastolic pressure. The arterial pulse becomes bounding as a result of increased stroke volume. Precordial palpation discloses variable left and right ventricular impulses as determined by the relative degree of left-sided volume overload and pulmonary hypertension. In the presence of a continuous aortopulmonary gradient, the classic "machinery" murmur of a PDA can be heard at the first or second left intercostal space below the left clavicle. As the pulmonary pressure rises, the diastolic component of the murmur becomes progressively shorter. With the development of Eisenmenger's physiology and equalization of aortic and pulmonary pressure, the entire murmur may disappear, and the clinical findings are dominated by pulmonary hypertension.

In adult patients with a significant left-to-right shunt, the ECG shows a bifid P wave in at least one limb lead consistent with left atrial enlargement and a variable degree of left ventricular hypertrophy. The PR interval is prolonged in about 20% of patients. In older patients, the chest radiograph shows calcification at the location of the PDA. Characteristically, the ascending aorta and pulmonary artery are dilated, and the left-sided chambers are enlarged. Echocardiography may not directly visualize the PDA but can accurately identify it by a Doppler signal that often parallels the length of the murmur. Left-sided heart dilation and pulmonary hypertension can be quantified and monitored. Cardiac catheterization to assess pulmonary vascular resistance is commonly indicated before closure.

TREATMENT

Rx

After ligation of a PDA in infancy or early childhood, cardiac function is commonly normal, and no special follow-up is required. If pulmonary artery pressure and pulmonary vascular resistance are substantially elevated, preoperative evaluation should assess the degree of reversibility. With Eisenmenger's disease, closure is contraindicated. Closure of a PDA either percutaneously or surgically is indicated in the presence of left heart enlargement or if prior endarteritis has occurred. Reported operative mortality rates vary from less than 1 to 8%, depending on the presence of calcification and the degree of pulmonary hypertension. Transcatheter or coil occlusion is an accepted procedure in adults. Residual shunt rates vary from 0.5 to 8%, depending on the device used. Small residual defects that are detected by echocardiography but are not associated with an audible murmur or hemodynamic findings do not appear to carry a significant risk for endarteritis.

Aortopulmonary Window

An aortopulmonary window is typically a large defect across the adjacent segments of both great vessels above their respective valves and below the pulmonary artery bifurcation. The pathophysiology is similar to that of a PDA. The shunt is usually large, so pulmonary vascular resistance rises rapidly and abolishes the aortopulmonary gradient in diastole. The murmur is usually best heard at the third left intercostal space. With a right-to-left shunt, differential cyanosis never occurs because the shunt is proximal to the brachiocephalic vessels. Differentiation of an aortopulmonary window from a PDA can usually be confirmed with echocardiography; the left-to-right shunt is seen in the main pulmonary artery in the aortopulmonary window compared with the left pulmonary artery bifurcation in PDA. Cardiac catheterization confirms the diagnosis and hemodynamics. Surgical repair is necessary unless pulmonary vascular obstructive disease precludes closure.

Pulmonary Arteriovenous Fistulas

Pulmonary arteriovenous fistulas can occur as isolated congenital disorders or as part of generalized hereditary hemorrhagic telangiectasia (Osler-Weber-Rendu syndrome). These fistulas typically occur in the lower lobes or the right middle lobe and can be small or large, single or multiple. The arterial supply usually comes from a dilated, tortuous branch of the pulmonary artery.

The most common finding is that of abnormal opacity on a chest radiograph in a patient with buccal ruby patches or in an otherwise healthy adult who has mild cyanosis. Shunting between deoxygenated pulmonary arterial blood and the oxygenated pulmonary venous blood results in a physiologic right-to-left shunt. The degree of shunting is typically small and not significant enough to result in dilation of the left atrium and ventricle. Heart failure is unusual. Hemoptysis can result if a fistula ruptures into a bronchus. In patients with hereditary hemorrhagic telangiectasia, angiomas occur on the lips and mouth as well as in the gastrointestinal tract and on pleural, liver, and vaginal surfaces. Epistaxis is most common, but cerebrovascular accidents can also occur. Patients with hereditary hemorrhagic telangiectasia can have symptoms that resemble those of a transient ischemic attack even in the absence of right-to-left shunting. On physical examination, cyanosis and clubbing can be notable or barely detectable. Auscultation can disclose soft systolic or continuous noncardiac murmurs on the chest wall adjacent to the fistula. The murmur typically increases with inspiration. The ECG is usually normal. The chest radiograph shows one or more densities, typically in the lower lobes or in the right middle lobe. An echocardiogram can confirm the presence of the fistula by showing early opacification of the left atrium in the absence of any other intracardiac communication when saline is injected into a peripheral vein. The absence of a hemodynamically significant shunt can be confirmed by documenting normal cardiac chamber size.

If the hypoxemia is progressive or if a neurologic complication is documented to have occurred because of paradoxical emboli, fistula closure should be considered. Options include percutaneous catheter techniques if the fistula is small and accessible or a pulmonary wedge resection or lobectomy if the fistula is large. Multiple or recurrent fistulas create a major therapeutic challenge.

Isolated Obstructive Lesions of the Right and Left Ventricular Outflow Tract

Complications of obstructive lesions of the outflow tract relate to the secondary effects of exposure to pressure overload in the chamber proximal to the obstruction. The inability to increase systemic or pulmonary blood flow in the face of a fixed obstruction can cause exercise intolerance, inadequate myocardial perfusion, ventricular arrhythmias, and sudden death.

RIGHT VENTRICULAR OUTFLOW TRACT OBSTRUCTION

Obstruction of the right ventricular outflow tract can occur at the level of the pulmonary valve (see later), above it in the main pulmonary artery or its branches, or below it in the right ventricle itself. Supravalvular and branch pulmonary artery stenoses are important and common complications in patients with tetralogy of Fallot (see later). Residual supravalvar pulmonary stenosis is sometimes seen after palliative pulmonary artery banding to decrease pulmonary blood flow in patients with large left-to-right shunts. Congenital branch pulmonary artery stenosis can occur in isolation or with valvar pulmonary stenosis, shunt lesions, or a variety of syndromes. Patients with Noonan's syndrome have a characteristic phenotypic facial appearance, short stature, and webbed neck; cardiac lesions may include a dysplastic pulmonary valve, left ventricular hypertrophic cardiomyopathy, and peripheral pulmonary artery stenosis. Supravalvular pulmonary stenosis can be seen with supravalvular aortic stenosis in Williams (elfin facies) syndrome.

Pulmonary atresia refers to an absent, imperforate, or closed pulmonary valve, which typically occurs in conjunction with other malformations. Pulmonary atresia with a nonrestrictive VSD is a complex cyanotic malformation that is discussed later.

Primary infundibular stenosis with an intact ventricular septum can result from a fibrous band just below the infundibulum. In a double-chambered right ventricle, obstruction is caused by anomalous muscle bundles that divide the right ventricle into a high-pressure chamber below the hypertrophied muscle bundles and a low-pressure chamber above the bundles and below the valve. The clinical features vary according to the presence or absence of other lesions, such as pulmonary valvular stenosis or VSD.

VALVULAR PULMONARY STENOSIS

Isolated congenital valvular pulmonary stenosis (Chapter 75) is a common lesion due to a bicuspid valve in 20% of cases, a dysplastic valve caused by myxomatous changes and severe thickening in 10% of cases, and an abnormal trileaflet valve in most of the remaining cases. Fusion of the leaflets results in a variable degree of thickening and calcification in older patients.

The 25-year survival of patients with valvular pulmonary stenosis is greater than 95% but is worse in those with severe stenosis and peak systolic gradients greater than 80 mm Hg. For patients with mild (<50 mm Hg gradients) and moderate (50 to 80 mm Hg gradients) pulmonary stenosis, bacterial endocarditis, complex ventricular arrhythmias, and progression of the stenosis are uncommon.

DIAGNOSIS

A patient with moderate or even severe pulmonary stenosis may be asymptomatic. With severe stenosis, exercise intolerance can be associated with presyncope and ventricular arrhythmias. Progressive right-sided heart failure is the most common cause of death. On physical examination of patients with significant pulmonary stenosis, jugular venous pressure has a dominant a wave, reflecting a noncompliant right ventricle. Palpation discloses a sustained parasternal lift of right ventricular hypertrophy. An expiratory systolic ejection click is characteristic if the leaflets are still mobile. In moderate or severe stenosis, a grade 3 or louder systolic murmur can be heard and felt in the second left interspace. The length of the murmur increases as it peaks progressively later in systole with an increasing degree of obstruction. If right-sided heart failure occurs, tricuspid insufficiency and systemic venous congestion develop. The ECG can show right axis deviation and tall, peaked right atrial P waves in lead II. With more than mild stenosis, the R wave exceeds the S wave in lead V_1. On chest radiography, the main pulmonary artery can be dilated even if the stenosis is mild. Characteristically, the left pulmonary artery is more dilated than the right because of the leftward direction of the high-velocity jet. A variable degree of right ventricular hypertrophy is manifested as right-sided chamber enlargement. Echocardiography can establish the diagnosis and determine the severity by Doppler ultrasound examination. Patients with valvar pulmonary stenosis do not require cardiac catheterization. The mean gradient at echocardiography correlates well with the gradient measured at cardiac catheterization and should be used for therapeutic decisions because peak instantaneous Doppler gradients tend to overestimate the severity of disease.

TREATMENT Rx

Depending on symptoms, percutaneous balloon valvotomy should be considered for patients with isolated valvar pulmonary stenosis and mean Doppler gradients of 30 mm Hg or greater unless there is moderate or severe pulmonary regurgitation. In the presence of a doming valve, pulmonary angioplasty is the procedure of choice for adults, who achieve persistently good results at 10-year follow-up. For patients with hypoplastic pulmonary arteries or subvalvular stenosis (double-chambered right ventricle), surgical resection of right ventricular muscle bands can be performed.

LEFT VENTRICULAR OUTFLOW TRACT OBSTRUCTION

Stenosis of the left ventricular outflow tract can occur at, below, or above the aortic valve. Discrete subaortic stenosis, most commonly caused by a fibromuscular ring just below the valve, accounts for 15 to 20% of all cases of congenital obstruction of the left ventricular outflow tract. Concomitant aortic insufficiency occurs in 50% of cases. Supravalvular aortic stenosis results from thickened media and intima above the aortic sinuses; early coronary atherosclerosis or even ostial coronary obstruction can occur.

CONGENITAL VALVULAR AORTIC STENOSIS

The normal aortic valve has three cusps and commissures. A unicuspid aortic valve accounts for most cases of severe aortic stenosis in infants (Chapter 75). A bicuspid aortic valve, which is the most common congenital cardiac malformation, functions normally at birth but often becomes gradually obstructed as calcific and fibrous changes occur; prolapse of one or both cusps can cause aortic insufficiency.

The pathophysiology of aortic stenosis depends not only on its severity but also on the age at diagnosis. When a bicuspid aortic valve becomes stenotic in adulthood because of degenerative changes, criteria for diagnosis and intervention parallel those for other forms of acquired aortic stenosis (Chapter 75). The estimated overall 25-year survival rate for patients with congenital valvular aortic stenosis diagnosed in childhood is 85%. Children with initial peak cardiac catheterization gradients of less than 50 mm Hg have long-term survival rates of higher than 90%, as opposed to survival rates of 80% in those with gradients of 50 mm Hg or greater.

DIAGNOSIS

Symptoms include angina, exertional dyspnea, presyncope, and syncope and may progress to heart failure. The auscultatory hallmark of a bicuspid aortic valve is an audible systolic ejection click that is typically of a higher pitch than the first heart sound and is best heard not at the cardiac base but at the apex. The sound is caused by sudden movement of the stenotic valve as it moves superiorly in systole and is followed by the typical aortic stenosis murmur (Chapter 75). When significant calcification of the valve results in reduced mobility, the ejection sound is no longer heard. The diagnosis is easily confirmed by two-dimensional echocardiography, with which the number and orientation of aortic cusps can readily be identified.

TREATMENT Rx

Conservative management is generally indicated for mild stenosis with a peak gradient of less than 25 mm Hg, but close supervision is required because 20% of these patients require an intervention during long-term follow-up. Unlimited athletic participation is allowed only for asymptomatic patients with peak gradients of less than 20 to 25 mm Hg, a normal ECG, and a normal exercise test. For children who are symptomatic or have gradients greater than 30 mm Hg but do not have significant aortic insufficiency, transcatheter aortic valvotomy is preferred. Aortic valvuloplasty can be considered in young adults, but calcification limits its success, and valve replacement is usually required (Chapter 75). For adults, treatment decisions are similar to those for aortic stenosis from other causes. For patients with subvalvular aortic stenosis, surgical intervention is indicated in the presence of peak gradients above 50 mm Hg, symptoms, or progressive aortic insufficiency.

COARCTATION OF THE AORTA

Aortic coarctation typically occurs just distal to the left subclavian artery at the site of the aortic ductal attachment or its residual ligamentum arteriosum. Less commonly, the coarctation ridge lies proximal to the left subclavian. A bicuspid aortic valve is the most common coexisting anomaly, but VSDs and PDAs are also seen. Pseudocoarctation refers to buckling or kinking of the aortic arch without the presence of a significant gradient.

The most common complications of aortic coarctation are systemic hypertension (Chapter 67) and secondary left ventricular hypertrophy with heart failure. Systemic hypertension is caused by decreased vascular compliance in the proximal aorta and activation of the renin-angiotensin system in response to renal artery hypoperfusion below the obstruction. Left ventricular hypertrophy occurs in response to chronic pressure overload. Congestive heart failure occurs most commonly in infants and then after 40 years of age. The high pressure proximal to the obstruction stimulates the growth of collateral vessels from the internal mammary, scapular, and superior intercostal arteries to the intercostals of the descending aorta. Collateral circulation increases with age and contributes to perfusion of the lower extremities and the spinal cord. This mechanism, although adaptive in a patient who has not undergone surgery, accounts for significant morbidity during surgery when the motor impairment results from inadequate protection of spinal perfusion. Aneurysms occur most notably in the ascending aorta and in the circle of Willis. Premature coronary disease is thought to be related to the resulting hypertension. Complications, including bacterial endarteritis at the coarctation site or, more commonly, endocarditis at the site of a bicuspid aortic valve, cerebrovascular complications, myocardial infarction, heart failure, and aortic dissection, occur in 2 to 6% of patients, more frequently in those with advancing age who have not undergone surgery.

DIAGNOSIS

Young adults may be asymptomatic with incidental systemic hypertension and decreased lower extremity pulses. Coarctation should always be considered in adolescents and young adult men with unexplained upper extremity hypertension. The pressure differential can cause epistaxis, headaches, leg fatigue, or claudication. Older patients have angina, symptoms of heart failure, and vascular complications.

On physical examination, the lower half of the body is typically slightly less developed than the upper half. The hips are narrow and the legs are short, in contrast to broad shoulders and long arms. Blood pressure measurements

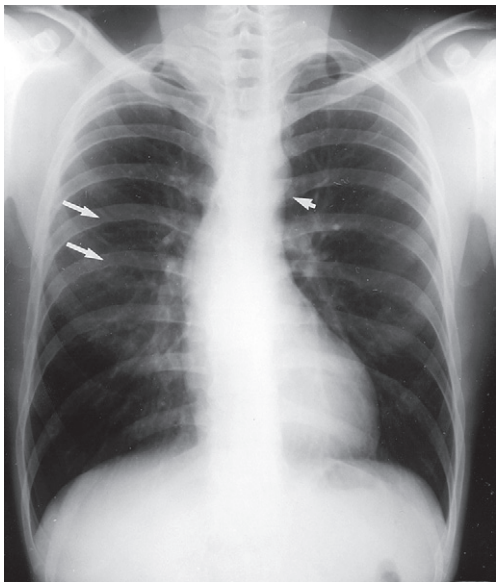

FIGURE 69-7. Chest radiograph of a patient with coarctation of the aorta. The radiographic *3* formed by the dilated subclavian artery above and the dilated aorta below *(short arrow)* is shown. Note the notching, best seen at the level of the seventh and eighth ribs *(long arrows)*. The dilated ascending aortic segment can also be seen.

should be obtained in each arm and one leg; an abnormal measurement is an increase of less than 10 mm Hg in popliteal systolic blood pressure compared with arm systolic blood pressure. The diastolic pressure should be the same in the upper and lower extremities. A pressure differential of more than 30 mm Hg between the right and the left arms is consistent with compromised flow in the left subclavian artery. Right brachial palpation characteristically reveals a strong or even bounding pulse compared with a slowly rising or absent femoral, popliteal, or pedal pulse. Examination of the eyegrounds can reveal tortuous or corkscrew retinal arteries. Precordial palpation is consistent with left ventricular pressure overload. On auscultation, a systolic ejection sound reflecting the presence of a bicuspid aortic valve should be sought. The coarctation itself generates a systolic murmur heard posteriorly, in the midthoracic region, the length of which correlates with the severity of the coarctation. Over the anterior of the chest, systolic murmurs reflecting increased collateral flow can be heard in the infraclavicular areas and the sternal edge or in the axillae.

In adult coarctation, the most common finding on the ECG is left ventricular hypertrophy. Chest radiographic findings are diagnostic. Location of the coarctation segment between the dilated left subclavian artery above and the leftward convexity of the descending aorta below results in the "3 sign" (Fig. 69-7). Bilateral rib notching as a result of dilation of the posterior intercostal arteries is seen on the posterior of the third to eighth ribs when the coarctation is below the left subclavian. Unilateral rib notching sparing the left ribs is observed when the coarctation occurs proximal to the left subclavian artery. Transthoracic echocardiography documents the gradient in the descending aorta and determines the presence of left ventricular hypertrophy. Magnetic resonance imaging (Chapter 56) is the best modality for visualizing the anatomy of the descending aorta. Cardiac catheterization should measure pressures and assess collaterals when surgery is contemplated.

TREATMENT

Rx

Intervention is recommended in patients who have gradients of 20 mm Hg or more on cardiac catheterization (Chapter 57) or who have evidence of significant collateral flow on imaging studies. The choice between catheter interventional and surgical intervention, which should be made in conjunction with a specialist, depends on the associated anomalies and the anatomy of the coarctation segment. Fifty percent of patients repaired when they are older than 40 years have residual hypertension, whereas those who have undergone surgery between the ages of 1 and 5 years have a less than 10% prevalence of hypertension on long-term follow-up. Balloon angioplasty is the treatment of choice for focal recoarctation in patients who have previously been operated on. The incidence of incomplete relief and restenosis is decreased in adults by endovascular stent placement. Focal complications include aortic aneurysms and, rarely, aortic rupture.

Anomalies of the Sinuses of Valsalva and Coronary Arteries

SINUS OF VALSALVA ANEURYSMS

At the base of the aortic root, the aortic valve cusps are attached to the aortic wall, above which three small pouches, or sinuses, are seated. The right coronary artery originates from one sinus and the left main coronary artery from a second; the third is called the *noncoronary sinus.* A weakness in the wall of the sinus can result in aneurysm formation with or without rupture. In more than 90% of cases, the aneurysm involves the right or noncoronary cusp. Rupture typically occurs into the right side of the heart at the right atrial or ventricular level with a resulting large left-to-right shunt driven by the high aortic pressure.

A previously asymptomatic young man typically has chest pain and rapidly progressing shortness of breath sometimes after physical strain. The physical examination is consistent with significant heart failure. Even if the communication is between the aorta and the right side of the heart, biventricular failure is not unusual. The classic murmur is loud and continuous, often with a thrill. A murmur of aortic insufficiency secondary to damage to the adjacent aortic valve may be superimposed. The chest radiograph shows volume overload of both ventricles with evidence of shunt vascularity and pulmonary venous congestion. The echocardiogram is diagnostic. Cardiac catheterization can verify the integrity of the coronary artery adjacent to the ruptured aneurysm.

Even though symptoms may abate as the heart dilates, progressive cardiac decompensation typically results in death within 1 year of the rupture. A ruptured sinus of Valsalva aneurysm therefore requires urgent surgical repair.

CORONARY ARTERY FISTULAS

Fistulas arise from the right or left coronary arteries and in 90% of cases drain into the right ventricle, the right atrium, or the pulmonary artery in order of decreasing frequency. Typically, young patients are asymptomatic, but supraventricular arrhythmias are seen with progressive dilation of the intracardiac chambers. Angina can occur as the fistula creates a coronary steal by diverting blood away from the myocardium. Heart failure is seen with large fistulas. A continuous murmur heard in a young, otherwise normal acyanotic, asymptomatic patient should suggest the diagnosis. Most fistulas are associated with a small shunt, and hence the murmur is often less than grade 3 and is heard in the precordial area. Unless the shunt is large, the ECG is normal, as is the chest radiograph. The echocardiogram, especially the transesophageal echocardiogram, is diagnostic. Percutaneous transcatheter closure with coil embolization is preferred, but surgical ligation is also an alternative.

ANOMALOUS ORIGIN OF THE CORONARY ARTERIES

The left main coronary artery normally arises from the left sinus of Valsalva and courses leftward, posterior to the right ventricular outflow tract. The right coronary artery arises from the right sinus of Valsalva and courses rightward to the right ventricle. Isolated ectopic or anomalous origins of the coronary arteries (see Fig. 57-8 in Chapter 57) are seen in 0.6 to 1.5% of patients undergoing coronary angiography.

The most common anomaly is ectopic origin of the left circumflex artery from the right sinus of Valsalva, followed by anomalous origin of the right coronary artery from the left sinus and anomalous origin of the left main coronary artery from the right sinus. If the anomalous coronary artery does not course between the pulmonary artery and aorta, the prognosis is favorable. Risks of ischemia, myocardial infarction, and death are greatest when the left main coronary artery courses between both great vessels.

Coronary arteries can also originate from the pulmonary trunk. If both the right and left arteries originate from the pulmonary trunk, death usually occurs in the neonatal period. If only the left anterior descending coronary artery originates from the pulmonary trunk, the rate of survival to adulthood is approximately 10%, depending on the development of collateral retrograde flow to the anomalous artery from a normal coronary artery. This collateral flow may cause a continuous murmur along the left sternal border, congestive heart failure from the large shunt, and a coronary steal syndrome as blood is diverted away from the normal artery.

A single coronary ostium can provide a single coronary artery that branches into right and left coronary arteries, the left then giving rise to the circumflex and the anterior descending arteries. The ostium can originate from the right or left aortic sinus. The coronary circulation is functionally normal unless one of the branches passes between the aorta and the pulmonary artery.

Diagnostic procedures include angiography, magnetic resonance imaging, and transesophageal echocardiography. For an anomalous coronary artery that originates from the pulmonary artery, surgical reimplantation into the aorta is preferred. For an anomalous artery that courses between the pulmonary artery and aorta, a bypass graft to the distal vessel is preferred.

SPECIFIC COMPLEX LESIONS

Tetralogy of Fallot

Tetralogy of Fallot, the most common cyanotic malformation, is characterized by superior and anterior displacement of the subpulmonary infundibular septum, which causes the tetrad of pulmonary stenosis, VSD, aortic override, and right ventricular hypertrophy. The VSD is perimembranous in 80% of cases. Additional cardiac anomalies include a right-sided aortic arch in up to 25% of patients. An anomalous left anterior descending artery originating from the right coronary cusp and crossing over the right ventricular outflow tract is seen in 10% of cases. Other associated anomalies include ASD, left superior vena cava, defects of the atrioventricular canal, and aortic insufficiency. With pulmonary atresia, pulmonary blood flow occurs through aortic to pulmonary collaterals. Life expectancy is limited unless staged reconstructive surgery is performed.

The physiology in unrepaired tetralogy of Fallot is determined by the severity and location of the pulmonic outflow obstruction and by the interaction of pulmonary and systemic vascular resistance across a nonrestrictive VSD. Because the pulmonary stenosis results in a relatively fixed pulmonary resistance, a drop in systemic vascular resistance as occurs with exercise is associated with increased right-to-left shunting and increasing cyanosis. A child who squats after running is attempting to reverse the process by increasing systemic vascular resistance by crouching with bent knees. Native pulmonary blood flow is typically insufficient. Unless a PDA has remained open, a cyanotic adult will typically have undergone a palliative procedure to increase pulmonary blood flow.

Examination of unrepaired patients reveals central cyanosis and clubbing. The right ventricular impulse is prominent. The second heart sound is single and represents the aortic closure sound with an absent or inconspicuous P_2. Typically, little or no systolic murmur is heard across the pulmonary valve because the more severe the obstruction, the more right-to-left shunting occurs and the less blood flows across a diminutive right ventricular outflow tract. A diastolic murmur of aortic insufficiency is often heard in adults. In the presence of a palliative systemic arterial to pulmonary artery shunt, the high-pressure gradient generates a loud continuous murmur. In a patient who has not undergone surgery, progressive infundibular stenosis and cyanosis occur. Before the advent of palliative surgery, mortality rates were 50% in the first few years of life, and survival past the third decade was unusual.

Complete surgical repair consists of patch closure of the VSD and relief of the right ventricular outflow tract obstruction. Adequate pulmonary blood flow is ensured by reconstruction of the distal pulmonary artery bed. Previous palliative shunts are usually taken down. Complete repair in childhood yields a 90 to 95% 10-year survival rate with good functional results, and 30-year survival rates may be as high as 85%. Total correction with low mortality and a favorable long-term follow-up is possible even in adulthood.

After repair, residual pulmonary stenosis, proximal or distal, with a right ventricular pressure greater than 50% of systemic occurs in up to 25% of patients. Some degree of pulmonary insufficiency is common, particularly if a patch has been inserted at the level of the pulmonary valve or if a pulmonary valvotomy has been performed. Residual VSDs can be found in up to 20% of patients. Patients may be asymptomatic or may have symptoms related to long-term complications after surgical repair. Symptoms can reflect residual right ventricular pressure or volume overload or arrhythmias at rest or with exercise. Angina can occur in a young patient if surgical repair has damaged an anomalous left anterior descending artery as it courses across the right ventricular outflow tract. In acyanotic adults, clubbing commonly regresses. A right ventricular impulse is often felt as a result of residual pulmonary insufficiency or stenosis. Typically, no functioning pulmonary valve is present, and hence the second heart sound is still single. A systolic murmur can represent residual pulmonary stenosis, residual VSD, or tricuspid insufficiency. A diastolic murmur can reflect aortic or pulmonary insufficiency. Ventricular arrhythmias are common after repair, with an incidence of sudden death as high as 5%.

The ECG in unrepaired tetralogy of Fallot shows right axis deviation, right atrial enlargement, and dominant right ventricular forces over the precordial leads. The most common finding after repair is complete right bundle branch block, which is seen in 80 to 90% of patients. The chest radiograph typically shows an upturned apex with a concave pulmonary artery segment giving the classic appearance of a boot-shaped heart. Figure 69-8 demonstrates the findings in an adult after repair. The apex is persistently upturned, although the pulmonary artery segment is no longer concave. Echocardiography can confirm the diagnosis and document intracardiac complications in repaired and unrepaired patients. Shunt patency can be determined by Doppler examination. Magnetic resonance imaging can accurately document stenosis in the distal pulmonary artery bed. Cardiac catheterization is reserved for patients in whom operative or reoperative treatment is contemplated or in whom the integrity of the coronary circulation needs to be verified.

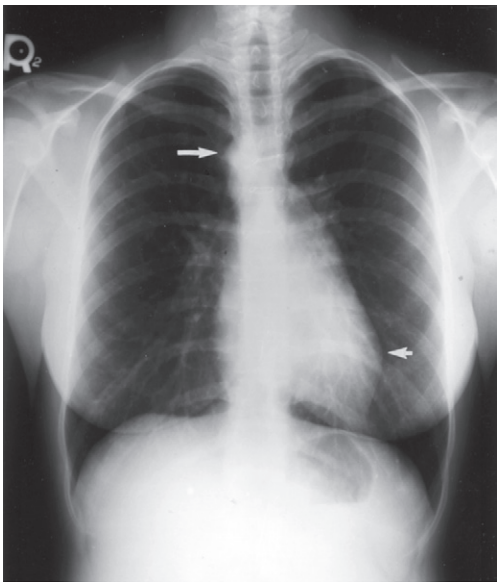

FIGURE 69-8. Chest radiograph of an adult after tetralogy of Fallot repair. A right aortic arch with rightward indentation of the trachea *(long arrow)* can be seen. The right ventricular apex remains upturned *(short arrow)*. Note the sternal wires consistent with intracardiac repair, clarifying the fullness of the pulmonary artery segment often seen after extensive enlargement of the right ventricular outflow tract.

Patients with a change in exercise tolerance, angina, or evidence of heart failure and those with symptomatic arrhythmias or syncope should be referred for complete evaluation. Surgical reintervention is generally considered when right ventricular pressure is more than two thirds as high as systemic pressure because of residual right ventricular outflow tract obstruction, free pulmonary regurgitation occurs with right ventricular dysfunction or sustained arrhythmias, or a residual VSD causes a significant shunt.

Complete Transposition of the Great Arteries

Complete transposition of the great arteries is the second most common cyanotic lesion, and surgically corrected adults are increasingly common. In simple transposition of the great arteries, the atria and ventricles are in their normal positions, but the aorta arises from the right ventricle, and the pulmonary artery arises from the left ventricle. When the aorta is anterior and rightward with respect to the pulmonary artery, as is most common, D-transposition is present. The native anatomy has the pulmonary and systemic circulations in parallel, with deoxygenated blood recirculating between the right side of the heart and the systemic circulation, whereas oxygenated blood recirculates from the left side of the heart to the lungs. The condition is incompatible with life unless a VSD, PDA, or ASD is present or an ASD is created; a hemodynamically significant VSD is present in 15% of cases. Subpulmonary obstruction of the left ventricular outflow tract occurs in 10 to 25% of cases.

The Senning or Mustard atrial baffle repairs, which were the first corrective procedures, redirect oxygenated blood from the left atrium to the right ventricle so that it may be ejected into the aorta while deoxygenated blood detours the right atrium and heads for the left ventricle and into the pulmonary artery. Although this operation results in acyanotic physiology, the right ventricle assumes a permanent position under the aorta and pumps against systemic pressures, a lifelong task for which it was not designed. When the subpulmonary obstruction is significant, the Rastelli procedure reroutes blood at the ventricular level by tunneling the left ventricle to the aorta inside the heart through a VSD. A conduit is then inserted outside the heart between

the left ventricle and aorta. More recently, the arterial switch operation transects the aorta and pulmonary artery above their respective valves and switches them to become realigned with their physiologic outflow tracts and appropriate ventricles. The proximal coronary arteries are translocated from the sinuses of the native aorta to the neoaorta (native pulmonary artery). In this operation, each ventricle reassumes the role that it was embryologically destined to fulfill.

If an adult patient is cyanotic and has a native intracardiac shunt or a palliative shunt, referral to an appropriate facility should be undertaken to explore the possibility of intracardiac repair. At present, adults with transposition of the great arteries most commonly have undergone an atrial baffle repair, with an expected 15-year survival rate of 75% and a 20-year survival rate of 70%. For patients with an atrial baffle procedure, symptoms include exercise intolerance, palpitations caused by bradyarrhythmias or atrial flutter, and right ventricular failure. The patient is typically acyanotic unless a baffle leak exists. The clinical findings are determined by the presence or absence of systemic right ventricular failure. On auscultation, the second heart sound is classically single. The ECG reveals sinus bradycardia, but nodal rhythms and heart block occur as the patient ages. The chest radiograph shows a variable degree of right ventricular enlargement. Echocardiography can be used to confirm the diagnosis and to explore related abnormalities. Cardiac catheterization is performed when an operation or reoperation is contemplated. Reoperation is performed in approximately 20% of patients for baffle-related complications, progressive left ventricular outflow tract stenosis, or severe tricuspid regurgitation.

Congenitally Corrected Transposition of the Great Arteries

In congenitally corrected transposition of the great arteries, the great arteries are transposed, the ventricles are inverted, but the atria remain in their normal position. The systemic circulation (left atrium, morphologic right ventricle, and aorta) and pulmonary circulation (right atrium, morphologic left ventricle, and pulmonary artery) are in series. The patient is therefore acyanotic unless an intracardiac shunt is also present. The right ventricle is aligned with the aorta and performs lifelong systemic work, which accounts in part for its eventual failure. Associated lesions include a VSD, pulmonary stenosis, and Ebstein's malformation of the left-sided tricuspid valve. Complete heart block develops at a rate of 2% per year. Patients with congenitally corrected transposition of the great arteries and no other associated defects can remain free of symptoms until the sixth decade, at which time significant atrioventricular valve regurgitation, failure of the right (systemic) ventricle, supraventricular arrhythmias, and heart block occur.

Right-Sided Ebstein's Anomaly

The septal and posterior cusps of the tricuspid valve are largely derived from the right ventricle as it liberates a layer of muscle that skirts away from the cavity to become valve tissue. When this process occurs abnormally, the posterior and septal cusps of the tricuspid valve remain tethered to the muscle and adhere to the right ventricular surface—hence the diagnostic hallmark of Ebstein's anomaly, apical displacement of the septal tricuspid leaflet.

In right-sided Ebstein's anomaly of the tricuspid valve, the right side of the heart consists of three anatomic components: the right atrium proper, the true right ventricle, and the atrialized portion of the right ventricle between the two. The displaced septal and posterior tricuspid leaflets lie between the atrialized right ventricle and the true right ventricle. In mild Ebstein's anomaly, the degree of tricuspid leaflet tethering is only mild, the anterior leaflet retains mobility, and the size of the true right ventricle is only mildly reduced. Severe Ebstein's anomaly is associated with severe tethering of the tricuspid leaflet tissue and a diminutive, hypocontractile true right ventricle. Functionally, the valve is regurgitant because it is unable to appose its three leaflets during ventricular contraction. Valvular regurgitation and asynchronous, abnormal right ventricular function cause the dilation and right-sided heart failure observed in the more severe forms of the lesion. The wide spectrum of severity of the anomaly is based on the degree of tricuspid leaflet tethering and the relative proportion of atrialized and true right ventricle. The most common associated cardiac defect, a secundum ASD or patent foramen ovale, is reported in more than 50% of patients. On physical examination, a clicking "sail sound" is heard as the second component of S_1 when tricuspid valve closure becomes loud and delayed.

The 12-lead ECG typically shows highly peaked P waves with a wide, often bizarre-looking QRS complex. Preexcitation occurs in 20% of patients; supraventricular tachyarrhythmias, atrial fibrillation, and atrial flutter occur in 30 to 40% of patients and constitute the most common findings in adolescents and adults with right-sided Ebstein's anomaly.

When patients of all ages are taken together, the predicted mortality is approximately 50% by the fourth or fifth decade. Complications include atrial arrhythmias due to severe right atrial enlargement and cyanosis caused by a right-to-left atrial shunt as tricuspid insufficiency increases and the right ventricle fails. Atrial arrhythmias, cyanosis, and the presence of an intra-atrial communication also increase the risk for stroke.

Intervention is considered when functional status or cyanosis worsens, significant atrial arrhythmias are documented, or a cerebrovascular accident occurs. Surgical options include replacement or repair of the tricuspid valve and closure of the ASD. The feasibility of tricuspid valvuloplasty depends on the size and mobility of the anterior tricuspid leaflet, which is used to construct a unicuspid right-sided valve.

Atrioventricular Canal Defect

Embryologic septation of the atrioventricular canal results in closure of the inferior portion of the interatrial septum and the superior portion of the interventricular septum. Septation is achieved with the growth of endocardial cushions, which also contribute to development of the mitral and tricuspid valves. Hence, the nomenclature *atrioventricular canal defect* or *endocardial cushion defect* is used to designate this group of anomalies.

A partial atrioventricular canal defect refers to an ostium primum ASD with a cleft mitral valve. The anomaly is manifested as a hemodynamic combination of an ASD with a variable degree of mitral regurgitation. The 12-lead ECG shows the typical findings of left axis deviation with a Q wave in leads I and aVL and a prolonged PR interval. The echocardiogram shows a defect in the inferior portion of the interatrial septum and a cleft mitral valve.

A complete atrioventricular canal defect is an uncommon defect consisting of a primum ASD, an inlet VSD that usually extends to the membranous interventricular septum, and a common atrioventricular valve. Adults who have not been operated on usually have Eisenmenger's syndrome unless concomitant pulmonary stenosis has protected the pulmonary vascular bed or the VSD has undergone spontaneous closure, in which case the physiologic consequences are similar to those of a partial atrioventricular canal.

Surgical repair of an atrioventricular defect consists of closing the interatrial or interventricular communication with reconstruction of the common atrioventricular valve or closure of the cleft in the mitral valve. An adult who has undergone repair may have significant residual regurgitation of the mitral or tricuspid valve. Even after surgery, acquired subaortic obstruction can occur in the long left ventricular outflow tract, which has a classic gooseneck deformity on cardiac angiography.

Univentricular Heart and Tricuspid Atresia

The terms *single ventricle, common ventricle*, and *univentricular heart* have been used interchangeably to describe the double-inlet ventricle, in which one ventricular chamber receives flow from both the tricuspid and mitral valves. In 75 to 90% of cases, the single ventricle is a morphologic left ventricle. Obstruction of one of the great arteries is common, and life expectancy is short without an operation. The patients most likely to survive to adulthood palliated or, rarely, without surgery have a single ventricle of the left morphologic type, with pulmonary stenosis protecting the pulmonary vascular bed.

In tricuspid atresia, no orifice is found between the right atrium and right ventricle, and an underdeveloped or hypoplastic right ventricle is present. The morphologic left ventricle is consistently normally developed and therefore becomes the single functional ventricle. Typically, blood flows into the right atrium, then through an obligatory ASD and to the left atrium, where it then proceeds to the left ventricle. Variable features include a VSD, the abnormal position of the great arteries, and the relative degree of pulmonary stenosis, all of which are used to classify tricuspid atresia. Without surgery, 50% of patients die in the first 6 months and 90% in the first decade.

Adult patients rarely have not been operated on. They may be acyanotic after the Fontan operation; if cyanotic and palliated, the patient may benefit from further palliation or may be eligible for the Fontan operation. With the Glenn shunt or the Fontan operation, a direct anastomosis is created between the systemic venous and pulmonary circulations. Venous blood flows passively from the systemic veins to the pulmonary circulation and returns oxygenated to a left-sided atrium and into the single functional ventricle, which then pumps oxygenated blood into the systemic circulation. The Glenn anastomosis diverts part of the systemic venous return to the lungs, whereas the Fontan procedure makes the patient acyanotic by diverting the entire systemic venous circulation to the pulmonary vascular bed. For optimal results,

a successful Fontan operation requires low pulmonary vascular resistance, preserved single ventricular function, and unobstructed anastomosis between the systemic veins and the pulmonary arteries. At 5-year follow-up, 80% or more of Fontan survivors are in New York Heart Association functional class I or II, with successful pregnancy reported in a small number of patients. When patients of all ages are considered together, 10-year survival rates vary from 60 to 70%. Late deaths are due to reoperation, arrhythmia, ventricular failure, and protein-losing enteropathy.

Vascular Malformations

AORTIC ARCH ANOMALIES

Vascular Rings and Other Arch Anomalies

One of the most frequent developmental errors of the aortic arch is an aberrant right subclavian artery originating distal to the left subclavian and coursing rightward behind the esophagus at the level of the third thoracic vertebrae. Although the finding is frequent, symptoms are uncommon. When symptoms occur, the term *dysphagia lusoria* has been used in reference to swallowing difficulties that result from esophageal compression. Abnormal development of the brachial arches and dorsal aorta can result in a variety of anomalies that lead to the formation of vascular rings around the trachea and esophagus. The outcome is often benign, but symptoms of respiratory compromise or dysphagia warrant surgery. When the left pulmonary artery arises from the right and passes leftward between the trachea and esophagus, a pulmonary artery sling occurs. Symptoms of tracheal compression warrant correction.

A right aortic arch occurs when the aortic arch courses toward the right instead of the left. Mirror-image branching is the most common anatomic variant. In most cases, this anomaly coexists with other congenital lesions, notably tetralogy of Fallot.

ANOMALOUS VENOUS CONNECTIONS

Anomalies of Systemic Venous Return

A persistent left superior vena cava can be fortuitously diagnosed on chest radiography or on echocardiography. Its clinical relevance depends on development of the coronary sinus. If the coronary sinus is normally formed, typically the left superior vena cava drains into the right atrium through the coronary sinus. If the coronary sinus is not normally developed, the persistent left superior vena cava drains into the left atrium, and cyanosis results from the obligatory right-to-left shunt. The latter commonly occurs with an ASD or a complex cardiac anomaly.

Venous return above the renal veins can be abnormal with inferior vena cava interruption and azygos or hemiazygos continuation. In the former, inferior vena cava flow above the renal veins continues into the azygos vein, which courses normally up the right of the spine to empty into the junction between the superior vena cava and right atrium. In a less common anatomic arrangement, the caval flow empties into a hemiazygos vein, which empties into a persistent left superior vena cava. The finding rarely occurs in isolation but can be seen in patients with associated simple or complex malformations.

Anomalies of Pulmonary Venous Return

In partial anomalous pulmonary venous return, one or more, but not all four, pulmonary veins are not connected to the left atrium. The most common pattern has the right pulmonary veins connected to the superior vena cava, usually with a sinus venosus ASD. Anomalous connection of the right pulmonary veins to the inferior vena cava results in a chest radiographic shadow that resembles a Turkish sword, hence the designation *scimitar syndrome*. Associated anomalies include hypoplasia of the right lung, anomalies of the bronchial system, hypoplasia of the right pulmonary artery, and dextroposition of the heart. Partial anomalous pulmonary venous return results in a left-to-right shunt physiology similar to that of an ASD.

In total anomalous pulmonary venous return, all the pulmonary veins connect abnormally to either the right atrium or one of the systemic veins above or below the diaphragm. Concurrent obstruction of the pulmonary veins is present when drainage occurs below the diaphragm and variable when drainage occurs above it. An ASD is essential to sustain life. One third of cases occur with major complex cardiac malformations.

In cor triatriatum, the pulmonary veins drain into an accessory chamber that is usually connected to the left atrium through an opening of variable size. The hemodynamic consequences are determined by the size of this opening and are similar to those of mitral stenosis. If symptoms of pulmonary venous hypertension occur, surgical treatment is indicated.

CARDIAC MALPOSITIONS

The normal heart is left sided and hence the designation *levocardia*. Cardiac malpositions are defined in terms of the intrathoracic position of the heart in relation to the position of the viscera (visceral situs), which are usually concordant with the position of the atria. That is, when the liver is on the right and the stomach is on the left, the atrium receiving systemic venous blood (right atrium) is right sided and the atrium receiving pulmonary venous blood (left atrium) is left sided. Asplenia and polysplenia syndromes are associated with a variety of complex cardiovascular malformations.

Dextrocardia and Mesocardia

In dextrocardia, the heart is on the right side of the thorax with or without situs inversus. When the heart is right sided with inverted atria, the stomach is right sided, and the liver is left sided, the combination is dextrocardia with situs inversus. In this arrangement, also called *mirror-image dextrocardia,* the ventricles are inverted, but so are the viscera and therefore the atria. The heart usually functions normally, and the diagnosis is often fortuitous. The heart sounds are louder on the right side of the chest, and the liver is palpable on the left. The chest radiograph shows a right-sided cardiac apex with a lower left hemidiaphragm and a right-sided stomach bubble. The ECG shows an inverted P and T wave in lead I with a negative QRS deflection and a reverse pattern between aVR and aVL. A mirror-image progression is seen from V_1 to a right-sided V_6 lead. An echocardiogram should be performed to ensure that intracardiac anatomy is normal.

When dextrocardia with situs solitus occurs, the ventricles are inverted but not the viscera and therefore not the atria. Associated severe cardiac malformations are typical.

In mesocardia, the heart is centrally located in the chest with normal atrial and visceral anatomy. The apex is central or rightward displaced on the chest radiograph. Typically, no associated cardiac malformations are present.

SPECIALIZED ISSUES

Endocarditis Prophylaxis

Prolonged survival of patients with complex congenital heart disease has resulted in a population at increased risk for infective endocarditis (Chapter 76). Adults with congenital heart disease should be informed about the risks of endocarditis. Any unexplained fever requires blood cultures to be drawn before antibiotics are initiated. Thorough transthoracic and transesophageal echocardiograms should be performed to assess the presence of vegetations. If infection of prosthetic material is suspected, early consultation with a specialist who has access to a congenital heart surgeon should be initiated because of the potential for rapid deterioration.

Antibiotic prophylaxis before dental procedures that involve manipulation of the gingiva, periapical regions of the teeth, or mucosal tissue is indicated in patients with previous infective endocarditis; unrepaired cyanotic lesions; palliative shunts or conduits; prosthetic valves or prosthetic materials used for valve repair; repaired congenital heart disease with prosthetic material or transcatheter device within 6 months of intervention; and repaired congenital heart disease with residual lesions at or adjacent to the site of a prosthetic patch or device (Chapter 76). It is also reasonable to consider prophylaxis against endocarditis before vaginal delivery at the time of membrane rupture in such patients. Prophylaxis is not indicated for nondental procedures in the absence of active infection.

Exercise

The goal of exercise evaluation is to assess the functional results of therapeutic interventions and to provide guidelines for exercise prescriptions. Patients with residual hemodynamic lesions or unrepaired congenital cardiac anomalies should be evaluated on an annual basis with a physical examination, an ECG, and a cardiac ultrasonographic examination if indicated. Pertinent additional tests may include Holter monitoring and exercise testing. Attention should be directed to the detection of pulmonary hypertension, arrhythmias, myocardial dysfunction, and symptoms such as exercise-induced dizziness, syncope, dyspnea, or chest pain.

A series of exercise guidelines have been proposed for major groups of congenital heart defects (Table 69-2). Patients beyond 6 months after repair of a single shunt lesion without pulmonary hypertension, arrhythmias, or evidence of myocardial dysfunction can participate in all sports. With

TABLE 69-2 EXERCISE RECOMMENDATIONS IN ADULTS WITH CONGENITAL HEART DISEASE

CONDITION	UNRESTRICTED	LOW-MODERATE INTENSITY*	PROHIBITED
ASD†	No PHT; no arrhythmia; normal ventricular function	PA pressure >40 mm Hg *with* normal ETT; no arrhythmia	Eisenmenger's
VSD†	Small; no PHT; no arrhythmia; normal ventricular function	Moderate VSD	Eisenmenger's
PDA†	Small; no PHT; no arrhythmia; normal ventricular function	PA pressure >40 mm Hg *with* normal ETT; no arrhythmia	Eisenmenger's
Coarctation‡	Gradient ≤20 mm Hg arm to leg; normal BP at rest and exercise	Gradient ≥20 mm Hg arm to leg *with* normal BP and normal ETT	Gradient ≥50 mm Hg arm to leg *or* aortic aneurysm
PS	Gradient <50 mm Hg; no arrhythmia; normal ventricular function	Gradient ≥50 mm Hg	Gradient ≥70 mm Hg *or* ventricular arrhythmia
AS	Gradient ≤20 mm Hg; normal ECG; normal ETT; asymptomatic	Gradient >20 mm Hg *with* normal ECG, normal ETT; asymptomatic	Gradient ≥50 mm Hg *or* ventricular arrhythmia
TOF after repair	Normal RV pressure; no shunt; no arrhythmia	Increased RV pressure *or* moderate PR *or* SVT	RV pressure ≥65% systemic *or* ventricular arrhythmia on ETT *or* severe PR
Mustard or Senning		No cardiomegaly, arrhythmia, or syncope; normal ETT	Cardiomegaly *or* arrhythmia at rest or exercise
c-TGA unoperated	No cardiomegaly; mild TR; no arrhythmia; normal ETT	Moderate RV dysfunction, moderate TR; no arrhythmia	Severe TR *or* uncontrolled arrhythmia
Ebstein's	Mild Ebstein's; no arrhythmia; operated with mild TR	Moderate TR *with* no arrhythmia	Severe Ebstein's *or* uncontrolled arrhythmia
Fontan		Normal O_2 saturation *with* near-normal ETT and ventricular function	Moderate-severe MR or TR *or* uncontrolled arrhythmia

*Based on peak dynamic and static components of exercise during competition for individual sports (see credit line).
†Unoperated or 6 months after surgery.
‡Unoperated or 1 year after surgery.
AS = aortic stenosis; ASD = atrial septal defect; BP = blood pressure; c-TGA = corrected transposition of the great arteries; ECG = electrocardiogram; ETT = exercise tolerance test; MR = mitral regurgitation; PA = pulmonary artery; PDA = patent ductus arteriosus; PHT = pulmonary hypertension; PR = pulmonary regurgitation; PS = pulmonary stenosis; RV = right ventricle; SVT = supraventricular tachyarrhythmia; TOF = tetralogy of Fallot; TR = tricuspid regurgitation; VSD = ventricular septal defect.
Based on guidelines recommended in Graham TP, Bricker TJ, James FW, et al. 26th Bethesda conference: recommendations for determining eligibility for competition in athletes with cardiovascular abnormalities. residual shunts, if the peak pulmonary artery pressure is less than 40 mm Hg in the absence of ventricular dysfunction or significant arrhythmias, patients can enjoy a free range of activity. Patients with elevated pulmonary vascular resistance are at risk of sudden death during intense exercise; although most self-limit their activity, participation in competitive sports is contraindicated. Patients with aortic and pulmonary stenosis should be counseled as recommended earlier, according to gradient severity. For patients with uncomplicated aortic coarctation, athletic participation is permitted if the arm-leg blood pressure gradient is 20 mm Hg or less at rest and the peak systolic blood pressure during exercise is normal. For patients after tetralogy of Fallot repair, repair of transposition of the great arteries, and the Fontan operation, exercise recommendations vary according to residual ventricular function and the presence or absence of arrhythmias.

ATHEROSCLEROSIS, THROMBOSIS, AND VASCULAR BIOLOGY

GÖRAN K. HANSSON AND ANDERS HAMSTEN

Atherosclerosis is the underlying cause of most cases of myocardial infarction, ischemic stroke, and peripheral arterial disease. It is also a major cause of chronic heart failure and vascular dementia. Atherosclerosis, which is a chronic inflammatory response to the accumulation of lipid in the artery wall, initially is typically characterized by clinically silent intimal plaques in arteries for years and even decades. Fissuring or erosion of atherosclerotic plaques triggers the formation of a thrombus that accumulates over seconds to minutes to cause acute ischemia of the end organ. This ischemia, in turn, results in the dramatic clinical manifestations. It is estimated that approximately 90% of cases of myocardial infarction (Chapter 73), 60% of strokes (Chapter 414), most cases of heart failure (Chapter 58), and up to one third of all cases of dementia (Chapter 409) are due to atherosclerosis.

RISK FACTORS FOR ATHEROSCLEROSIS

The major risk factors that promote the development of atherosclerosis are an elevated low-density lipoprotein (LDL) cholesterol level, a low high-density lipoprotein (HDL) level (Chapter 213), cigarette smoking, type 2 diabetes (Chapter 237), hypertension (Chapter 67), and a family history of coronary heart disease, ischemic stroke, or peripheral arterial disease. Other conditions thought to increase the risk of atherosclerotic disease include abdominal obesity, hypertriglyceridemia, high plasma levels of lipoprotein (a) [Lp(a)], hyperfibrinogenemia, the inflammatory marker C-reactive protein (CRP), and physical inactivity. Other emerging risk factors, including uric acid, psychosocial stress, encompassing external stressors (e.g., job stress,

life events, and financial problems), and reactions to stress (e.g., depression [Chapter 404], anxiety, psychosocial distress, and sleep disturbances [Chapter 100]), also appear to contribute. Elevation of plasma total homocysteine is also associated with increased cardiovascular risk, but it is possible that chronic renal dysfunction accounts for at least some of the vascular pathology seen in hyperhomocysteinemia.

An atherogenic lipoprotein phenotype has been defined as the presence of a predominance of small, dense LDL particles, hypertriglyceridemia, and low plasma HDL cholesterol concentration. This lipoprotein phenotype, which is strongly linked to obesity, insulin resistance, hypertension, and abnormalities in postprandial lipoprotein metabolism, is similar to the so-called metabolic syndrome, in that both are associated with a cluster of atherogenic and thrombotic risk factors—raised plasma levels of fibrinogen, plasminogen activator inhibitor-1 (PAI-1), and coagulation factor VII, as well as platelet hyperactivity.

FORMATION OF ATHEROSCLEROTIC LESIONS

Atherosclerosis is thought to be initiated when apolipoprotein B (apoB100)-containing lipoproteins, predominantly LDL, accumulate in the vascular intima, the innermost layer of the artery (Fig. 70-1). Small dense LDL particles are particularly prone to accumulate in the intima, where they associate with proteoglycans of the extracellular matrix. Lipoprotein lipase produced locally in the artery can bridge LDL to the extracellular matrix, and phospholipase and sphingomyelinase actions may contribute to the entrapment of LDL. Once trapped in the artery wall, LDL particles can be attacked by enzymes such as myeloperoxidase and NADPH oxidases; they may also be modified by nonenzymatic oxidation. During oxidative modification of LDL, certain biologically active oxidized phospholipid species are released and activate endothelial cells and macrophages. Such activation leads to production of chemokines and expression of leukocyte adhesion molecules that together instigate recruitment of monocytes and T cells to the intima. Local growth factors induce recruited monocytes to develop into macrophages.

In the intima, macrophages take up oxidized LDL through their scavenger receptors, start to accumulate cholesterol, and are gradually transformed into cholesterol-laden foam cells. Some macrophages in the intima produce proinflammatory mediators, including tumor necrosis factor (TNF), interleukin-1 (IL-1), proinflammatory eicosanoids, radical oxygen and nitrogen species, and prothrombotic factors.

T cells that are stimulated to enter the intima may recognize antigens presented by macrophages. These antigens include components of LDL, other endogenous proteins, and possibly microbial antigens. Activated intimal T cells produce T_H1-type cytokines, such as interferon-γ, TNF, and lymphotoxin, all of which are strongly proatherogenic. With the entry and activation of T cells and macrophages, the accumulation of lipid in the intima leads to the chronic inflammatory disease process of atherosclerosis.

Although adaptive immunity is believed to exert a net proatherogenic effect, antiatherogenic immune responses against LDL involve activation of regulatory T cells, secretion of the anti-inflammatory cytokines IL-10 and transforming growth factor-β, and production of anti-LDL antibodies. In addition to T cells and macrophages, atheroma formation is also stimulated by dendritic cells that take up and present antigen and by mast cells that secrete enzymes and bioactive mediators.

Triglyceride-rich lipoprotein remnant particles, which have adverse effects on endothelial function, penetrate into the subendothelial space of normal intima and atherosclerotic plaques, where they are retained. The LDL-like Lp(a) lipoprotein particle exerts both proatherogenic and prothrombotic actions.

Conversely, antiatherogenic HDL particles counteract the formation of atherosclerotic lesions. These particles mediate cholesterol efflux from cells by acting as acceptors of cholesterol delivered from specific transport proteins termed adenosine triphosphate–binding cassette (ABC) A1 and G1. In addition, HDL particles carry anti-inflammatory and antioxidant proteins.

GROWTH, DEATH, AND THE PROGRESSION OF DISEASE

Early atherosclerotic lesions grow by the accumulation of cholesterol; infiltration of inflammatory cells; the activation, proliferation, and death of such cells; and the gradual development of a core that contains cellular debris and lipids. As a tissue response to this process, smooth muscle cells form a

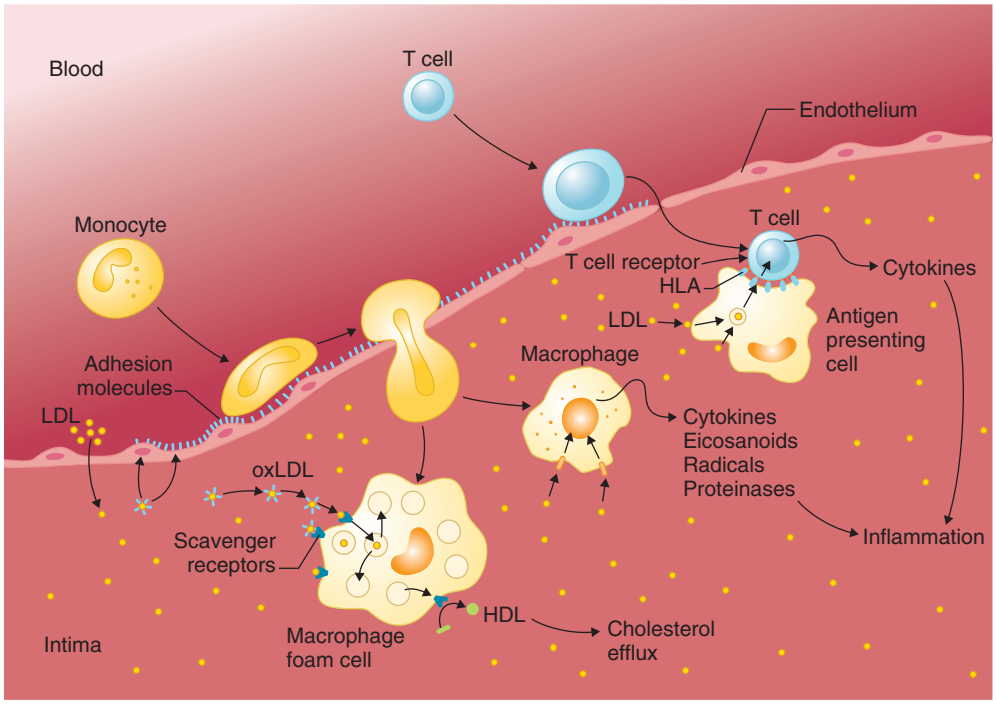

FIGURE 70-1. Formation of atherosclerotic plaques. Low-density lipoproteins (LDL) transit from the blood stream to the arterial intima and accumulate under the endothelial cell layer. LDL particles undergo oxidative modification in the intima (denoted by spikes on LDL particles), thereby leading to their binding to scavenger receptors and uptake by macrophages, which accumulate cholesterol and develop into foam cells. Cholesterol efflux to high-density lipoprotein (HDL) counteracts the tendency to foam cell formation. Molecules released from oxidatively modified LDL activate endothelial cells to express leukocyte adhesion molecules that promote binding of monocytes and T cells to the surface of the artery. Chemokines stimulate monocytes and T cells to migrate into the intima, where the monocytes differentiate into macrophages. Although many macrophages develop into foam cells, some are activated, thereby leading to release of proinflammatory cytokines, eicosanoids, radicals, and proteases. T cells entering through similar mechanisms as monocytes can recognize local antigens, such as LDL components, which are presented to them by antigen-presenting cells (dendritic cells and macrophages) that express HLA molecules. T cells whose receptors can recognize local antigens are activated, thereby leading to release of a host of cytokines that can activate macrophages and enhance vascular inflammation. (Modified from Hansson GK. Inflammation, atherosclerosis, and coronary artery disease. *N Engl J Med.* 2005;352:1685-1695.)

subendothelial cap structure dominated by collagen fibers that are produced by these cells. The collagen cap mechanically stabilizes the plaque and creates a barrier between the hemostatic components of the blood and the thrombogenic material of the plaque. Until the plaque is far advanced, compensatory enlargement ("remodeling") of the arterial wall prevents it from significantly protruding into the arterial lumen. However, after the plaque enlarges to a sufficient size, the lumen narrows as the plaque grows, and the artery remodels inward, often accompanied by exaggerated or paradoxical vasoconstriction.

PLAQUE ACTIVATION, THROMBOSIS, AND INFARCTION

The atherosclerotic process typically is silent for months, years, and even decades, and it may never result in clinical manifestations. However, if and when the plaque's surface is damaged, thrombotic occlusion of the artery may ensue. Surface continuity may be damaged by fissuring (so-called plaque rupture, observed in 60 to 80% of cases of acute coronary syndrome) or surface erosion (present in 20 to 40% of cases with coronary thrombosis, especially women and young victims of sudden coronary death). Fissures and erosions stimulate atherothrombosis by exposing thrombogenic material inside the plaque, such as phospholipids, tissue factor, and matrix molecules, to platelets and coagulation factors (Fig. 70-2). Platelet aggregates formed on exposed surfaces are stabilized by a fibrin network. Tissue factor, expressed in vascular smooth muscle cells and macrophages of the atherosclerotic plaque, is the primary cellular initiator of the blood coagulation cascade that leads to fibrin formation. Atherothrombi expand rapidly and can fill the lumen within minutes, thereby leading to ischemia and infarction.

The cause of plaque rupture remains unclear. Clinical studies have associated ischemic atherothrombotic events such as myocardial infarction (Chapter 73) and stroke (Chapter 414) with infections and stressful events. Histopathologic analysis shows increased inflammation with infiltration of macrophages, activated T cells, dendritic cells, and mast cells, as well as reduced thickness of the fibrous cap and increased neovascularity at sites of plaque rupture and thrombosis. Ruptured plaques also tend to have a large necrotic lipid core. In contrast, plaques underlying erosions do not have a large lipid core and show less inflammation compared with ruptured plaques.

Several members of the matrix metalloproteinase and cysteine proteinase families are found at sites of plaque rupture and have been implicated in plaque rupture, but their effects on the composition and size of lesions are complex. Apoptosis of inflammatory cells and smooth muscle cells, which are contained in the plaque and are likely to contribute to plaque rupture, may be initiated by activation of the death receptor group of the TNF receptor superfamily. Apoptotic macrophages release tissue factor, and a reduced number of smooth muscle cells leads to matrix depletion and destabilizes the plaque. In addition, activated T cells inhibit matrix synthesis by production of interferon-γ, a cytokine that inhibits collagen fiber formation as well as proliferation of smooth muscle cells.

Although a range of factors contribute to atherothrombosis, the precise sequence of events is not yet known. Similarly, the precise role of the activation of coagulation pathways and platelets, combined with the inhibition of fibrinolysis, remains to be defined. Importantly, plaque rupture frequently occurs without clinical manifestations, possibly reflecting variation in the thrombotic response depending on the thrombogenicity of exposed plaque constituents, local hemorrheology, shear-induced platelet activation, systemic clotting activity, fibrinolytic function, and the sensitivity of the end organ to ischemia.

PRINCIPLES OF ANTIATHEROSCLEROTIC THERAPY

Current treatment of atherosclerosis aims at controlling risk factors and maintaining perfusion in affected arteries. However, progress in understanding the pathogenesis of atherosclerosis is expected to result in more direct approaches. To date, firmly established interventions include smoking cessation, dietary and pharmacologic reduction of LDL cholesterol (Chapter 213), and management of blood pressure (Chapter 67). Available data also strongly support intervention directed toward hyperglycemia (Chapter 237), low HDL cholesterol levels (Chapter 213), hypertriglyceridemia (Chapter 213), obesity (Chapter 227), and physical inactivity (Chapter 15). Statins clearly reduce atherosclerotic lesions and inhibit their progression. Statins also can prevent nitroglycerin-induced endothelial dysfunction and nitrate tolerance. Aspirin and other inhibitors of platelet aggregation, β-adrenergic receptor blockers, and angiotensin-converting enzyme inhibitors or angiotensin II antagonists are also part of the routine secondary prevention of coronary heart disease (Chapter 71). Inhibitors of platelet aggregation are widely used for secondary prevention of atherosclerotic cardiovascular disease. Aspirin inhibits formation of proaggregatory prostaglandins, whereas other inhibitors of platelet aggregation modulate

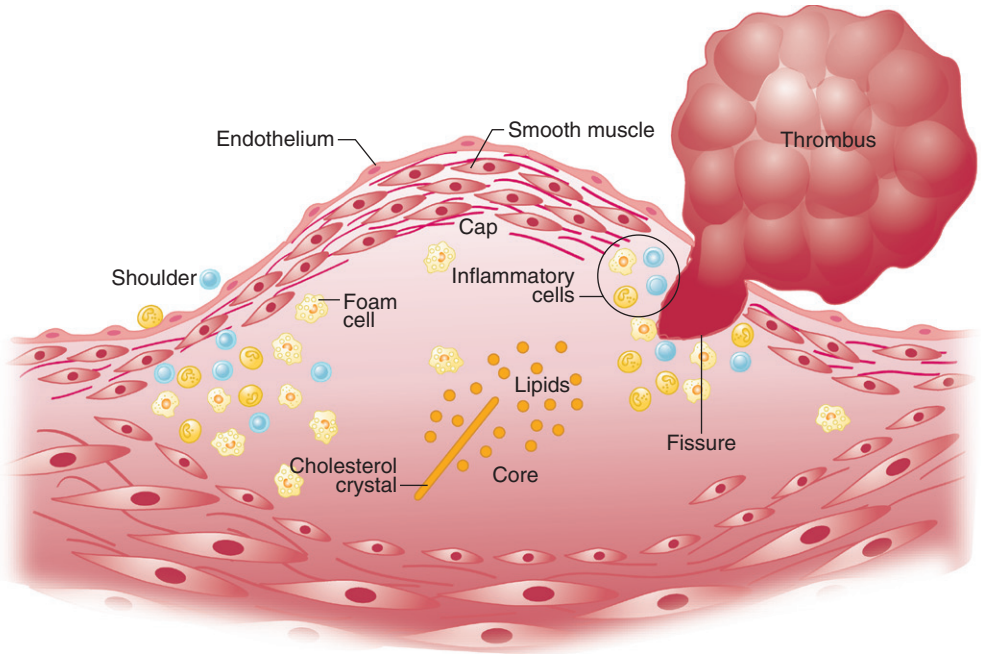

FIGURE 70-2. Plaque rupture and atherothrombosis. The advanced atherosclerotic plaque has a central core with lipids, especially cholesterol, live and dead cells, necrotic material from dead foam cells, and calcium salts. The plaque is overlaid by a fibrous cap that consists of smooth muscle cells and collagen (produced by the muscle cells) and covered by an intact layer of endothelial cells. Inflammatory cells (macrophages, T cells, mast cells, dendritic cells, and occasional B cells) are interspersed with these components and are particularly abundant in the shoulder regions of plaques, where fissures (also called ruptures) may expose thrombogenic core material (e.g., lipids, collagen, tissue factor) to blood components. This event triggers platelet aggregation and humoral coagulation, thereby leading to thrombus formation at the site of fissuring. Thrombi may expand locally to obstruct blood flow or they may detach to cause embolization. (Modified from Hansson GK. Inflammation, atherosclerosis, and coronary artery disease. *N Engl J Med.* 2005;352:1685-1695.)

expression of platelet adhesion molecules. Nitroglycerin and similar compounds that mimic the action of endogenous nitric oxide remain the most important vasodilators used in secondary prevention (Chapter 71). In one preliminary trial, eicosapentaenoic acid reduced coronary events for 4 to 6 years after treatment.[5]

FUTURE DIRECTIONS

Novel therapeutic opportunities that are currently being considered include new targets for lipid-lowering treatment, use of new immunosuppressing and anti-inflammatory compounds, and vaccination with disease-related antigens. Investigational agents targeting atherogenic lipoproteins include inhibitors of squalene synthase, microsomal triglyceride transfer protein, proprotein convertase subtilisin kexin type 9 (PCSK9), and antisense oligonucleotides to apoB. Compounds targeting HDL include liver X receptor (LXR) agonists, inhibitors of endothelial lipase, and apoA-I mimetic peptides. Statins (Chapter 213) have an array of beneficial actions that are independent of LDL cholesterol reduction, including attenuation of inflammation and inhibition of antigen presentation. Besides their beneficial effects on lipid and blood glucose levels, peroxisome proliferator-activated receptor (PPAR) agonists (Chapter 237) exhibit direct antiatherosclerotic effects in experimental studies.

Members of the TNF superfamily of proinflammatory proteins, eicosanoids, and cell surface proteins promoting antigen-specific T-cell activation are particularly promising targets of anti-inflammatory therapy, whereas stimulation of anti-inflammatory signaling pathways represents a different potential antiatherosclerotic therapy. Inhibition of secreted and lipoprotein-associated phospholipase A_2 is already being examined in clinical trials. Similarly, vaccination against immunogenic epitopes in the protein and lipid moieties of LDL may induce anti-inflammatory regulatory immunity and reduce LDL uptake in cells of the atherosclerotic lesion.

ANGINA PECTORIS AND STABLE ISCHEMIC HEART DISEASE

WILLIAM E. BODEN

DEFINITION

Ischemic heart disease is most commonly caused by obstruction or stenosis of one or more of the coronary arteries by atheromatous plaque (Chapter 70). Obstruction can result in myocardial ischemia and infarction (Chapters 72 and 73) with associated symptoms of angina, ischemia, myocardial remodeling, heart failure (Chapter 58), arrhythmic complications (Chapters 63, 64, 65), and ultimately death.

Angina pectoris is generally a consequence of a supply-demand imbalance between an activity that increases cardiac workload or "demand," thereby resulting in an increase in heart rate, blood pressure, or both, and the inability of the narrowed epicardial coronary arteries (Chapter 57) to augment antegrade flow or "supply" in response to this increase in demand. Such an imbalance classically results in chest discomfort (Chapter 50) of varying intensity and duration. Angina pectoris is generally defined as a discomfort in the chest or adjacent areas caused by myocardial ischemia. Often, angina is described incorrectly as "chest pain." The term *angina*, however, derives from a neologism of two Latin words, "angor animi," which literally translates into "fear of life being extinguished ('from the breast')," according to Heberden's original description in 1768. Had Heberden been trying to convey the term for chest pain, he would more likely have used the Latin term *dolor pectoris*.

Grading of Angina Pectoris

The Canadian Cardiovascular Society (CCS) angina grading scale is a widely used four-point ordinal scale that classifies angina pectoris from mild (class I: angina occurring only during strenuous or prolonged physical activity) to severe (class IV: inability to perform any activity without angina, or angina at rest) and includes the full spectrum of angina from chronic stable to unstable (see Table 50-5 in Chapter 50). Operationally, the CCS angina scale permits clinicians to categorize patients as mild or stable (generally CCS classes I and II) versus severe or unstable (typically CCS classes III and IV). Other grading systems include a specific activity scale, which is based on the metabolic cost of specific activities, and an anginal score, which integrates the clinical features and tempo of angina with electrocardiographic (ECG) changes and offers independent prognostic information beyond that provided by age, gender, ventricular function, and coronary anatomy.

EPIDEMIOLOGY

It is currently estimated that 17,600,000 adults in the United States have heart disease, 10,200,000 of whom have angina pectoris and 8,500,000 of whom have had acute myocardial infarction (MI). Approximately 785,000 Americans will experience a new ischemic heart disease event annually, and about 470,000 will have a recurrent event. In 2006, ischemic heart disease accounted for 52% of all deaths caused by cardiovascular disease and was the single most frequent cause of death in American men and women, resulting in more than one in every six deaths. The economic burden of ischemic heart disease in the United States in 2010 has been estimated at $177.1 billion. Despite the sustained decline in age-specific case-fatality rates from coronary artery disease over the past several decades, ischemic heart disease is now the leading cause of death worldwide, and it is expected that this rate of rise will continue to accelerate over the coming decade as a consequence of the epidemic rise in obesity (Chapter 227), type 2 diabetes (Chapter 237), and the metabolic syndrome, which may give rise to an increasing risk of developing premature coronary artery disease in younger generations. The World Health Organization has projected that, over the next decade, the global number of deaths from coronary artery disease will increase by 46% from 7.6 million in 2005 to 11.1 million in 2020. An estimated 8 million patients come to emergency departments annually for chest pain, and approximately 1.5 million of them are hospitalized with the acute coronary syndrome (ACS; Chapter 72). Although women may have typical angina less frequently than men, more women than men in the United States die annually of ischemic heart disease or its complications, and, overall, ischemic heart disease is the most common cause of death in women.

PATHOBIOLOGY

Angina is the most frequent clinical expression of myocardial ischemia. Ischemia, which rapidly develops when a mismatch arises between myocardial oxygen needs and myocardial oxygen supply, can manifest clinically in many different ways besides angina, from no symptoms (e.g., silent ischemia) to unstable angina, MI, or sudden cardiac death. It may remain stable for many years in selected patients or may be rapidly progressive with an abrupt change in frequency and tempo over days to weeks. Conversely, atherosclerosis, which is the most common cause of myocardial ischemia, may evolve for years without any manifestations of ischemia.

In contrast to the inherent pathogenetic complexity mediated by differing mechanisms associated with abrupt plaque rupture, fissuring, or erosion in patients with ACS (Chapters 70 and 72), the pathogenesis of chronic stable

angina is, by comparison, seemingly less complicated and heterogeneous because it fundamentally involves a myocardial supply-demand mismatch. In most patients with stable ischemic heart disease, the process of atherosclerosis involves a fundamentally different histopathology (small lipid core with a thick or very thick fibrous cap and a low proclivity to rupture) compared with ACS or unstable angina, in which the principal histopathologic picture is that of a large lipid core subtended by a thinned, inflamed cap, which harbors the high-risk or vulnerable plaque with a high proclivity for rupture (Chapter 70).

Two major pathogenetic mechanisms may result in myocardial ischemia and angina in the chronic setting: so-called demand angina, which is caused by an increase in myocardial oxygen requirements and workload, and supply angina, which is caused by diminished oxygen delivery to myocardial tissue. Demand angina is a consequence of the increased myocardial oxygen (O_2) requirements that occur with increased physical activity, emotion, or stress. In a patient with chronic, restricted O_2 delivery owing to atherosclerotic narrowing of a coronary artery, this increased demand may precipitate angina. Other extracardiac precipitants of angina include the excessive metabolic demands imposed by fever, thyrotoxicosis (Chapter 233), severe anemia (Chapter 161) from blood loss, tachycardia from any cause (Chapters 62, 63, 64), and hypoglycemia (Chapter 238).

By contrast, supply angina may occur in patients with either unstable angina (Chapter 72) or chronic stable angina by transient reductions in myocardial O_2 delivery as a consequence of coronary vasoconstriction with resulting dynamic coronary stenosis. In the presence of coronary luminal narrowing due to atherosclerosis, superimposed platelet thrombi and leukocytes may elaborate vasoconstrictor substances, such as serotonin and thromboxane A_2, whereas endothelial damage in diseased coronary arteries may decrease production of vasodilator substances such as nitric oxide and adenosine. The result is an abnormal vasoconstrictor response to exercise and other stimuli, such as exogenously administered adenosine or the paradoxical vasoconstrictor response to the typical flow-mediated reactive hyperemia associated with brachial artery compression. In some clinical settings, patients who have normal coronary arteries or non-flow-limiting stenoses may exhibit dynamic obstruction alone, which can cause myocardial ischemia and result in angina at rest (Prinzmetal's [variant] angina). Conversely, in patients with severe fixed obstruction to coronary blood flow, only a minor increase in dynamic obstruction can reduce blood flow below a critical level and cause myocardial ischemia.

The pathophysiologic basis for angina and ischemia in patients with stable ischemic heart disease has important implications for the selection of antiischemic agents. The greater the contribution from increased myocardial O_2 requirements to the imbalance between supply and demand, the greater the likelihood that agents such as β-blockers or heart rate–lowering calcium antagonists will provide clinical benefit, whereas nitrates and calcium antagonists with more potent vasodilatory properties (particularly the dihydropyridines) will be more beneficial to alleviate angina and ischemia mediated by coronary vasoconstriction.

Although the most common cause of ischemic heart disease is atherosclerotic narrowing of the epicardial coronary arteries resulting in flow-limiting obstruction to blood flow, obstructive coronary artery disease may also have nonatherosclerotic causes, such as congenital abnormalities of the coronary arteries (Chapter 69), vasospasm, myocardial bridging, coronary arteritis in association with systemic vasculitides (Chapter 278), and radiation-induced coronary disease (Chapter 19). Myocardial ischemia and angina pectoris may also occur in the absence of obstructive coronary artery disease, as in the case of aortic valve disease (Chapter 75), hypertrophic cardiomyopathy (Chapter 60), and idiopathic dilated cardiomyopathy. Moreover, ischemic heart disease may coexist with these other forms of heart disease.

CLINICAL MANIFESTATIONS

History

It is important to recognize that there are many causes of chest pain (see Table 50-2 in Chapter 50), that angina-like chest pain may not represent ischemic heart disease (Table 71-1), that ischemic heart disease causes symptoms other than anginal pain (Table 71-2), and that nonatherosclerotic coronary artery abnormalities may cause ischemic chest pain (Table 71-3).

Angina pectoris has four cardinal clinical features: the character of the discomfort, its site and distribution, its provocation, and its duration. The character of anginal discomfort is typically described as a pressure sensation that conveys a feeling of strangling and anxiety (Chapter 50). Other adjectives frequently used to describe this discomfort include heavy, squeezing, constricting, viselike, suffocating, and, at times, crushing. In some patients, the quality of the sensation is more vague and atypical (often in women and elderly patients), and these patients may describe the discomfort as a burning sensation in the mid-epigastrium or as an uncomfortable, numb sensation. Anginal equivalents (i.e., symptoms of myocardial ischemia other than angina), such as dyspnea, fatigue, lightheadedness or dizziness, and gastric eructations, may likewise be described.

The site and distribution of anginal discomfort are predominantly midsternal or retrosternal but can be precordial. Radiation is common, usually to the left neck and shoulder and down the ulnar surface of the left arm; the right arm and the outer surfaces of both arms may also be involved. Discomfort that radiates to the jaw may be confused with dental pain. Epigastric discomfort alone or in association with chest pressure may occur. Provocation of angina is classically caused by physical exertion or activity, emotional stress, exposure to the cold, sexual intercourse, or eating a large meal. Angina that occurs at rest or nocturnally often heralds a change in the pattern from stable to unstable and may indicate that there is an incipient plaque rupture leading

TABLE 71-1 PROBABILITY (%) OF CORONARY ARTERY DISEASE BY AGE, GENDER, AND SYMPTOMS

GENDER	AGE (yr)	DEFINITE ANGINA	ATYPICAL ANGINA	NONCARDIAC CHEST PAIN
Men	30-39	83	46	3
	40-49	88	57	12
	50-59	94	71	18
	60-69	95	78	31

TABLE 71-2 NON–CHEST PAIN SYMPTOMS OF CHRONIC ISCHEMIC HEART DISEASE

DYSPNEA
Dyspnea on exertion
Dyspnea at rest
Paroxysmal nocturnal dyspnea
Temporal change of increasing exertional dyspnea with declining effort tolerance
NON–CHEST LOCATIONS OF DISCOMFORT (EITHER EXERTIONAL OR AT REST)
Neck or mandibular discomfort or pain
Throat tightness
Shoulder discomfort
Upper arm or forearm discomfort (more often left-sided)
Interscapular or infrascapular discomfort
MID-EPIGASTRIC OR ABDOMINAL
Mid-epigastric burning, often postprandially
Sharp abdominal pain (atypical, but more common in women)
Right-upper quadrant discomfort (may mimic gallbladder disease or pancreatitis)
Nausea and/or vomiting (often associated with increased vagal tone secondary to inferior myocardial ischemia or infarction)
DIAPHORESIS
EXCESSIVE FATIGUE AND WEAKNESS
Often a discernible prodrome of increasing fatigue with declining effort tolerance
DIZZINESS AND SYNCOPE
Uncommon, unless precipitated or exacerbated by alterations in heart rate or rhythm (e.g., bradyarrhythmia, tachyarrhythmia, heart block), blood pressure (e.g., hypotension), or cardiac output (e.g., decreased cerebral perfusion)

TABLE 71-3 NONATHEROSCLEROTIC CAUSES OF ISCHEMIC CHEST PAIN

PRIMARY CARDIAC CAUSE
Coronary artery abnormalities
Coronary spasm
Coronary arteritis
Coronary dissection
Coronary artery anomalies
Radiation-induced coronary disease
Myocardial bridging
Aortic stenosis
Hypertrophic cardiomyopathy
Dilated cardiomyopathy
Tachycardia
PRIMARY NONCARDIAC CAUSE
Anemia
Sickle cell disease
Hypoxemia
Carbon monoxide poisoning
Hyperviscosity (e.g., polycythemia)
Hyperthyroidism
Pheochromocytoma

to ACS. Vasospastic (or Prinzmetal's) angina may occur spontaneously at rest or nocturnally without provocation.

The typical duration of an episode of angina pectoris is brief. An episode usually begins gradually and reaches its maximal intensity over a period of minutes before abating. It is unusual for angina pectoris to peak and trough in less than a minute, and it is common that patients with exertional angina usually prefer to rest, sit, or stop walking during episodes that may be precipitated by the offending activity. Chest discomfort that persists for more than 15 to 20 minutes, especially at rest or nocturnally, is likely to represent ACS or MI. By contrast, features that suggest a noncardiac etiology of angina pectoris include pleuritic pain, pain reproduced by movement or palpation of the chest wall or arms, sharp or constant pain lasting for many hours, pain or discomfort that a patient can localize to the chest wall with the tip of one finger, or very brief episodes of pain lasting seconds (Chapter 50). Typical angina pectoris is generally relieved within minutes by rest or the use of sublingual, oral, or cutaneous nitroglycerin. The response to sublingual nitroglycerin is often a helpful diagnostic tool, although it should be emphasized that some noncardiac pain (e.g., esophageal spasm) may also respond to nitroglycerin.

Although chest discomfort is usually the predominant symptom in chronic (stable) angina, unstable angina, Prinzmetal's (variant) angina, microvascular angina, and acute MI, chest discomfort is absent, atypical, or not prominent in some patients. Patients with chronic ischemic heart disease may complain predominantly or exclusively of dyspnea, diminishing exercise tolerance or weakness. Others will first present with an abnormal exercise test result or other evidence of myocardial ischemia without any symptoms. Some patients will present with cardiac arrhythmias or even sudden cardiac death.

Physical Examination

Many patients with stable ischemic heart disease present with normal physical findings, but a diligent physical examination may reveal findings that represent either the consequences of myocardial ischemia or evidence of risk factors for coronary artery disease. Inspection of the eyes may reveal a corneal arcus, and examination of the skin may show xanthomas (see Fig. 50-12 in Chapter 50). Retinal arteriolar changes are common in patients with coronary artery disease who have hypertension or diabetes mellitus (see Figs. 431-26 and 431-24 in Chapter 431).

The cardiac examination is generally of limited benefit in evaluating patients with chest pain or establishing a diagnosis of ischemic heart disease. During an episode of chest discomfort, myocardial ischemia may produce either a third or fourth heart sound.

Myocardial ischemia also can cause a transient holosystolic or mid-late systolic apical murmur owing to reversible papillary muscle dysfunction that results in mitral regurgitation. These murmurs are more prevalent in patients with extensive coronary artery disease, especially with inferior or inferoposterior ischemia owing to right coronary artery disease. It is important to distinguish such a murmur from the murmur of aortic stenosis or obstructive hypertrophic cardiomyopathy (see Tables 50-7 and 50-8 in Chapter 50). A displaced left ventricular (LV) apical impulse, particularly if dyskinetic, is a sign of significant LV systolic dysfunction.

If patients have coexisting heart failure, an elevated jugular venous pressure, pulmonary rales, and peripheral edema may be present (Chapter 58). The physical examination may reveal other implicating or contributing conditions, such as thyroid enlargement (Chapter 233) or severe anemia (Chapter 161).

DIAGNOSIS AND EVALUATION

In addition to a careful history and physical examination, assessment of patients with stable ischemic heart disease includes the 12-lead ECG, measurement of biochemical and inflammatory markers, and noninvasive diagnostic testing. The first goal is to assess the patient's probability of ischemia so that an appropriate evaluation can expedite effective therapy (Fig. 71-1).

Resting Electrocardiogram

Although there may be focal, diagnostic findings of ST segment depression and T wave inversions (Fig. 71-2) on the resting ECG in chronic ischemic heart disease, even patients with extensive anatomic coronary artery disease may have a normal tracing at rest. In addition to myocardial ischemia, other conditions that can produce ST-T wave abnormalities include LV hypertrophy and dilation due to long-standing hypertension and valvular heart disease (e.g., aortic stenosis, hypertrophic cardiomyopathy), electrolyte abnormalities, neurogenic effects, and antiarrhythmic drugs. The presence of new ST-T wave abnormalities on the resting ECG, however, can be helpful in the diagnosis of coronary artery disease and may correlate with the severity of the underlying heart disease.

In addition to focal ST-T wave abnormalities, the ECG may reveal various conduction disturbances, most frequently left bundle branch block and left anterior fascicular block (Chapter 54). The finding of abnormal Q waves is relatively specific for the presence of previous MI but may not help to determine when such an event occurred. Arrhythmias, especially ventricular premature beats (Chapter 65), may be present on the ECG but have a low sensitivity and specificity for coronary artery disease.

During a spontaneous episode of angina pectoris or during exertion or stress, the ECG becomes abnormal in 50% or more of patients with normal resting ECGs. The most common abnormality observed is focal ST segment depression, usually in one or more ECG lead groups, which signifies the presence of subendocardial ischemia. On occasion, transient, but diminutive, ST segment elevation and normalization of previous resting ST-T wave depression or inversion (pseudonormalization) may develop during chronic angina and ischemia, although ST segment elevation is far more commonly observed in ACS patients with plaque rupture.

Laboratory Testing

In patients with new-onset or worsening symptoms, a troponin level can distinguish MI and ACS from stable ischemic heart disease (Chapters 72 and 73). An elevated plasma concentration of brain natriuretic peptide does not help diagnose stable ischemic heart disease but is suggestive of heart failure (Chapter 58) and is associated with a higher risk of future cardiovascular events. High-sensitivity C-reactive protein, an acute phase reactant of inflammation, has a strong and consistent relationship to the risk of future cardiovascular events, and an elevated level may warrant more aggressive diagnostic evaluation and therapy.

All patients with chronic angina should have biochemical evaluation of total cholesterol, low-density lipoprotein (LDL) cholesterol, high-density lipoprotein (HDL) cholesterol, triglyceride, serum creatinine (estimated glomerular filtration), and fasting blood glucose levels (Table 71-4). Other biochemical markers that are not routinely recommended but are associated with higher risk of future cardiovascular events include lipoprotein (a), apoprotein B, small dense LDL cholesterol, and lipoprotein-associated phospholipase A_2 (Lp-PLA_2). Homocysteine levels correlate with the risk of developing coronary heart disease, but randomized trials have failed to demonstrate a reduction of clinical events when elevated homocysteine levels are reduced; as a result, screening for an elevated homocysteine level is not recommended.

Noninvasive Testing

Noninvasive stress testing with a standard ECG treadmill or bicycle exercise, radionuclide imaging (Chapter 56), stress echocardiography (Chapter 55), or newer diagnostic modalities such as cardiac magnetic resonance (CMR;

Chapter 56) or positron-emission tomography (PET; Chapter 56) (Fig. 71-3) is a useful and clinically important approach to establishing the diagnosis and prognosis in patients with stable ischemic heart disease. The predictive accuracy of these tests is defined not only by their sensitivity and specificity but also by the prevalence of disease (or pretest probability) in the population under study. Noninvasive testing should be performed only if the incremental information is likely to alter the planned management strategy. Thus, the value of noninvasive stress testing is greatest when the pretest likelihood is intermediate because the test result is likely to have the greatest effect on the post-test probability of coronary artery disease and, hence, on clinical decision making.

Each noninvasive test has a sensitivity and specificity (Table 71-5), which, when combined with a patient's pretest probability (see Table 71-1), can yield a post-test probability for coronary artery disease (Fig. 71-4). The choice among tests depends on the patient's characteristics (Table 71-6).

Exercise Electrocardiography

An exercise ECG is the preferred test in patients who have suspected angina pectoris and are considered to have a moderate probability of coronary artery disease if the resting ECG is normal (i.e., ST segments are not obscured by structural heart disease or medication), provided that subjects are capable of achieving an adequate workload. Interpretation of the exercise ECG should include the exercise capacity achieved (duration and metabolic equivalents of the external workload; see Table 50-3 in Chapter 50), the magnitude and extent of ST segment deviation, and clinical and hemodynamic responses to exercise.

The exercise test protocol is usually adjusted to a patient's tolerance, aiming for 6 to 12 minutes of exercise time (i.e., Bruce protocol stages II to

ACC/AHA 2002 guideline update for the management of patients with chronic stable angina—summary article: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Committee on Management of Patients with Chronic Stable Angina). *Circulation.* 2003;107:149-158.

TABLE 71-6 SUGGESTED NONINVASIVE TESTS IN DIFFERENT TYPES OF PATIENTS WITH STABLE ANGINA

Exertional angina, mixed angina, walk-through angina, postprandial angina with or without prior myocardial infarction	
Normal resting ECG	Treadmill exercise ECG test
Abnormal, uninterpretable resting ECG	Exercise myocardial perfusion scintigraphy (^{201}Tl, ^{99m}Tc-sestamibi) or exercise echocardiography
Unsuitable for exercise	Dipyridamole, adenosine, or regadenoson myocardial perfusion scintigraphy, dobutamine stress echocardiography
Atypical chest pain with normal or borderline abnormal resting ECG or with nondiagnostic stress ECG, particularly in women	Exercise myocardial perfusion scintigraphy, exercise echocardiography
Vasospastic angina	ECG during chest pain, ST segment ambulatory ECG, exercise test
Dilated ischemic cardiomyopathy with typical angina or for assessment of hibernating or stunned myocardium	Regional and global ejection fraction by radionuclide ventriculography or two-dimensional echocardiography, radionuclide myocardial perfusion scintigraphy; in selected patients, flow and metabolic studies with positron emission tomography
Syndrome X	Treadmill exercise stress ECG, coronary blood flow by positron emission tomography, Doppler probe
Known severe aortic stenosis or severe hypertrophic cardiomyopathy with stable angina	Exercise stress tests contraindicated; dipyridamole, adenosine, or regadenoson myocardial perfusion scintigraphy in selected patients; coronary angiography preferred
Mild aortic valvar disease or hypertrophic cardiomyopathy with typical exertional angina	"Prudent" treadmill myocardial perfusion scintigraphy, dipyridamole or adenosine or regadenoson myocardial perfusion scintigraphy

ECG = 12-lead electrocardiogram.

IV) to achieve maximal oxygen consumption and to elicit objective evidence of inducible ischemia, if present. Exercise stress testing is generally very safe, with death or MI occurring in less than one case per 2500 tests, when such provocative testing is avoided in patients with severe aortic stenosis, severe hypertension, or uncontrolled heart failure. Other contraindications are acute MI, symptomatic arrhythmias, acute pulmonary embolism, and suspected acute aortic dissection. Relative contraindications are hypertension greater than 200 mm Hg systolic or 110 mm Hg diastolic, hypertrophic cardiomyopathy, and high-degree atrioventricular block.

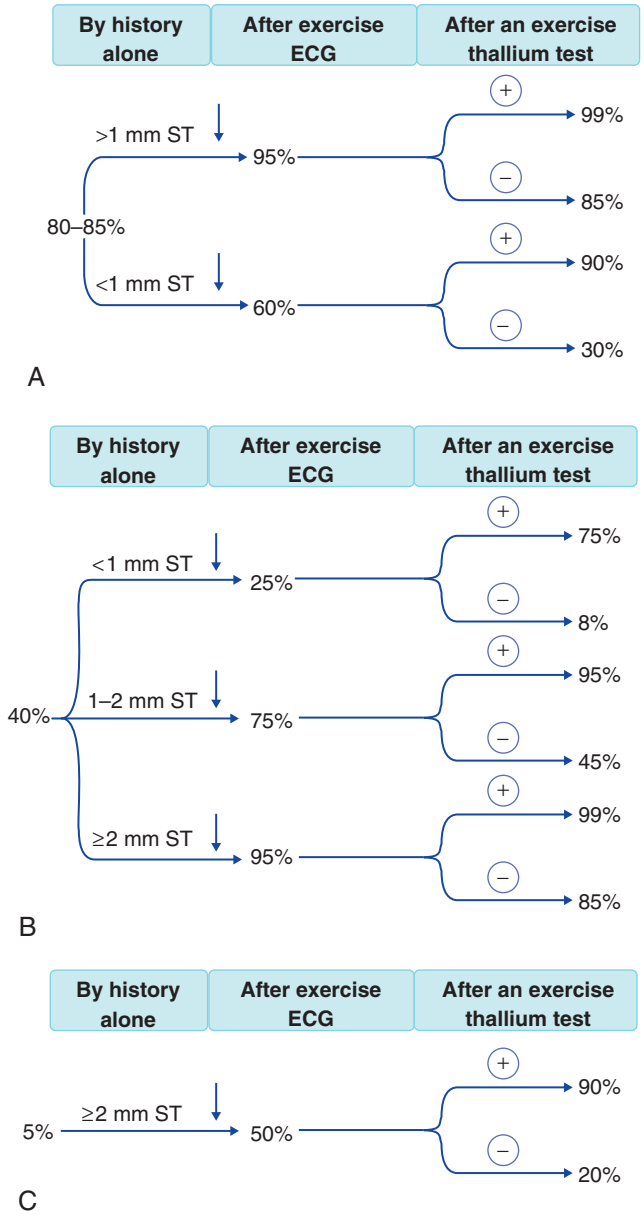

FIGURE 71-4. Approximate probabilities of coronary artery disease in different patient groups. A, Approximate probability of coronary artery disease before and after noninvasive testing in a patient with typical angina pectoris. These percentages demonstrate how the sequential use of an electrocardiogram (ECG) and an exercise thallium test may affect the probability of coronary artery disease in a patient with typical angina pectoris. **B,** Approximate probability of coronary artery disease before and after noninvasive testing in a patient with atypical angina symptoms. **C,** Approximate probability of coronary artery disease before and after noninvasive testing in an asymptomatic subject in the coronary artery disease age range. (Redrawn from Branch WB Jr, ed. *Office Practice of Medicine,* 3rd ed. Philadelphia: WB Saunders; 1994:45.)

Concomitant antianginal therapy (notably the use of β-blockers) reduces the sensitivity of exercise testing as a screening tool. If the purpose of the exercise test is to diagnose ischemia, it should be performed, whenever possible, before initiating β-blockers, or 2 to 3 days after their discontinuation.

Nuclear Cardiology Imaging

Stress myocardial perfusion imaging (Chapter 56) using single-photon emission computed tomography (SPECT) with simultaneous electrocardiographic testing (see Fig. 56-1 in Chapter 56) is particularly helpful in the diagnosis of coronary artery disease in patients with abnormal resting ECGs and among those in whom ST segment responses cannot be interpreted accurately, such as patients with repolarization abnormalities caused by LV hypertrophy, those with left bundle branch block, and those receiving digitalis. Its sensitivity and specificity are superior to exercise electrocardiography alone in detecting coronary artery disease, especially multivessel disease, in identifying regional perfusion defects that may localize to and correlate with diseased vessels, and in delineating the magnitude and extent of ischemic and infarcted myocardium. Treadmill testing is preferred for patients who are capable of performing such physical activity because of the additional diagnostic and prognostic information achieved with graded exercise. In the 40 to 50% of patients who are unable to exercise adequately, however, pharmacologic vasodilator stress with dipyridamole, adenosine, or regadenoson may be the preferred approach to noninvasive testing.

Stress Echocardiography

Stress two-dimensional echocardiography using exercise or pharmacologic stress can detect regional ischemia by identifying new wall motion abnormalities (see Fig. 55-5 in Chapter 55). Additional clinical information regarding associated structural heart disease, chamber dimensions, and valve function can be readily obtained. Exercise echocardiography can detect the presence of coronary artery disease with a similar accuracy as achieved with stress myocardial perfusion imaging and is useful for localizing and quantifying ischemic myocardial segments. Pharmacologic stress is usually performed with dobutamine in patients who are unable to exercise and in those unable to achieve adequate heart rates with exercise.

Ambulatory Ischemic Monitoring

Patients with symptomatic myocardial ischemia have episodes of silent ischemia that occur with the activities of daily living and are detectable on ambulatory monitoring but go unrecognized clinically because of the absence of angina or anginal equivalents. Although such "silent myocardial ischemia" may be detected during 24-hour ambulatory ECG recordings and may provide a quantitative estimate of the frequency and duration of ischemic episodes, its sensitivity for detecting coronary artery disease is much less reliable than that of exercise ECG.

Stress Cardiac Magnetic Resonance Imaging

Pharmacologic stress perfusion with CMR imaging is becoming increasingly available in many centers and may provide additional diagnostic capability in detecting the presence of structural heart disease, in addition to suspected coronary artery disease. CMR with gadolinium enhancement is the most accurate way to diagnose a scar from a prior MI (see Fig. 56-7 in Chapter 56).

Chest Roentgenography

Unless there is no history of prior MI, heart failure, or structural heart disease, the chest radiograph (Chapter 53) is usually normal in patients with chronic angina or stable ischemic heart disease. If an enlarged cardiac silhouette is present, it is generally indicative of a previous MI with LV dilation and cardiac remodeling. Other causes of cardiomegaly include long-standing hypertension, concomitant valvular heart disease, pericardial effusion, or nonischemic cardiomyopathy.

Cardiac Computed Tomographic Angiography

Cardiac computed tomographic angiography (CCTA; Chapter 56) is a highly sensitive method to detect coronary calcification (see Fig. 56-2 in Chapter 56), which is strongly associated with coronary atherosclerosis and can also provide noninvasive angiography of the proximal coronary arteries. Although coronary calcification is a highly sensitive (approximately 90%) finding in patients with coronary artery disease, the specificity for identifying patients with obstructive coronary artery disease is much lower (approximately 50%). Because of the potential unnecessary testing from false-positive results, CCTA is currently not recommended as a routine screening approach for suspected obstructive coronary artery disease in individuals at low risk (<10% 10-year estimated risk of coronary events). CCTA can be coupled with PET imaging in a hybrid PET and computed tomography scanner, which can provide a quantitative assessment of coronary anatomy along with regional myocardial blood flow and cardiac metabolism.

Diagnostic Coronary Angiography

Despite the continued evolution of noninvasive diagnostic testing, invasive coronary angiography (Chapter 57) remains the gold standard for anatomic definition of coronary artery disease. Among patients with the clinical diagnosis of stable ischemic heart disease referred for coronary angiography, a 70% or more luminal diameter narrowing is found in one (about 25%), two (about 25%), or all three (about 25%) epicardial coronary arteries, in about 75% of cases; another 5 to 10% of patients have obstruction of the left main

TABLE 71-7 CORONARY ANGIOGRAPHY FOR DIAGNOSIS AND RISK STRATIFICATION IN PATIENTS WITH CHRONIC ANGINA AND STABLE ISCHEMIC HEART DISEASE

FOR INITIAL DIAGNOSTIC INDICATION
Recommended on the basis of evidence or general consensus
Patients with suspected angina and evidence of intermediate-high risk, moderate-severe ischemia on noninvasive testing, or a changing angina pattern who have survived sudden cardiac death or serious ventricular arrhythmia
Weight of evidence or opinion is in favor
Uncertain diagnosis after noninvasive testing, and the benefit of a more certain diagnosis outweighs the risk and cost of coronary angiography
Inability to undergo noninvasive testing because of disability, illness, or morbid obesity
Occupational requirement for a definitive diagnosis
Suspected nonatherosclerotic cause of myocardial ischemia
Suspicion of a coronary spasm
High pretest probability of left main or three-vessel disease
Recurrent hospitalization for chest pain in the absence of definitive diagnosis
Overriding desire for a definitive diagnosis and a greater than low probability of CAD
Not recommended
Significant comorbidity in patients in whom the risk of coronary arteriography outweighs the benefit of the procedure
Overriding personal desire for a definitive diagnosis and a low probability of CAD
FOR INITIAL RISK STRATIFICATION OR TREATMENT INDICATION
Recommended on the basis of evidence or general consensus
With disabling (CCS class III and class IV) chronic stable angina despite medical therapy
With high-risk criteria on noninvasive testing regardless of anginal severity
Patients with angina who have survived sudden cardiac death or serious ventricular arrhythmia
Angina and symptoms and signs of congestive heart failure
Clinical characteristics that indicate a high likelihood of severe CAD
Weight of evidence or opinion is in favor
Significant left ventricular dysfunction (EF < 45%), CCS class I or class II angina, and demonstrable ischemia but less than high-risk criteria on noninvasive testing
High-risk criteria suggesting ischemia on noninvasive testing
Inadequate prognostic information after noninvasive testing
Clinical characteristics that indicate a high likelihood of severe CAD
CCS class I or class II angina, preserved left ventricular function (EF > 45%), and less than high-risk criteria on noninvasive testing
CCS class III or class IV angina that improves to class I or class II with medical therapy
CCS class I or class II angina but intolerance (unacceptable side effects) to adequate medical therapy
Not recommended
CCS class I or class II angina in patients who respond to medical therapy and who have no evidence of ischemia on noninvasive testing
Patients who prefer to avoid revascularization after adequate explanation

CAD = coronary artery disease; CCS = Canadian Cardiovascular Society; CHD = coronary heart disease; EF = ejection fraction.

Modified from Gibbons RJ, Abrams J, Chatterjee K, et al. ACC/AHA 2002 guideline update for the management of patients with chronic stable angina—summary article: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Committee on Management of Patients with Chronic Stable Angina). *Circulation.* 2003;107:149-158.

coronary artery; and the remaining 15 to 20% have no flow-limiting coronary obstructions. These data emphasize the persisting role of coronary angiography for diagnostic purposes (Table 71-7), but angiography is also helpful for risk stratification in patients with clear-cut angina and ischemic heart disease. In patients with less severe coronary stenoses (i.e., 50 to 70% on angiography), coronary intravascular ultrasonography (see Fig. 57-7 in Chapter 57) can substantially enhance the quantification of obstruction and vulnerability of the coronary atheroma to future instability. A pressure wire positioned proximal and distal to a coronary stenosis can measure the severity of the stenosis and determine whether functionally significant flow reduction may be ameliorated by myocardial revascularization.

Differential Diagnosis of Angina

Many common noncardiac disorders may present with clinical features that can be confused with angina pectoris (see Table 50-2 in Chapter 50). In some instances, symptoms may be indistinguishable from ischemic heart disease. For example, many patients with angina have coexisting esophageal disorders (Chapter 140), and both angina and esophageal discomfort may be relieved by nitroglycerin (Chapter 50). A distinguishing feature from angina is that esophageal discomfort is often relieved by antacids, proton pump inhibitors, or food.

Costochondritis can mimic angina but can typically be distinguished by the presence of well-localized pain on palpation. However, pressure, if applied too firmly to the anterior chest wall during examination of a patient with suspected angina pectoris, may elicit symptoms of discomfort even in normal subjects. Cervical radiculopathy may cause pain radiating to the shoulders, neck, or upper arms and can be confused with angina. However, this condition typically causes a constant ache that is often exacerbated by neck movement or rotation and may be accompanied by a focal sensory deficit or radiculopathy.

Pulmonary hypertension (Chapter 68) can cause exertional chest discomfort that may share many of the characteristics of angina pectoris. It is believed that right ventricular ischemia during physical exertion may cause this discomfort along with associated symptoms of exertional dyspnea, dizziness, and syncope. Findings on physical examination typically include a parasternal lift, a loud (and sometimes palpable) pulmonary component of the second heart sound, and findings of right ventricular hypertrophy on ECG.

Chest pain may also be an important presenting clinical feature of pulmonary embolism (Chapter 98). Physical findings typically include tachycardia and tachypnea, an accentuated pulmonic component of the second heart sound, and occasionally a right-sided S_4 gallop. Pleuritic discomfort suggests pulmonary infarction, whereas a history of pain exacerbated by inspiration or deep breathing, along with a pleural friction rub, usually helps distinguish it from angina pectoris.

Acute pericarditis (Chapter 77) may be confused with the discomfort of angina pectoris, but pericarditis tends to cause chest pain that is generally sharp, is not relieved by rest or nitroglycerin, is exacerbated by movement or deep breathing, and is associated with a pericardial friction rub that may be evanescent. Aortic dissection (Chapter 78), which may present with acute, severe chest pain, may be confused with an acute MI but generally not with angina.

Risk Stratification

Clinical and noninvasive criteria can be used in a complementary fashion to refine the estimate of risk for the individual patient with stable ischemic heart disease (Table 71-8). Clinical characteristics that include age, male sex, diabetes mellitus, previous MI, and the presence of symptoms typical of angina are predictive of the presence of coronary artery disease. Heart failure and LV dysfunction (generally defined by an ejection fraction < 50%), the severity and extent of angina, and associated symptoms such as dyspnea are also important predictors of outcome in patients with stable ischemic heart disease.

The simple classification of disease into single-, double-, or triple-vessel or left main coronary artery disease remains the most widely used approach (Table 71-9). Additional prognostic information is provided by the severity and extent of coronary luminal narrowing and its location. For example, high-grade lesions of the left main coronary artery or its equivalent, as defined by severe proximal left anterior descending and proximal left circumflex coronary artery disease, are particularly life-threatening. The SYNTAX trial has permitted the identification of subsets of coronary artery disease patients into three tertiles of low-, moderate-, and high-risk anatomic findings, based on multiple lesional characteristics (see Tables 71-8 and 71-9). It should be kept in mind, however, that the plaque causing the most severe chronic stenosis is not necessarily the one that will subsequently rupture to cause acute coronary syndrome or acute MI.

TREATMENT Rx

Comprehensive management of angina and stable ischemic heart disease (Fig. 71-5) entails multiple therapeutic approaches to the identification and treatment of associated diseases that can precipitate or worsen angina and ischemia (Table 71-10): cardiac risk factor identification and intervention; application of pharmacologic and nonpharmacologic interventions for secondary prevention; pharmacologic and symptomatic management of angina and ischemia; and myocardial revascularization with percutaneous coronary intervention (PCI) or coronary artery bypass graft (CABG) surgery, when indicated (Table 71-11). A multidimensional management approach integrates all of these considerations, often simultaneously, in each patient. Among pharmacotherapies, three drug classes are classified as being "disease modifying" in that they have been demonstrated to reduce mortality and morbidity in patients with stable ischemic heart disease and preserved LV function: aspirin,

TABLE 71-8 USING THE RESULTS OF NONINVASIVE RISK STRATIFICATION TO GUIDE CLINICAL DECISION MAKING

HIGH RISK (>3% ANNUAL MORTALITY RATE)
Severe resting left ventricular dysfunction (LVEF < 35%)
High-risk treadmill score (≤ −11)*
Severe exercise left ventricular dysfunction (exercise LVEF < 35%)
Stress-induced large perfusion defect (particularly if anterior)
Stress-induced multiple perfusion defects of moderate size
Large, fixed perfusion defect with left ventricular dilation or increased lung uptake (^{201}Tl)
Stress-induced moderate perfusion defect with left ventricular dilation or increased lung uptake (^{201}Tl)
Echocardiographic wall motion abnormality (involving more than two segments) developing at low dose of dobutamine or at a low heart rate (<120 beats/min)
Stress echocardiographic evidence of extensive ischemia
INTERMEDIATE RISK (1-3% ANNUAL MORTALITY RATE)
Mild to moderate resting left ventricular dysfunction (LVEF = 35-49%)
Intermediate-risk treadmill score (−11 < score < 5)*
Stress-induced moderate perfusion defect without left ventricular dilation or increased lung intake (^{201}Tl)
Limited stress echocardiographic ischemia with a wall motion abnormality only at higher doses of dobutamine involving two segments or less
LOW RISK (<1% ANNUAL MORTALITY RATE)
Low-risk treadmill score (≥ 5)*
Normal or small myocardial perfusion defect at rest or with stress†
Normal stress echocardiographic wall motion or no change of limited resting wall motion abnormalities during stress†

*Score = (duration of exercise in minutes) − (5 × mm of ST segment depression) − (4 × angina score), where 0 = no angina, 1 = nonlimiting angina, and 2 = angina that causes discontinuation of the test.
†Although the published data are limited, patients with these findings will probably not be at low risk in the presence of either a high-risk treadmill score or severe resting left ventricular dysfunction (LVEF < 35%).
LVEF = left ventricular ejection fraction.

angiotensin-converting enzyme (ACE) inhibition, and effective lipid lowering. Other therapies such as nitrates, β-blockers, calcium antagonists, and ranolazine have been shown to improve angina, exercise performance, and reduce ischemia, but have not been proved to reduce mortality in patients with stable ischemic heart disease.

Disease-Modifying Therapies

Careful attention to lifestyle and the management of coronary risk factors is essential (Fig. 71-6). Such secondary prevention strategies can reduce the risk of progressive coronary disease, morbidity, and mortality.

Drugs That Alter Lipid Metabolism

Each 1% increase in the LDL cholesterol level results in a 2 to 3% increase in risk for coronary events (Chapter 51). Large, randomized clinical trials in patients with ischemic heart disease have shown a consistent and significant reduction in mortality and cardiac events with statin therapy (Chapter 213). Patients with stable angina should routinely be treated with statins to a target of less than 70 mg/dL,[1] using any of a variety of specific statin drugs (see Table 213-5 in Chapter 213).

Gemfibrozil, a fibrate at 1200 mg daily, can reduce fatal and nonfatal MI in men who have coronary heart disease and normal levels of LDL cholesterol but who also have low levels of HDL cholesterol and elevated triglycerides,[2] but fibrates have not been shown to reduce overall mortality despite about a 10% reduction in major cardiovascular events.[3] Other cholesterol-lowering agents such as ezetimibe or bile acid sequestrants can be used instead of statins in those who are intolerant or can be added to high-dose statins in those in whom the LDL goal has not been achieved, but there are no studies to indicate whether these agents reduce cardiac events or mortality.

Each 1-mg/dL decline in HDL cholesterol is associated with a 2 to 3% increase in the risk of MI and death from cardiac causes. Nicotinic acid raises HDL cholesterol by about 25 to 30% on an average at doses of 1 to 2 g/day, but its use has been limited by side effects, notably flushing. Nicotinic acid reduces carotid artery intimal media thickness, a surrogate for atherosclerotic progression, but clinical outcomes data are lacking. Cholesteryl ester transfer protein inhibitors may be quite effective in raising HDL levels but have had no benefit in clinical trials to date.

Angiotensin-Converting Enzyme Inhibitors

ACE inhibitor administration (see Table 67-5 in Chapter 67) reduces cardiac events, cardiovascular mortality, and all-cause mortality in patients with risk factors for or with previously diagnosed coronary artery disease,[1,4] including high-risk patients with vascular disease or diabetes and patients with stable coronary artery disease and no clinical evidence of heart failure. By contrast, ACE inhibitors do not appear to prevent future cardiac events in post-MI patients with preserved LV function. Whether angiotensin receptor blockers have similar benefits in patients with chronic angina and stable ischemic heart disease is not yet known.

Antiplatelet Agents and Anticoagulants

Aspirin reduces the risk of adverse cardiovascular events by 33% in patients with stable angina. The reduction in vascular events is comparable for doses of 75 to 150 mg daily and 160 to 325 mg daily, but daily doses of less than 75 mg have less benefit.[5] Therefore, in the absence of contraindications, aspirin, 75 to 325 mg once daily, should be administered routinely in all patients with angina and stable ischemic heart disease.

Clopidogrel (Chapter 37), which is the most widely used thienopyridine in the treatment of patients with coronary artery disease, is of proven benefit when combined with aspirin to reduce the composite end point of death, MI, or stroke in patients after an acute coronary event. The standard regimen is an initial loading dose of 300 to 600 mg orally, followed by a maintenance dose of 75 mg daily. In patients with angina and stable ischemic heart disease, however, adding clopidogrel to low-dose (75 to 162 mg/day) aspirin does not reduce the primary composite end point of MI, stroke, or death from cardiovascular causes,[6] so clopidogrel should be reserved for patients who cannot tolerate aspirin or who have had an acute coronary event (Chapter 72) or a stent implantation (Chapter 74). Prasugrel is a new thienopyridine that is approved in patients with ACS and in those who undergo PCI with stent placement, but it has not yet been studied in the medical management of patients with chronic angina and stable coronary artery disease.

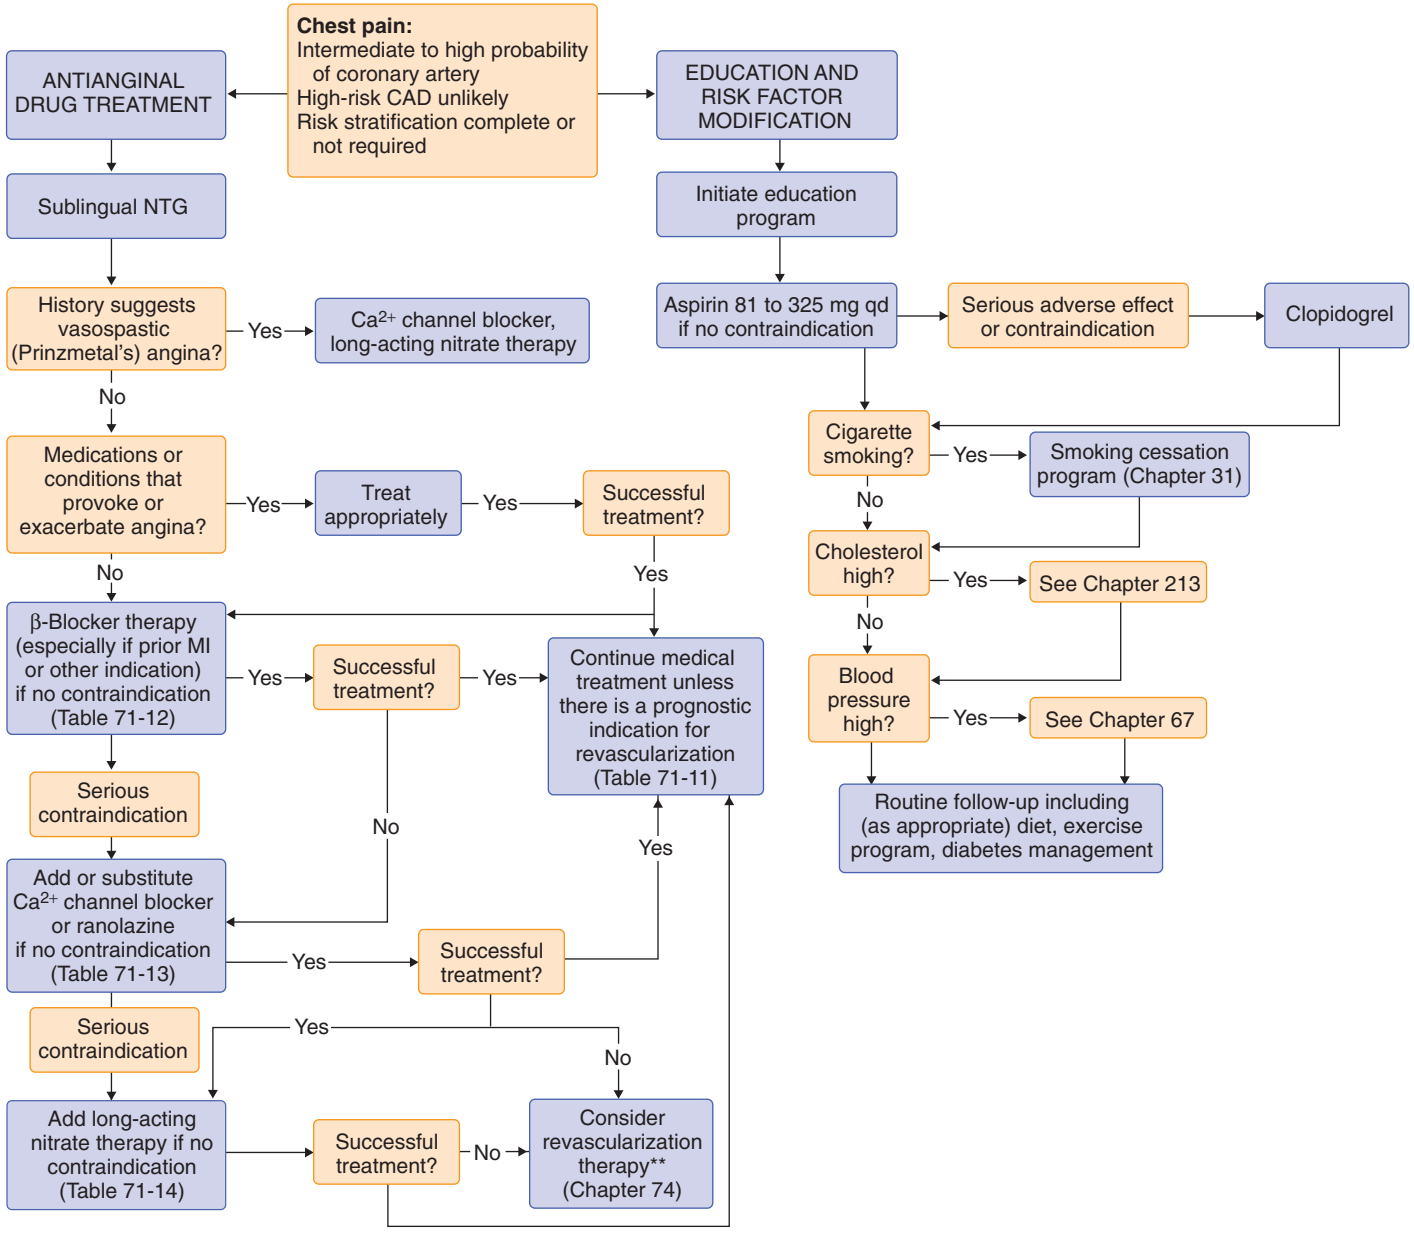
Warfarin is generally as effective as aspirin for preventing coronary events in patients with angina and is preferred over aspirin for patients with concomitant atrial fibrillation (Chapter 66), but it is associated with a higher risk of bleeding. Combination therapy with warfarin plus aspirin is superior to aspirin alone if the international normalized ratio is maintained above 2.0, but the benefit of the combination must be weighed against a 1 per 100 patient years risk of bleeding.[7] Anticoagulants are more commonly used in Europe than in America.

Therapeutic Agents to Reduce Angina and Ischemia

The goal of antianginal therapy is to reduce symptoms of cardiac ischemia and to improve quality of life. β-Blockers, which prevent the binding of catecholamines to the β-adrenergic receptor, lower heart rate and myocardial contractility, thereby reducing myocardial workload, myocardial oxygen demand, and ischemia and anginal symptoms. β-Blockers raise the ischemic threshold and delay or prevent the onset of angina with exercise. β-Blockers also reduce the rate of secondary cardiac events and sudden cardiac death in post-MI patients, but there have been no placebo-controlled outcome trials in

angina patients. All β-blockers appear to be equally effective in patients with chronic stable angina (Table 71-12). The β-blocker dose should be titrated to a target resting heart rate of 50 to 60 beats per minute as tolerated by the patient.

Calcium-channel blockers (Table 71-13) reduce afterload owing to their peripheral vasodilatory effects and thus lower myocardial workload and myocardial oxygen demand. Calcium-channel blockers also reduce coronary vascular resistance and inhibit coronary vasospasm by preventing coronary arterial smooth muscle contraction. This favorable reduction in myocardial oxygen demand, coupled with an increase in myocardial oxygen supply, results in a reduction in angina and ischemia. Nondihydropyridine calcium-channel blockers, such as verapamil and diltiazem, also reduce heart rate. Conversely, dihydropyridine calcium channel antagonists, such as amlodipine, have greater effect on vascular smooth muscle, are better peripheral and coronary vasodilators, and hence may have advantages for use in the hypertensive patient with angina. In randomized clinical trials, calcium-channel blockers and β-blockers are generally equally effective in relieving angina, improving time to onset of angina, and improving time to ischemic ST depression during exercise. Because calcium-channel blockers have not been shown to reduce death or MI in patients with stable or previously unstable ischemic heart disease, these agents are usually used in patients who cannot tolerate β-blockers or who require additional pharmacotherapy to control their symptoms. When used with β-blockers, care must be taken not to cause symptomatic bradycardia with verapamil and diltiazem. When used alone, diltiazem is



*Conditions that exacerbate or provoke angina:

Medications:	**Other medical problems:**	**Other cardiac problems:**
Vasodilators	Profound anemia	Tachyarrhythmias
Excessive thyroid replacement	Uncontrolled hypertension	Bradyarrhythmias
Vasoconstrictors	Hyperthyroidism	Valvular heart disease (espec. AS)
	Hypoxemia	Hypertrophic cardiomyopathy

**At any point in this process, based on coronary anatomy, severity of anginal symptoms, and patient preferences, it is reasonable to consider evaluation for coronary revascularization. Unless a patient is documented to have left main, three-vessel, or two-vessel CAD with significant stenosis of the proximal left anterior descending coronary artery, there is no demonstrated survival advantage associated with revascularization in low-risk patients with chronic stable angina; thus, medical therapy should be attempted in most patients before considering PTCA or CABG.

FIGURE 71-5. Algorithm for the treatment of stable angina. AS = aortic stenosis; CABG = coronary artery bypass graft; CAD = coronary artery disease; MI = myocardial infarction; NTG = nitroglycerin; PTCA = percutaneous transluminal coronary angioplasty. ACC/AHA/ACP-ASIM Pocket Guidelines.* Philadelphia: Elsevier Science; 2000.)

TABLE 71-10 TREATMENT OF PATIENTS WITH STABLE ANGINA

GENERAL MEASURES
Rule out and control aggravating conditions
Associated noncardiac diseases
Associated cardiac disease
Use of drugs aggravating angina
Smoking cessation
Dietary counseling for body weight and lipid control
Exercise prescription
Treat to targets
Hypertension
Blood lipids
Diabetes
PHARMACOLOGIC THERAPY: RECOMMENDATIONS FOR PHARMACOTHERAPY TO PREVENT MI AND DEATH AND TO REDUCE SYMPTOMS
Recommended on the basis of evidence or general consensus
Aspirin in the absence of contraindications
β-Blockers as initial therapy in the absence of contraindications in patients with prior MI or without prior MI
Angiotensin-converting enzyme inhibitor in all patients with CAD who also have diabetes or left ventricular systolic dysfunction
Low-density lipoprotein-lowering therapy in patients with documented or suspected CAD and LDL cholesterol greater than 130 mg/dL, with a target LDL of less than 100 mg/dL
Sublingual nitroglycerin or nitroglycerin spray for the immediate relief of angina
Calcium-channel antagonists or long-acting nitrates as initial therapy for reduction of symptoms when β-blockers are contraindicated
Calcium-channel antagonists or long-acting nitrates in combination with β-blockers when initial treatment with β-blockers is not successful
Calcium-channel antagonists and long-acting nitrates as a substitute for β-blockers if initial treatment with β-blockers leads to unacceptable side effects
Weight of evidence or opinion is in favor
Clopidogrel when aspirin is contraindicated
Long-acting nondihydropyridine calcium-channel antagonists instead of β-blockers as initial therapy
In patients with documented or suspected CAD and LDL cholesterol level of 100 to 129 mg/dL, several therapeutic options are available (Level of Evidence: B)
Lifestyle and/or drug therapies to lower LDL to less than 100 mg/dL
Weight reduction and increased physical activity in persons with the metabolic syndrome
Institution of treatment of other lipid or nonlipid risk factors; consider use of nicotinic acid or fibric acid for elevated triglycerides or low HDL cholesterol
Angiotensin-converting enzyme inhibitor in patients with CAD or other vascular disease
Usefulness unclear
Low-intensity anticoagulation with warfarin in addition to aspirin
Not recommended
Dipyridamole
Chelation therapy

CAD = coronary artery disease; HDL = high-density lipoprotein; LDL = low-density lipoprotein; MI = myocardial infarction.

From Gibbons RJ, Abrams J, Chatterjee K, et al. ACC/AHA 2002 guideline update for the management of patients with chronic stable angina—summary article: a report of the American College of Cardiology/American Heart Association Task Force on practice guidelines (Committee on the Management of Patients with Chronic Stable Angina). *J Am Coll Cardiol.* 2003;41:159-168.

TABLE 71-11 CURRENT RECOMMENDATIONS FOR MYOCARDIAL REVASCULARIZATION IN PATIENTS WITH CHRONIC STABLE ANGINA

CABG SURGERY VERSUS MEDICAL THERAPY
Among patients with medically refractory angina pectoris, CABG surgery is indicated for symptom improvement.
Among patients with medically stable angina pectoris, CABG surgery is indicated to prolong life in left main coronary artery disease or three-vessel disease (regardless of left ventricular function) and, possibly, to help symptoms.
CABG surgery may be indicated for prolongation of life if the proximal left anterior descending coronary artery is involved (regardless of the number of diseased vessels).
CABG surgery may reduce the composite end point of death, myocardial infarction, or stroke in diabetic patients with extensive multivessel (two- to three-vessel) coronary artery disease compared with medical therapy.
PCI VERSUS MEDICAL THERAPY
For the initial management of patients with stable ischemic heart disease, PCI does not reduce the risk of death, myocardial infarction, or other major cardiovascular events when added to optimal medical therapy.
Among patients with medically refractory angina pectoris, PCI is indicated for symptom improvement.
PCI may be indicated in the presence of severe myocardial ischemia, regardless of symptoms. PCI does not appear to improve survival compared with medical treatment among patients with one- or two-vessel disease.
In the absence of symptoms or myocardial ischemia, PCI is not indicated (merely for the presence of an anatomic stenosis).
PCI VERSUS CABG SURGERY
For single-vessel disease, PCI and CABG surgery provide excellent symptom relief, but repeated revascularization procedures are required more frequently after PCI. Intracoronary stenting is preferred to regular PCI, but direct comparison with CABG surgery is limited.
For treated diabetic patients with two- or three-vessel disease, CABG surgery is the treatment of choice.
For nondiabetic patients, multivessel PCI and CABG surgery are acceptable alternatives. The choice of PCI or CABG surgery for initial treatment depends primarily on local expertise and the patient's and physician's preferences.
In general, PCI is preferred for patients at low risk and CABG surgery for patients at high risk.

CABG = coronary artery bypass graft; PCI = percutaneous coronary intervention.

often preferred because the dihydropyridine calcium-channel blockers can increase the heart rate.

Nitrates (Table 71-14) continue to be widely prescribed for antianginal treatment and are effective when administered sublingually, orally, or topically. They act as vasodilators by entering vascular smooth muscle, where they are metabolized to nitric oxide, which relaxes vascular smooth muscle, including in coronary arteries. These effects reduce angina by improving coronary blood flow. Nitrates also lower preload owing to their venodilator effects, with a resulting reduction in LV end-diastolic pressure and wall tension, which, in turn, lowers subendocardial oxygen demand. When used in patients with stable angina, nitrates improve exercise tolerance, time to onset of angina, and ST segment depression during treadmill exercise testing. Long-acting nitrates, which are frequently combined with β-blockers and calcium-channel blockers, have additive antianginal and anti-ischemic effects in patients with stable ischemic heart disease. Sublingual nitroglycerin or oral spray can terminate an angina attack and can be used as prophylaxis to prevent exertional angina. Long-acting nitrates administered orally or transdermally are used to prevent angina and to improve exercise tolerance. For avoidance of nitrate tolerance or tachyphylaxis, an 8- to 12-hour nitrate-free interval daily is recommended. Nitroglycerin and nitrates can cause vasodilation-induced headache, a decrease in blood pressure, and, more rarely, severe hypotension with bradycardia due to activation of the vagal Bezold-Jarisch reflex. Because the vasodilation by nitroglycerin is markedly exaggerated and prolonged in the presence of the phosphodiesterase inhibitors sildenafil (Viagra), vardenafil (Levitra), and tadalafil (Cialis), these agents and nitrates should not be used concurrently.

Ranolazine (initiated at a dose of 500 mg twice daily and titrated up to a maximal dose of 1000 mg twice daily) is the newest U.S. Food and Drug Administration–approved antianginal agent and the first new drug class for angina since calcium-channel blockers were introduced clinically 30 years ago. Ranolazine acts by reducing intracellular calcium overload in ischemic myocytes by inhibiting late inward sodium current entry. The net effect of reduced late inward sodium current is a reduction in LV wall tension and myocardial oxygen demand, thereby reducing angina and ischemia. Ranolazine increases exercise tolerance in patients with stable angina, reduces episodes of recurrent ischemia, and provides additional antianginal benefit in patients who are already on intensive antianginal therapy with β-blockers and calcium-channel blockers. In patients with ACS, ranolazine also reduces hemoglobin A_{1c} concentrations in diabetic patients, and it is associated with a reduction in arrhythmic events, in particular, episodes of ventricular tachycardia and atrial fibrillation. Although ranolazine can minimally prolong the QT interval (on average, 6 to 8 msec), it has not been shown to increase the risk of torsades de pointes. Its precise role in the management of stable angina remains to be determined.

Nonpharmacologic Treatment

Enhanced external counterpulsation (EECP) is an alternative treatment for patients with refractory angina. EECP is generally administered as 35 sequential treatments (1 hour daily; 5 days/week) over 7 weeks. EECP does not reduce ischemia on myocardial perfusion imaging, and the mechanisms underlying

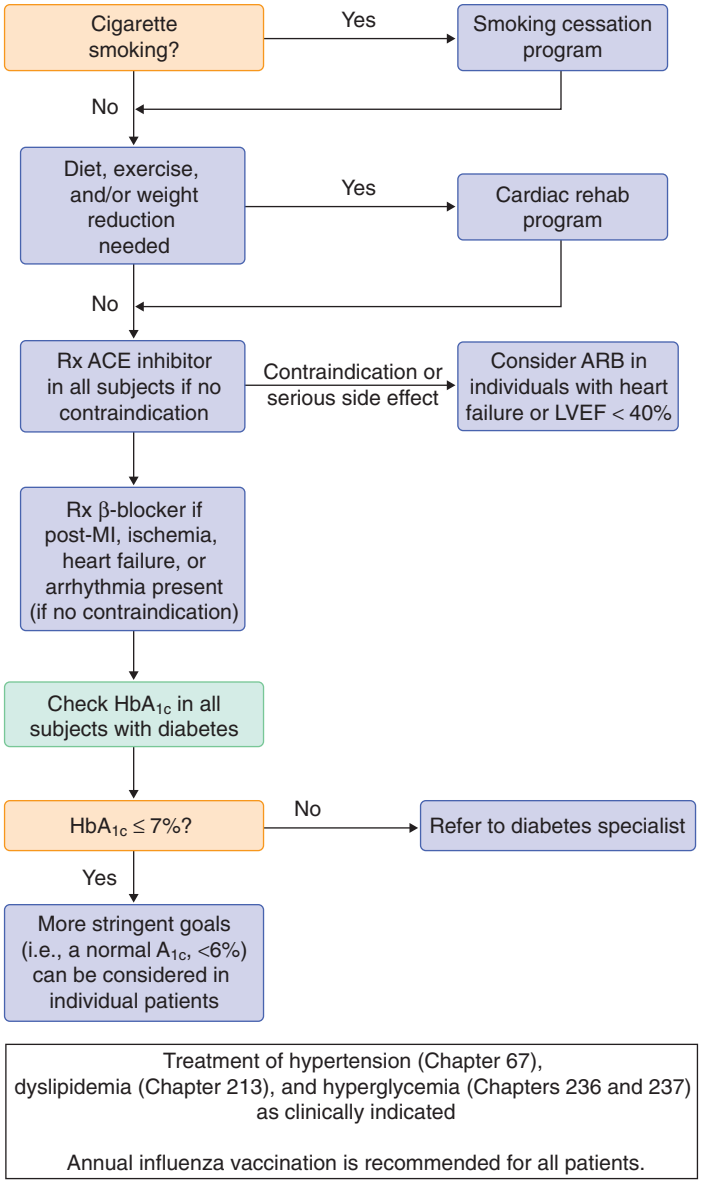


FIGURE 71-6. Approach to lifestyle interventions and pharmacotherapy. ACE = angiotensin-converting enzyme; ARB = angiotensin receptor blocker; HbA_{1c} = hemoglobin A_{1c}; LVEF = left ventricular ejection fraction; MI = myocardial infarction; Rx = prescribe.

its effects are poorly understood. Possible mechanisms include durable hemodynamic changes that reduce myocardial O_2 demand, improvement in myocardial perfusion by diastolic augmentation of retrograde coronary flow, and improved endothelial function. Although EECP increased the time to ST segment depression during exercise testing, reduced angina, and improved health-related quality of life for at least 1 year in one randomized, double-blind study of patients with chronic stable angina, its role in the treatment of angina remains unclear.[8]

Myocardial Revascularization

Coronary revascularization with either PCI or CABG (Chapter 74) can prolong life, reduce major cardiovascular events, and improve health status, quality of life, and functional capacity in selected patients with chronic, stable ischemic heart disease.

Comparisons of PCI with Optimal Medical Therapy

Randomized clinical trials comparing PCI with medical therapy in patients with stable coronary heart disease are few in number, and many recruited patients predominantly with single-vessel disease and were completed before the routine use of coronary stenting and contemporary aggressive preventive medical therapy. In general, these studies showed benefits of PCI in terms of symptoms[10] but not in terms of subsequent MI or death.[11] In the most recent trial of modern PCI (the Clinical Outcomes Utilizing Revascularization and Aggressive druG Evaluation [COURAGE] trial), including stents, versus aggressive medical therapy, there were no significant differences in the composite primary outcome of all-cause mortality or nonfatal MI or in stroke or hospitalization for ACS between the two strategies during a 2.5- to 7.0-year (median, 4.6-year) follow-up period.[12] PCI improved symptoms for 2 years, especially in patients with more severe angina, but differences were no longer present at 36 months, at which time both PCI and intensive medical therapy led to better symptom control than was noted at baseline. Because PCI as an initial management strategy in patients with stable coronary artery disease does not reduce death, MI, or other major cardiovascular events when added to optimal medical therapy, the importance of preventive pharmacotherapy and lifestyle modification for secondary prevention of major cardiovascular events in patients with stable CHD must be paramount.

Comparisons of CABG with Medical Therapy

Randomized trials comparing CABG with medical therapy indicate that a greater severity of ischemia, a greater extent of disease, and the presence of LV dysfunction favor a greater magnitude of benefit of CABG over medical therapy on survival. CABG prolongs survival in patients with significant left main coronary artery disease irrespective of symptoms, in patients with multivessel coronary artery disease and impaired LV function (ejection fraction < 50%), and in patients with three-vessel coronary artery disease that includes the proximal left anterior descending coronary artery. Patients with extensive multivessel coronary artery disease appear to benefit more from CABG surgery, particularly if they also have diabetes, whereas PCI is most appropriate for patients with one- or two-vessel coronary artery disease. Of note is that these randomized trials found little difference in mortality between CABG surgery and medical therapy at 1 year, but the benefits of CABG surgery over medical therapy steadily emerged over the next 3 to 5 years. Thereafter, the benefits of CABG surgery diminished, perhaps as a result of late occlusion of saphenous vein grafts, progression of disease in the nonbypassed native coronary arteries, and increasing rates of CABG surgery in the medical group among those with high-risk anatomy and severe symptoms ("crossovers"). It is important to emphasize that very few patients in these early trials received arterial grafts (which would likely improve the long-term results of CABG surgery), aspirin to prevent graft occlusion, lipid-lowering drugs to mitigate late graft disease progression, or inhibitors of the renin-angiotensin-aldosterone system. With improvements in operative techniques, more common use of antiplatelet-agents, more intensive use of disease-modifying therapies, and more aggressive risk factor management over the past decade, the benefits of modern-day CABG surgery compared with contemporary medical therapy may have changed.

Comparisons of PCI with CABG Surgery for Multivessel Coronary Artery Disease

Of the randomized outcomes trials that have compared PCI with CABG in patients with multivessel coronary artery disease, most excluded patients with significant left main coronary artery disease and were conducted in an era before the advent of stents and other advances in PCI technology, including newer adjunctive medical therapies that are increasingly in widespread clinical use. The Bypass Angioplasty Revascularization Investigation (BARI) trial found no overall difference in survival or MI rates between percutaneous balloon angioplasty and CABG surgery at 10 years, but CABG provided a significantly better survival advantage in patients with diabetes.[13] CABG also was associated with a greater initial improvement in angina and with a diminished frequency of repeat revascularization procedures compared with balloon angioplasty. A significant survival advantage was observed in patients with previously treated diabetes who underwent CABG rather than angioplasty.

More recently, the BARI-2D trial of 2368 diabetic patients with coronary artery disease who were randomized to prompt revascularization with PCI or CABG versus delayed or no revascularization with optimal medical therapy found no significant difference for the primary end point of total mortality.[14] Thus, the BARI-2D results replicate the principal finding of the COURAGE trial[10]—namely, that an initial strategy of PCI provides no incremental clinical benefit over intensive medical therapy and lifestyle intervention alone, and that an "optimal medical therapy first" instead of a "PCI first" strategy seems justifiable in many diabetic patients with coronary disease.

In a randomized trial of CABG or PCI patients with three-vessel or left main coronary artery disease, rates of major adverse cardiac or cerebrovascular events (i.e., death from any cause, stroke, MI, or repeat revascularization) at 12 months were significantly higher in the PCI group (18% vs. 12% for CABG), in large part because of an increased rate of repeat revascularization (14% vs. 6%).[15] At 12 months, the rates of death and MI were similar between the two groups, although stroke was significantly more likely to occur with CABG (2.2% vs. 0.6% with PCI). Thus, based on these 1-year findings, CABG still is generally considered the preferred option for patients with three-vessel or left main coronary artery disease.

In summary, among those who remain symptomatic despite intensive treatment, or who have substantial ischemia or extensive coronary artery disease, revascularization with either PCI or CABG is appropriate, depending on the anatomic complexity of disease (see Table 71-11; Chapter 73). CABG surgery appears to be preferable to PCI in symptomatic patients with three-vessel or

left main coronary artery disease and in diabetic patients with stable ischemic heart disease. PCI provides equivalent survival outcomes, but repeat procedures are more often needed, and symptomatic outcomes are generally not as good as after CABG.[16] Whether newer stent technologies will alter these findings remains unclear.

Other Anginal Syndromes

Variant Angina or Prinzmetal's Angina

The diagnosis of variant or Prinzmetal's angina is based on the documentation of transient ST segment elevation during an episode of chest pain in the absence of a severe, fixed coronary stenosis. Prinzmetal's variant angina typically is caused by an occlusive spasm superimposed on a nonsevere coronary artery stenosis. In some patients, however, no underlying stenoses are seen, or the underlying stenosis may be severe. Associated Raynaud's phenomenon and migraine headache have been described in some patients, suggesting that the syndrome may be part of a more generalized vasospastic disorder.

The chest pain occurs predominantly at rest, although approximately one third of patients may also experience pain during exercise. There is a predilection for the pain to wake the patient in the early morning hours when sympathetic activity is increasing. The syndrome is often cyclical, with periods of exacerbation with repetitive episodes of chest pain that may persist only for seconds or be more prolonged and severe, alternating with periods with few or no symptoms. The pain is typically relieved by nitroglycerin. The ST segment elevation accompanying the pain signifies transmural ischemia owing to total abrupt occlusion of a nonsignificant stenosis in the absence of adequate collateral circulation. The subsequent rapid reperfusion may explain the high prevalence of severe life-threatening arrhythmias.

Coronary angiography, with a provocative test for spasm such as injection of acetylcholine into the affected coronary artery, usually precipitates the syndrome. Such testing is useful to establish the diagnosis and to assess the response to therapy, especially in patients with normal or nearly normal coronary angiograms, in whom the diagnosis is otherwise unclear. Dihydropyridine calcium-channel blockers (e.g., amlodipine, 5 to 10 mg orally per day) are preferred in patients with Prinzmetal's angina.

Microvascular Angina with Normal Coronary Angiography

Angina can occur despite normal coronary arteries, even after an acetylcholine challenge. More detailed testing may reveal increased coronary resistance and an inability to increase coronary resistance and increase coronary flow in response to stimuli such as exercise, adenosine, dipyridamole, and atrial pacing.

Symptoms occur most frequently at rest and often in relation to emotional stress. Periods of exacerbation commonly alternate with symptom-free periods. The syndrome is more frequent in women, and some patients have an altered perception of pain or hypersensitivity to certain stimuli.

The diagnosis requires objective documentation of ischemia based on ST-T segment changes, a metabolic abnormality, a transient regional perfusion defect or new wall motion abnormality on echocardiography, or endothelial dysfunction that limits blood flow reserve. Abnormal endothelium-dependent vasoreactivity can be associated with regional myocardial perfusion defects on SPECT and PET imaging.

β-blockers may be useful, particularly when a relative tachycardia, hypertension, or decreased heart rate variability on Holter monitoring is present. Nitroglycerin can relieve symptoms in approximately 50% of patients, and long-acting nitrates or calcium antagonists are sometimes helpful.

The prognosis in general is favorable and not different from that of a general age-matched population in the absence of coronary artery disease. However, some studies have indicated that an ischemic response to exercise is associated with increased mortality.

Silent Myocardial Ischemia

Up to 20% of patients with ischemic heart disease may not present with angina. Such patients are often described as having silent myocardial ischemia. Some patients are totally asymptomatic despite obstructive coronary artery disease, which may be severe. Others have silent ischemia after a prior documented MI. The third and most common form occurs in patients who may also exhibit the usual forms of chronic stable angina, unstable angina, and Prinzmetal's angina. When monitored, these patients, who typically have silent ischemia episodes in addition to symptomatic ischemia, are sometimes referred to as having *mixed angina*. This mixed angina is estimated to be present in approximately one third of all treated patients with angina, although an even higher prevalence has been reported in diabetic patients. In these patients, about 85% of ambulant ischemic episodes occur without chest pain, and 66% of angina episodes are not accompanied by ST segment depression, suggesting that overt angina pectoris is merely the "tip of the ischemic iceberg." Pharmacologic agents that reduce or abolish episodes of symptomatic ischemia also reduce or abolish episodes of silent ischemia.

PROGNOSIS WITH OPTIMAL MANAGEMENT

Modern treatments have improved the prognosis of patients with stable ischemic heart disease to an annual mortality rate of 1 to 3% and a 1 to 2% rate of major ischemic events. The 1-year rate of cardiovascular death is now 1.9% (95% confidence interval [CI], 1.7 to 2.1), with a 2.9% (95% CI, 2.6 to 3.2) rate of all-cause mortality, and a 4.5% (95% CI, 4.2 to 4.8) rate of the combined outcome of cardiovascular death, MI, or stroke.

Recurrent angina is a common subsequent complaint in many patients with stable ischemic heart disease—even those who were initially treated successfully with PCI. About 30% of patients continue to experience angina one or more times per week, with associated greater physical limitation and worse quality of life, and almost 80% of patients who underwent initially successful PCI for chronic angina still take one or more antianginal agents at 1 year.

Selection of optimal treatment requires a full understanding of the potential risks and benefits of each treatment approach. In patients with stable symptoms who have not had an adequate trial of medical therapy (e.g., 8 to 12 weeks of multifaceted medical therapy and lifestyle intervention), such an initial approach of aggressive medical therapy is recommended. For patients whose angina or quality of life is not adequately controlled with optimal medical therapy, revascularization with either PCI or CABG surgery should be considered. Although the results of randomized trials must be individualized for specific patients, a multidisciplinary approach to clinical decision

making can ensure that all therapeutic options are fully and transparently discussed so that patients are offered the most appropriate evidence-based treatment recommendations.

ACUTE CORONARY SYNDROME: UNSTABLE ANGINA AND NON–ST ELEVATION MYOCARDIAL INFARCTION

RICHARD A. LANGE AND L. DAVID HILLIS

DEFINITION

The term *acute coronary syndrome* (ACS) is used to describe the continuum of myocardial ischemia (unstable angina pectoris) or infarction (with or without concomitant ST segment elevation). The patient with *unstable angina* has cardiac chest pain that is new, worsening (i.e., more severe, prolonged, or frequent than previous episodes of angina), or occurring at rest, *without* serologic evidence of myocyte necrosis (i.e., no elevation of serum concentrations of troponin or the MB isoenzyme of creatine kinase [CK-MB]). The patient with cardiac chest pain *with* serologic evidence of myonecrosis and without ST segment elevation is said to have a *non–ST segment elevation myocardial infarction* (MI). Because unstable angina and non–ST segment elevation MI are characterized by the absence of ST segment elevation, they are collectively termed *non–ST segment elevation ACS*, or NSTE-ACS (Fig. 72-1). The patient with acute-onset cardiac chest pain, serologic evidence of myonecrosis, and persistent (>20 minutes) ST segment elevation is said to have an *ST segment elevation MI* (Chapter 73).

EPIDEMIOLOGY

More than 1.4 million individuals in the United States are hospitalized annually with ACS, of whom approximately two thirds have NSTE-ACS. More than half of those with NSTE-ACS are older than 65 years, and almost half are women. NSTE-ACS is more common in individuals with one or more risk factors for atherosclerosis (Chapter 51), peripheral vascular disease, or a chronic inflammatory disorder, such as rheumatoid arthritis, psoriasis, or infection.

Most subjects with ACS have so-called *primary* ACS, which is precipitated by rupture of a coronary arterial atherosclerotic plaque, with subsequent platelet aggregation and thrombus formation, leading, in turn, to compromised blood flow in the involved artery. An occasional individual has so-called *secondary* ACS, which is caused by a transient or sustained marked imbalance between myocardial oxygen supply and demand. Substantial reductions in oxygen supply, for example, can be caused by severe systemic arterial hypotension, anemia, or hypoxemia; dramatic increases in oxygen demand can be caused by fever, tachycardia, severe systemic arterial hypertension, or thyrotoxicosis. In the subject thought to have secondary ACS, therapy should be directed at correcting the underlying cause.

PATHOBIOLOGY

The precipitating event in almost all subjects with NSTE-ACS is atherosclerotic coronary arterial plaque rupture or erosion, with subsequent platelet aggregation and thrombus formation, leading to subtotal occlusion of the involved artery. In an occasional patient with extensive collateral blood supply to the region of myocardium that is perfused by an occluded artery, total thrombotic occlusion of the artery leads to NSTE-ACS rather than to ST segment elevation MI.

Rarely, intense vasospasm of a segment of an epicardial coronary artery, due to focal endothelial dysfunction (i.e., Prinzmetal's angina) or drug ingestion (caused, for example, by cocaine, chemotherapeutic agents, or one of the serotonin receptor agonist "triptans"), causes a transient or sustained compromise of coronary arterial blood flow, with resultant NSTE-ACS. Spontaneous coronary arterial dissection, which occurs most often in peripartum women and patients with vasculitis, may result in NSTE-ACS.

Plaque Rupture

Atherosclerotic coronary arterial plaque rupture (Chapter 70) or erosion is the initiating event in most patients with NSTE-ACS. Several factors may play a role in the deterioration of the protective fibrous cap that separates the atheroma in the vessel wall from the coronary arterial lumen. Local and systemic inflammation, mechanical features, and anatomic changes contribute to the transformation of a stable atherosclerotic plaque to a so-called "vulnerable" plaque, the rupture of which triggers platelet adherence, activation, and aggregation, with subsequent thrombus formation.

The deposition of oxidized low-density lipoprotein (LDL) in the coronary arterial wall stimulates an inflammatory response, which results in the accumulation of macrophages and T lymphocytes at the plaque border. These inflammatory cells secrete cytokines (e.g., interferon-γ), which inhibit collagen synthesis and deposition, as well as enzymes (e.g., matrix metalloproteinases and cathepsins), which promote collagen and elastin degradation, thereby rendering the overlying fibrous cap vulnerable to rupture.

Systemic inflammation may play a role in plaque rupture as evidenced by the predisposition of individuals with chronic gingivitis, rheumatoid arthritis, and chronic or acute infection to develop ACS. Angiographic and angioscopic studies of the coronary arteries of ACS patients often demonstrate plaque ulceration and thrombosis at more than one site, thereby suggesting that a systemic and diffuse inflammatory process is present.

The mechanical characteristics and location of coronary arterial plaques appear to influence their stability. For example, thin fibrous caps are more likely to erode or rupture than are thick ones. Sites of low shear stress, such as vessel bifurcations, have reduced production of endothelial vasodilator substances (i.e., nitric oxide and prostacyclin), accelerated accumulation of lipids and inflammatory cells, increased degradation of the extracellular matrix, and thinning of the fibrous cap, all of which contribute to plaque instability.

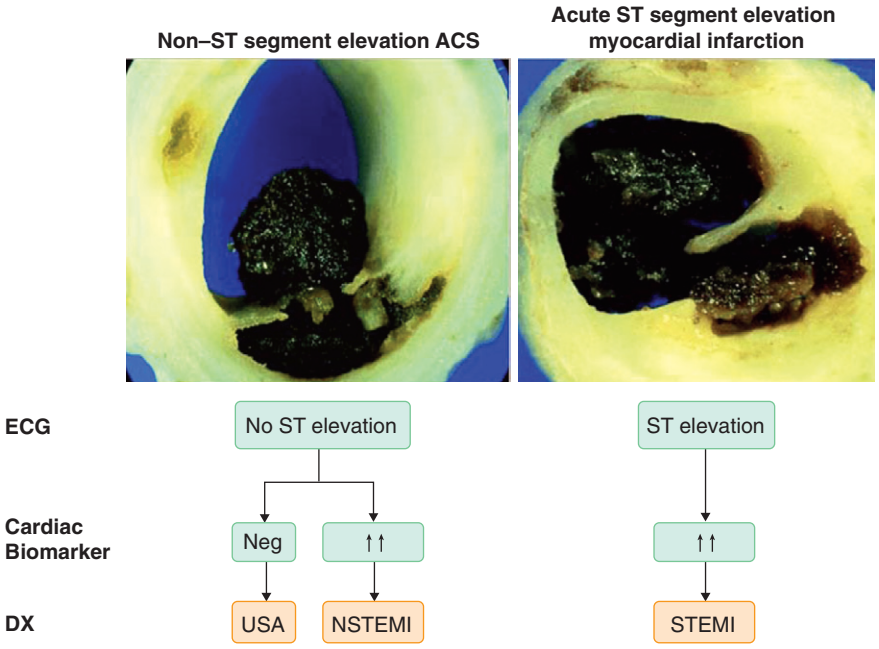

FIGURE 72-1. Acute coronary syndrome (ACS). Symptomatic, morphologic, electrocardiographic (ECG), and serologic findings in patients with various kinds of ACS. Subjects with ACS usually complain of chest pain. If the involved coronary artery is totally occluded by fresh thrombus (shown on the *right*), the patient's ECG reveals ST segment elevation; cardiac biomarkers subsequently are elevated; and he or she is diagnosed with an ST segment elevation myocardial infarction (STEMI). If the involved coronary artery is partially occluded by fresh thrombus (shown on the *left*), the patient's ECG does not show ST segment elevation. If cardiac biomarkers are not elevated, he or she is diagnosed with unstable angina (USA). If cardiac biomarkers are elevated, the patient is diagnosed with a non–ST segment elevation MI (NSTEMI). Dx = diagnosis.

Detailed histologic examination of evolving atherosclerotic plaques reveals a rich neovascularization that is the result of angiogenic peptides, such as fibroblast growth factors, vascular endothelial growth factor, placental growth factor, oncostatin M, and hypoxia-inducible factor, which are secreted by smooth muscle cells, inflammatory cells, and platelets. This neovascularization contributes to the growth of atheroma and to leukocyte trafficking, plaque hemorrhage, and destabilization.

Thrombus Formation

Platelets play a pivotal role in the pathobiology of ACS. Following erosion or rupture of a "vulnerable" plaque, circulating platelets *adhere* to the exposed subendothelial proteins, after which they are *activated*. With activation, the platelets change shape from discoid to stellate, thereby increasing the surface area on which thrombin formation can occur. The platelets then release the contents of their intracellular granules (i.e., thromboxane, serotonin, adenosine diphosphate, von Willebrand factor, fibrinogen) into the immediate environment and promote focal vasoconstriction of the adjacent arterial segment and activation of nearby platelets. Platelets also augment their number of surface glycoprotein IIb/IIIa receptors and the affinity of these receptors to bind circulating fibrinogen. The result is platelet *aggregation*, which occurs as fibrinogen binds to the glycoprotein IIb/IIIa receptors of adjacent platelets, thereby creating a "platelet plug."

Simultaneously with formation of the platelet plug, activation of the coagulation system with the generation of thrombin is a powerful stimulator of platelet activation and aggregation. In addition, thrombin converts fibrinogen to fibrin, which is incorporated into the thrombus. Subtotal coronary arterial occlusion by this platelet-rich thrombus compromises blood flow in the involved artery, thereby resulting in an imbalance of oxygen supply and demand of the myocytes perfused by the artery. Distal embolization of platelet-rich thrombi from the site of a ruptured plaque contributes to the compromise in blood flow. If the supply-demand imbalance is transient, the involved myocytes become ischemic but do not die because the ischemia is of insufficient duration to cause necrosis. The patient typically complains of cardiac chest pain at rest, but serologic evidence of myonecrosis, as evidenced by elevated serum concentrations of troponin or CK-MB, is absent; a diagnosis of *unstable angina* is made. In contrast, if the supply-demand imbalance is sustained, ischemic myocytes begin to die, and infarction occurs. The patient typically complains of cardiac chest pain at rest, and serologic evidence of myonecrosis confirms the diagnosis of *non–ST segment elevation MI.*

CLINICAL MANIFESTATIONS

Symptoms

The patient with NSTE-ACS typically complains of retrosternal pressure, squeezing, or heaviness that may be intermittent and recurrent or persistent (Chapter 50). If the episodes are intermittent and recurrent, the duration of each episode may range from only a few minutes to several hours. The chest pain may radiate to the left arm, neck, or jaw, and it may be accompanied by diaphoresis, nausea, abdominal pain, dyspnea, or syncope.

Atypical presentations of NSTE-ACS are not uncommon and may include aching or vague chest discomfort, epigastric pain, acute-onset indigestion, unexplained fatigue, or dyspnea. Such atypical complaints are often observed in younger (25 to 40 years of age) and older (>75 years of age) patients, women, and patients with diabetes mellitus, chronic renal insufficiency, or dementia.

Women with NSTE-ACS are more likely to have diabetes mellitus, hypertension, hyperlipidemia, and heart failure and to be older than men. They are less likely to be smokers or to have had a previous MI or coronary revascularization.

Physical Examination

The patient with NSTE-ACS often has a normal physical examination. On occasion, evidence of left ventricular dysfunction (Chapter 58), such as basilar rales or a ventricular gallop, hypotension, or peripheral hypoperfusion, may accompany an episode of NSTE-ACS or appear shortly thereafter. An important goal of the physical examination is to exclude noncardiac causes of the subject's symptoms (i.e., costochondritis, pneumothorax, pulmonary embolism, pneumonia) and nonischemic cardiac disorders (i.e., aortic dissection, pericarditis, severe systemic arterial hypertension) that can cause chest pain, other symptoms, or an elevation of cardiac biomarkers (Chapter 50). Accordingly, differences in blood pressure between the upper and lower limbs, decreased lung sounds, friction rubs, and pain on sternal palpation suggest a diagnosis other than NSTE-ACS. Other findings on physical examination—such as an elevated blood pressure, pallor, or increased sweating or tremor—point toward precipitating conditions, such as uncontrolled hypertension (Chapter 67), anemia (Chapter 161), or thyrotoxicosis (Chapter 233), respectively.

DIAGNOSIS

The patient with suspected ACS should be evaluated promptly because an expedient and accurate diagnosis permits the timely initiation of appropriate therapy, which can reduce the rate of complications. The initial assessment should be directed at determining whether the subject's symptoms are likely caused by myocardial ischemia, MI, or some other disorder. The likelihood of ACS can be estimated from the history, physical examination, and electrocardiogram (ECG) (Table 72-1).

In the acute setting, the presence or absence of traditional risk factors for atherosclerosis is far less important for determining the presence or absence of ACS than are the patient's symptoms, ECG findings, and serologic evidence of myonecrosis. As a result, these long-term risk factors are not the key factors that should be used to determine whether an individual should be evaluated, hospitalized, or treated for ACS.

TABLE 72-1 LIKELIHOOD THAT SYMPTOMS AND SIGNS REPRESENT AN ACUTE CORONARY SYNDROME CAUSED BY CORONARY ARTERIAL PLAQUE RUPTURE

HIGH LIKELIHOOD
Any of the following features:
Chest or left arm pain as the main symptom, similar in nature to previously noted angina
Known coronary artery disease
Evidence on physical exam of transient mitral regurgitation murmur, hypotension, diaphoresis, or pulmonary edema
New or transient ST segment deviation (≥1 mm) or T wave inversion in multiple precordial leads
Elevated serum troponin or CK-MB concentration
INTERMEDIATE LIKELIHOOD
Absence of high-likelihood features and any of the following:
Chest or left arm discomfort as main symptom
Age > 70 yr
Male gender
Diabetes mellitus
Extracardiac vascular disease
Q waves, ST segment depression (0.5-1 mm), or T wave inversion (>1 mm) in leads with dominant R waves
Normal cardiac troponin or CK-MB
LOW LIKELIHOOD
Absence of high- or intermediate-likelihood features, but may have:
Probable ischemic symptoms in the absence of any of the intermediate likelihood characteristics
Recent cocaine use
Chest discomfort reproduced by palpation
T wave flattening or inversion < 1 mm in leads with dominant R waves
Normal electrocardiogram
Normal serum troponin or CK-MB concentration

Modified from Anderson JL, Adams CD, Antman EM, et al. ACC/AHA 2007 Guidelines for the management of patients with unstable angina/non-ST-elevation myocardial infarction. *Circulation.* 2007;116:e148-e304.

Conditions that increase the likelihood that the symptomatic patient is experiencing myocardial ischemia or MI include older age, male gender, diabetes mellitus, extracardiac vascular disease, and chest pain radiating to the left arm, neck, or jaw as the presenting symptom. Myocardial ischemia is highly likely if anginal symptoms are accompanied by ECG abnormalities (i.e., ST segment depression or elevation ≥1 mm in magnitude or T wave inversion in multiple precordial leads), elevated serum concentration of troponin or CK-MB, or evidence of left ventricular dysfunction.

In a patient with known coronary artery disease, typical symptoms are likely to be caused by myocardial ischemia or MI rather than by another condition, particularly if the patient confirms that his or her symptoms are similar to previous anginal episodes. Conversely, a young individual who has a normal ECG and no risk factors for atherosclerosis is unlikely to be having ACS even when complaining of chest pain with features consistent with ischemia or infarction.

It is important to inquire about the use of cocaine and methamphetamines in the patient with suspected ACS, especially patients who are less than 40 years of age or have few traditional risk factors for atherosclerosis. These drugs can increase myocardial oxygen demand and concomitantly decrease oxygen supply by causing vasospasm and thrombosis. A urine toxicologic analysis should be considered when substance abuse is suspected as a cause of or contributor to ACS.

Electrocardiogram

An ECG should be obtained and examined promptly in the patient with suspected ACS. An ECG obtained during a symptomatic episode is particularly valuable. If the patient has persistent (>20 minutes) ST segment elevation, prompt reperfusion therapy should be initiated (Chapter 73). Transient ST segment abnormalities that develop during a symptomatic episode at rest and resolve when the patient is asymptomatic strongly suggest NSTE-ACS. ST segment depression (or transient ST segment elevation) and T wave abnormalities occur in up to 50% of NSTE-ACS patients.

A completely normal ECG does not exclude the possibility of NSTE-ACS; in fact, about 5% of patients who are discharged from the emergency department and ultimately diagnosed with ACS have a normal ECG. Ischemia or infarction in the territory of the left circumflex coronary artery often escapes detection with a standard 12-lead ECG, but it may be detected with right-sided leads (V_{4R} and V_{3R}) or posterior leads (V_7 to V_9). In the patient whose initial ECG is normal, subsequent ECGs should be obtained in the first 24 hours and during symptomatic episodes, and they should be compared with previous tracings to identify new ST segment or T wave abnormalities. Deep (>2 mm), symmetrical T wave inversion in the anterior chest leads is often associated with a hemodynamically significant stenosis of the left main or proximal left anterior descending coronary artery.

More than half of all episodes of myocardial ischemia are asymptomatic. On-line continuous computer-assisted 12-lead ST segment monitoring is a valuable diagnostic tool for detecting such episodes. Continuous ST segment monitoring also adds independent prognostic information to the resting ECG, serum cardiac enzymes, and other variables.

Serum Biomarkers

Troponin (Chapter 73) is detectable in the blood with conventional assays within 3 to 4 hours of the onset of myonecrosis, but in some individuals, its detection may be delayed for up to 8 hours. As a result, single negative assessment of serum troponin is insufficient to exclude MI in a patient with recent symptoms. To demonstrate or to exclude myonecrosis, repetitive blood sampling and troponin measurements should be performed 6 to 12 hours after the initial evaluation of the patient and following any additional episodes of chest pain. High sensitivity troponin assays can detect extremely small amounts of troponin in the blood, thereby improving the early (i.e., within 2 hours of symptom onset) diagnosis of MI. Troponin levels can be measured in the hospital's central chemistry laboratory or with point-of-care instruments at the patient's bedside using desktop devices or handheld bedside rapid qualitative assays. The advantage of point-of-care systems for avoiding delays must be weighed against their higher costs and the need for stringent quality control. In addition, point-of-care assays are qualitative or semiquantitative and observer dependent, whereas the central laboratory provides more accurate quantitative information concerning biomarker concentrations.

Up to one third of ACS patients whose serum CK-MB concentrations are normal have detectable serum concentrations of troponin T and I, indicating that myonecrosis has occurred and establishing the diagnosis of NSTE-MI. Current recommendations call for the use of the serum troponin concentration for acute risk stratification at the time of the patient's arrival to hospital.

Noninvasive Testing

The patient considered to have a low likelihood for ACS (based on the history, physical examination, ECG, and serum biomarkers) should undergo timely stress testing (Chapter 50), which does not absolutely establish or exclude the presence of coronary artery disease but has a high enough predictive value to guide acute decision making. Alternatively, multidetector computed tomographic (CT) coronary angiography has a high (>98%) negative predictive value to exclude coronary artery disease when performed and interpreted at centers experienced in its use. Conversely, the patient who is believed to be at intermediate or high risk for ACS and who continues to have typical ischemic chest pain with ECG abnormalities or elevated cardiac biomarkers should not undergo urgent diagnostic stress testing or CT coronary angiography; when such patients become symptom free with medical therapy and otherwise do not have indications for coronary angiography (see later), stress testing, often with myocardial perfusion imaging, should be performed before hospital discharge.

An echocardiogram may be helpful in the patient with chest pain if the ECG is nondiagnostic (i.e., minimal ST segment or T wave abnormalities). If left ventricular hypokinesis or akinesis is observed during an episode of chest pain and then improves when symptoms resolve, myocardial ischemia is likely. In the patient with T wave inversion in the anterior leads of uncertain etiology, hypokinesis of the left ventricular anterior wall suggests that the observed T wave abnormality is due to a severe stenosis of the left anterior descending coronary artery. Because echocardiography can help evaluate and identify alternative causes for the patient's chest pain, such as myocarditis (Chapter 60), aortic dissection (Chapter 78), or pulmonary embolism (Chapter 98), it is recommended in patients whose diagnosis is uncertain.

Coronary Angiography

Coronary angiography (Chapter 57) should be performed in patients who are thought to be at high risk for a cardiac ischemic event (death, MI, or recurrent ischemia) in the ensuing days, weeks, and months (see later); have spontaneous or inducible myocardial ischemia despite appropriate medical therapy; or have a confusing or difficult clinical presentation and a subsequent inconclusive noninvasive evaluation. The results of angiography help determine whether revascularization is appropriate and, if so, whether it should be attempted surgically (through coronary artery bypass grafting [CABG]) or percutaneously (through percutaneous coronary intervention [PCI]) (Chapter 74).

In patients with NSTE-ACS, coronary angiography demonstrates more than 50% luminal diameter narrowing of the left main coronary artery in about 15% of patients, of all three major epicardial coronary arteries in about 30 to 35% of patients, of two of the three epicardial arteries in about 20 to 30% of patients, and of one major epicardial artery in 20 to 30% of patients. About 15% of patients have no coronary arterial narrowing of hemodynamic significance. Women with NSTE-ACS are likely to have less extensive coronary artery disease than men, and patients with non–ST segment elevation MI on average have more extensive disease than those with unstable angina.

The coronary arterial lesion responsible for NSTE-ACS (the so-called culprit lesion) typically is asymmetrical or eccentric, with scalloped or overhanging edges and a narrow base or neck. These angiographic features reflect underlying plaque disruption and thrombus formation. Although obvious thrombus is visible angiographically in only one third of patients with NSTE-ACS, coronary angioscopy shows plaque rupture with overlying thrombus in most.

If the patient had previous coronary angiography, the culprit lesion usually can be seen to have progressed substantially. Interestingly, the lesion that is the nidus for ACS often is not severely stenotic when assessed on the previous angiogram; in fact, two thirds of culprit lesions previously had less than 50% luminal diameter narrowing (and, therefore, would not have been considered appropriate for surgical or percutaneous revascularization).

During the months after a NSTE-ACS, the culprit coronary arterial lesion is more likely to progress and to precipitate another ACS than are other lesions in the same patient. Lesions with irregular borders, overhanging edges, or obvious thrombus at angiography are more likely to precipitate another ACS in the ensuing months when compared with those that do not display these morphologic characteristics.

Risk Assessment and Triage

The initial evaluation of the patient with possible or suspected ACS should focus on an assessment of his or her risk of acutely sustaining a cardiac ischemic event (death, MI, or recurrent ischemia). Patients may be admitted immediately to a coronary intensive care unit or to an intermediate care unit, watched carefully in a monitored chest pain evaluation unit, or discharged home based on their risk of an MI (Fig. 72-2; see Fig. 50-1 in Chapter 50). Patients considered to be at low risk for a cardiac ischemic event should be discharged home, with further evaluation performed as an outpatient. Conversely, patients not at low risk should be hospitalized for further evaluation and treatment.

After the initial triage decision is made, urgent therapeutic interventions are based on the risk of adverse events in the coming hours, days, weeks, and months—estimated by using either the Thrombolysis in Myocardial Infarction (TIMI) or Global Registry of Acute Coronary Events (GRACE) risk algorithm—balanced against the risk of a bleeding complication from intensive medical therapy (Table 72-2) or an adverse event from an invasive cardiac procedure. Based on this initial assessment, the patient's therapy can be tailored, thereby reducing the likelihood of adverse events.

Although serum markers of myonecrosis comprise only one of the TIMI or GRACE risk variables, the presence of this variable alone appears to identify the patient as being "high risk." However, although elevated serum markers indicate myonecrosis, they provide no insight into its cause: in some subjects, myonecrosis occurs with disease entities other than coronary artery disease (e.g., pulmonary embolism, decompensated heart failure, severe hypertension or tachycardia, anemia, sepsis). Thus, when evaluating the patient with possible ACS, the presence of elevated serum markers should be assessed in conjunction with other variables.

Increasing age is associated with a higher incidence of both ACS-related cardiac ischemic events and complications from intensive medical therapy and invasive cardiac procedures. Even though elderly people are at increased risk of such treatment-related complications, they nonetheless derive a greater absolute and relative benefit from such intensive therapy when compared with younger individuals. Apart from this initial risk assessment, the ACS patient's general medical and cognitive status, anticipated life expectancy, risk of treatment-related complications, and, most importantly, personal preferences should be evaluated and considered.

Once the risk status of the ACS patient is established, management is initiated and tailored to the patient's risk of sustaining a subsequent ischemic cardiac event or a treatment-related complication (Table 72-3). For example, the patient considered to be at low risk of a subsequent ischemic event does not benefit from intensive antithrombotic therapy or routine coronary angiography and revascularization. Conversely, in patients considered to be at high risk of sustaining an ischemic event, optimal therapy—including coronary angiography and revascularization (if appropriate)—results in a substantial 20 to 40% decrease in the risk of recurrent ischemia and MI and an approximately 10% reduction in mortality. In short, the magnitude of benefit of intensive therapy correlates with the patient's level of risk.

TABLE 72-2 RISK VARIABLES FOR ISCHEMIC EVENTS AND BLEEDING COMPLICATIONS

1. RISK VARIABLES PREDICTIVE OF DEATH, MYOCARDIAL INFARCTION, OR RECURRENT ISCHEMIA
A. Thrombolysis in Myocardial Infarction (TIMI) Score*
Age > 65 yrs
Three or more risk factors for atherosclerosis
Known coronary artery disease (previous coronary arteriography or myocardial infarction)
Two or more episodes of anginal chest pain in the 24 hr before hospitalization
Use of aspirin in the 7 days before hospitalization
ST segment deviation ≥ 0.5 mV
Elevated serum concentrations of troponin or CK-MB
B. Global Registry of Acute Coronary Events (GRACE)†
Age
Heart failure class
Heart rate
Systolic blood pressure
ST segment deviation
Cardiac arrest during presentation
Serum creatinine concentration
Elevated serum markers of myonecrosis
2. RISK FACTORS FOR BLEEDING COMPLICATIONS WITH INTENSIVE THERAPY‡
Female gender
Older age
Renal insufficiency
Low body weight
Tachycardia
Systolic arterial pressure (high or low)
Anemia
Diabetes mellitus

*Individuals with three or more of these variables are considered to be "high risk," whereas those with 0, 1, or 2 are considered to be "low risk." (From Diez JG, Cohen M. Balancing myocardial ischemic and bleeding risks in patients with non-ST-segment elevation myocardial infarction. *Am J Cardiol.* 2009;103:1396-1402.)

†Each variable is assigned a numerical score based on its specific value, and the eight scores are summed to yield a total score, which is applied to a reference nomogram to determine the patient's risk. The GRACE application tool is available online at *www.outcomes-umassmed.org/grace*. (From Brieger D, Fox KA, Fitzgerald G, et al. Predicting freedom from clinical events in non-ST-elevation acute coronary syndromes: the Global Registry of Acute Coronary Events. *Heart.* 2009;95:888-894.)

‡The patient's bleeding risk can be estimated with the tool available at *www.crusadebleedingscore.org*. (From Subherwal S, Bach RG, Chen AY, et al. Baseline risk of major bleeding in non-ST-segment-elevation myocardial infarction: the CRUSADE [Can Rapid risk stratification of Unstable angina patients Suppress ADverse outcomes with Early implementation of the ACC/AHA Guidelines] Bleeding Score. *Circulation.* 2009;119:1873-1882.)

Differential Diagnoses

Several cardiac and noncardiac conditions, some of which are potentially life-threatening, may mimic NSTE-ACS. The patient with a pulmonary

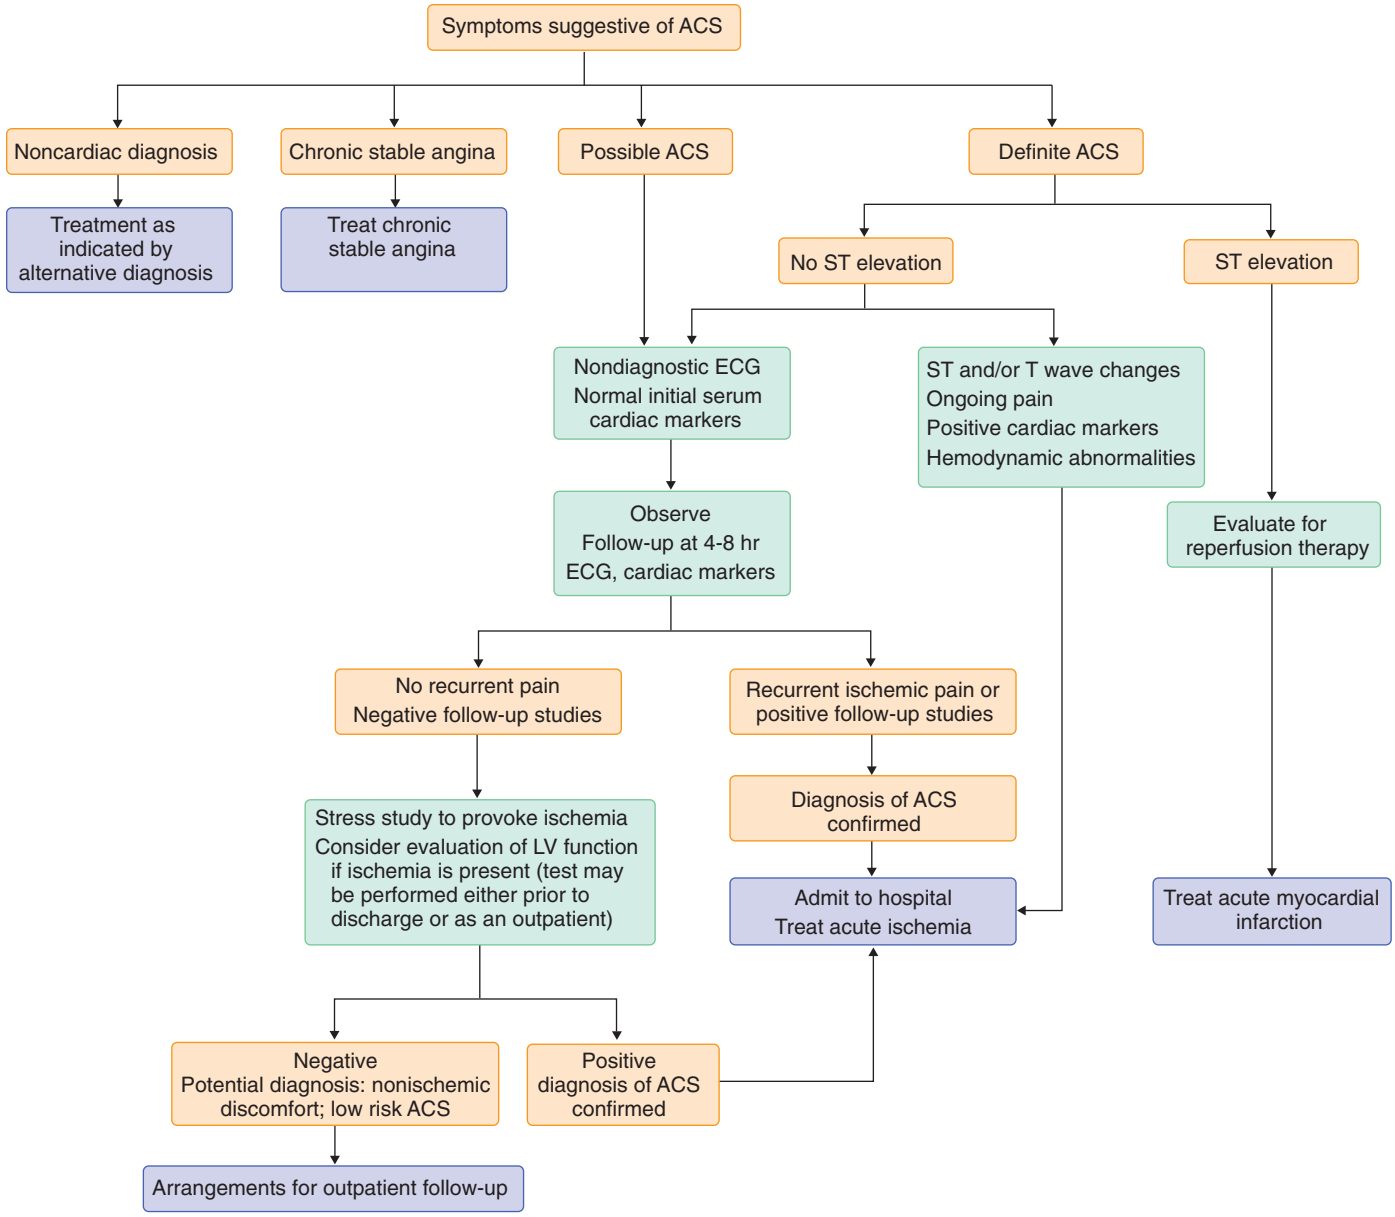

FIGURE 72-2. Initial triage for patients with symptoms suggestive of an acute coronary syndrome (ACS). ECG = electrocardiogram; LV = left ventricular. (Modified from Anderson JL, Adams CD, Antman EM, et al. ACC/AHA 2007 guidelines for the management of patients with unstable angina and non-ST-segment elevation myocardial infarction. A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines. *Circulation.* 2007;116:e148-e304.)

embolism (Chapter 98) often complains of dyspnea and chest pain and may have ECG abnormalities and elevated serum concentrations of troponin and CK-MB. Aortic dissection (Chapter 78) should be considered and excluded because the therapies for NSTE-ACS are contraindicated in patients with this condition. Stroke (Chapter 414) and subarachnoid hemorrhage (Chapter 415) may be accompanied by ECG abnormalities, segmental wall motion abnormalities, and elevated serum biomarker concentrations. Underlying chronic cardiac conditions, such as valvular heart disease (i.e., aortic stenosis, aortic regurgitation) and hypertrophic cardiomyopathy (Chapter 60), may be associated with symptoms similar to those of NSTE-ACS, elevated serum biomarker concentrations, and ECG abnormalities. Myocarditis (Chapter 60), pericarditis (Chapter 77), and myopericarditis often cause chest pain that resembles angina, ECG abnormalities, and elevated serum biomarker concentrations. A flu-like or upper respiratory tract infection often precedes or accompanies these conditions. Patients with "stress cardiomyopathy" (takotsubo syndrome) typically have chest pain, ST segment abnormalities and deeply inverted T waves, and mildly elevated serum biomarker concentrations (Chapter 60).

PREVENTION AND TREATMENT

The goals of treatment of the patient with NSTE-ACS are to prevent recurrent ischemia by correcting the imbalance between myocardial oxygen supply and demand; to prevent thrombus propagation; and to stabilize the "vulnerable" plaque. Antianginal medications, such as nitroglycerin, β-adrenergic blockers, and calcium-channel blockers, favorably affect myocardial oxygen supply and demand, thereby preventing recurrent ischemia. Antiplatelet and antithrombotic agents retard thrombus propagation, and statins promote plaque stabilization. Once the risk status of the ACS patient is established, treatment is initiated (see Table 72-3).

Every NSTE-ACS patient, regardless of the level of risk, should promptly receive antianginal medications, antiplatelet therapy (aspirin and clopidogrel), and a statin, unless contraindicated. A "low-risk" patient should also receive unfractionated heparin but not more intensive antiplatelet or anticoagulant therapy because anticoagulation beyond aspirin, clopidogrel, and heparin increases the risk of bleeding without further reducing the risk of an ischemic cardiac event. Routine coronary angiography and revascularization are not beneficial and should be reserved for the patient with recurrent ischemia despite intensive medical therapy.

TABLE 72-3 MANAGEMENT STRATEGIES FOR PATIENTS WITH ACUTE CORONARY SYNDROME

THERAPY	INITIATION	DURATION	DOSE, ROUTE, AND DURATION	BENEFIT VS. PLACEBO (REDUCED INCIDENCE OF …)
LOW-RISK PATIENT				
Antianginal				
β-Blocker*	Immediately	Hospitalization ± indefinitely	Metoprolol, 5 mg IV boluses (three given 2 to 5 minutes apart) then 50 mg orally twice daily titrated up to 100 mg twice daily or atenolol, 5-10 mg IV bolus then 100 mg orally daily	Recurrent ischemia
Nitroglycerin	Immediately	Hospitalization ± indefinitely	0.3 to 0.6 mg sublingually or 5 to 10 μg/min IV initially and increased by 10 μg/min every 5 min	Not studied
Diltiazem or verapamil*	Immediately	Hospitalization ± indefinitely	30 to 90 mg orally four times daily or up to 360 mg of long-acting preparation orally daily	MI, recurrent ischemia
Lipid Lowering				
Statin	Before hospital discharge	Indefinitely	Atorvastatin, up to 80 mg orally daily	Recurrent ischemia
Antiplatelet				
Aspirin	Immediately	Indefinitely	162-325 mg orally initial dose then 81 mg orally daily	Death, MI
Clopidogrel	Immediately	1-12 mo	300 mg orally initial dose then 75 mg orally daily	MI, recurrent ischemia
Anticoagulant				
Unfractionated heparin	Immediately	2 to 5 days	60 U/kg IV bolus then 12 U/kg IV adjusted to achieve an aPTT of 50 to 70 sec	Death or MI (combined)
HIGH-RISK PATIENT				
Antianginal				
β-Blocker*	Immediately	Hospitalization ± indefinitely	Metoprolol, 5 mg IV boluses (three given 2 to 5 minutes apart) then 50 mg orally twice daily titrated up to 100 mg twice daily or atenolol, 5-10 mg IV bolus then 100 mg orally daily	Death, MI, recurrent ischemia
Nitroglycerin	Immediately	Hospitalization ± indefinitely	0.3 to 0.6 mg sublingually or 5 to 10 μg/min IV initially and increased by 10 μg/min every 5 min	Not studied
Diltiazem or verapamil*	Immediately	Hospitalization ± indefinitely	30 to 90 mg orally four times daily or up to 360 mg of long-acting preparation orally daily	MI, recurrent ischemia
Lipid Lowering				
Statin	Before hospital discharge	Indefinitely	Atorvastatin, up to 80 mg orally daily	Recurrent ischemia
Antiplatelet				
Aspirin	Immediately	Indefinitely	162-325 mg orally initial dose then 81 mg orally	Death, MI
Clopidogrel	Immediately	≥12 mo	300 mg orally initial dose then 75 mg orally daily	MI, recurrent ischemia
Glycoprotein IIb/IIIa inhibitor (eptifibatide, tirofiban, or abciximab)	At time of PCI	12-24 hr post-PCI	Abciximab, 0.25 mg/kg IV bolus then 0.125 μg/kg/min IV (max 10 μg/min) for 12 hr or eptifibatide, 180 μg/kg IV bolus then 2.0 μg/kg/min IV for 18-24 hr or tirofiban, 0.4 μg/kg/min IV for 30 min then 0.1 μg/kg/min IV for 12 to 24 hr	MI
Anticoagulants				
Unfractionated heparin or	Immediately	2 to 5 days; discontinue after successful PCI	60 U/kg IV bolus then 12 U/kg IV adjusted to achieve an aPTT of 50 to 70 sec	Death or MI (combined)
Enoxaparin or	Immediately	Duration of hospitalization (up to 8 days); discontinue after successful PCI	1 mg/kg subcutaneously twice daily	MI, recurrent ischemia†
Bivalirudin	Immediately	Up to 72 hr; discontinue 4 hr after PCI	0.1 mg/kg IV bolus then 1.75 mg/kg/hr IV	Bleeding‡
Invasive Management				
Coronary angiography followed by revascularization (if appropriate)	Up to 36-80 hr after hospitalization; within 24 hr in "very high risk" patients			MI, recurrent ischemia

*Avoid in the patient with decompensated heart failure, hypotension, or hemodynamic instability.
†As compared with unfractionated heparin.
‡As monotherapy compared with heparin and glycoprotein IIb/IIIa inhibitor combination.
aPTT = activated partial thromboplastin time; IV = intravenous; MI = myocardial infarction; PCI = percutaneous coronary intervention.
Modified from Lange RA, Hillis LD. Optimal management of acute coronary syndromes. *N Engl J Med.* 2009;260:2237-2240.

Conversely, the high-risk patient should receive antianginal medications, antiplatelet therapy (aspirin and clopidogrel), a statin, more intensive anticoagulant therapy, and coronary angiography followed by revascularization (if indicated). In the patient whose coronary anatomy is suitable, revascularization reduces the incidence of ischemia and recurrent MI, and in certain patients (see later), it improves survival.

Antianginal Therapy

Nitroglycerin

Nitroglycerin (Chapter 71), which is a venodilator at low doses and an arteriolar dilator at higher doses, may prevent recurrent ischemia in patients with unstable angina, but no studies of sufficient statistical power have determined whether it reduces the risk of MI in this patient population. In patients who complain of recurrent symptoms, nitroglycerin should be given sublingually or by buccal spray (0.3 to 0.6 mg). Patients with ongoing or recurrent chest pain should receive intravenous nitroglycerin (5 to 10 µg/minute using nonabsorbable tubing), with escalation of the dose in increments of 10 µg/minute until symptoms resolve or adverse effects develop. Nitroglycerin's most common adverse effects are headache, nausea, dizziness, hypotension, and reflex tachycardia.

Nitrate tolerance can be avoided by providing the patient with a "nitrate-free" period (i.e., a brief cessation of drug administration). Nitroglycerin should not be given to the patient who has received a phosphodiesterase-5 inhibitor (i.e., sildenafil, tadalafil, or vardenafil) within the previous 24 to 48 hours, as severe hypotension may ensue.

β-Adrenergic Blockers

β-Adrenergic blockers diminish symptoms and the risk of MI in patients who are not already taking a β-blocker at the time of hospital admission. In the normotensive patient without ongoing chest pain or tachycardia, metoprolol should be initiated at 50 mg orally every 6 to 8 hours, with the dose increased (to 100 mg twice daily) as necessary to control heart rate, blood pressure, and symptoms. In high-risk patients and in patients with tachycardia or elevated systemic arterial pressure, metoprolol should be administered intravenously (3 boluses of 5 mg each given 5 minutes apart) initially, after which an oral dose should be initiated. A reasonable target heart rate is 50 to 60 beats per minute at rest.

β-Blockers should not be administered to patients with decompensated heart failure, hypotension, hemodynamic instability, or advanced atrioventricular block. Because most patients with chronic obstructive pulmonary disease or peripheral vascular disease tolerate β-blockers without difficulty, these conditions should not preclude their use.

Calcium-Channel Blockers

Calcium-channel blockers, which cause coronary and systemic arterial vasodilation, increase coronary arterial blood flow and lower systemic arterial pressure. The nondihydropyridine calcium-channel blockers, diltiazem and verapamil, slow heart rate and are recommended for the patient with a contraindication to a β-adrenergic blocker or persistent or recurrent symptoms despite treatment with nitroglycerin or a β-blocker. Oral diltiazem (30 to 90 mg four times daily of the short-acting preparation or up to 360 mg once daily of the long-acting preparation) is the preferred agent because studies have shown that it reduces the incidence of myocardial ischemia and recurrent MI in patients with NSTE-ACS.[4] Diltiazem is contraindicated in patients with left ventricular dysfunction or pulmonary vascular congestion. Caution should be exercised when combining a β-blocker with diltiazem because the two drugs may act synergistically to depress left ventricular systolic function as well as sinus and atrioventricular nodal conduction. Short-acting nifedipine should not be administered to the patient with ACS unless the patient is already receiving a β-blocker because it may increase the risk of death. The risks and benefits of long-acting dihydropyridines in patients with NSTE-ACS are undefined.

Antiplatelet Agents

In patients with NSTE-ACS, *aspirin* (Chapter 36), 75 to 1300 mg daily, reduces the risk of death or MI by roughly 50%.[5] Because high-dose aspirin increases the risk of gastrointestinal bleeding but is no more efficacious than low-dose aspirin, the patient should be treated with 75 to 162 mg daily, unless contraindicated (i.e., the patient has an aspirin allergy or active bleeding). Once initiated, aspirin therapy should be continued indefinitely.

Clopidogrel (Chapter 37) is a thienopyridine that blocks the $P2Y_{12}$ adenosine diphosphate (ADP) receptor, thereby diminishing ADP-mediated platelet activation. Its antiplatelet activity is synergistic with aspirin because the two agents inhibit different platelet-activating pathways. Clopidogrel is a prodrug that must be metabolized by the cytochrome P-450 system to the active form. Polymorphisms in the cytochrome P-450 isoform CYP2C19, present in 15 to 20% of individuals, slow metabolism of the prodrug to the active form, thereby reducing the magnitude of platelet inhibition.

In patients with NSTE-ACS, the addition of clopidogrel to aspirin reduces the composite end point of cardiovascular death, nonfatal MI, or stroke by 20% (2.1% reduction in absolute risk) compared with treatment with aspirin alone.[6] The benefit of an aspirin-clopidogrel combination is seen as early as 24 hours after drug initiation and persists for the 12 months of the study; an increase in minor bleeding is observed in those receiving both agents.

Dual antiplatelet therapy (aspirin and clopidogrel) should be administered routinely to the ACS patient, unless contraindicated. The patient who is allergic to or intolerant of aspirin should receive clopidogrel alone. Because maximal platelet inhibition occurs 3 to 5 days after clopidogrel is initiated unless a large dose is given initially, the patient should receive a loading dose of 300 to 600 mg, then 75 mg daily for at least 1 year.

Clopidogrel treatment increases the risk of bleeding in the patient undergoing CABG. Clopidogrel should not be initiated in likely candidates for CABG; if already begun, it should be discontinued 5 days before the planned surgery. Drugs that are potent inhibitors of the CYP2C19 enzyme should not be administered with clopidogrel because they affect the metabolism to its active form and reduce its antiplatelet effects. Such drugs include omeprazole, esomeprazole, cimetidine, fluconazole, ketoconazole, voriconazole, etravirine, felbamate, fluoxetine, and fluvoxamine. For clopidogrel-treated patients who need antacid therapy, treatment with ranitidine or pantoprazole is recommended.

Prasugrel (Chapter 37) is another thienopyridine with a greater antiplatelet effect and a more rapid onset of action than clopidogrel. In patients with ACS who are referred for PCI, prasugrel in combination with aspirin reduces ischemic events (i.e., a combination of cardiovascular death, nonfatal MI, and stroke) by 20% compared with concomitant clopidogrel and aspirin (2.2% absolute risk reduction) therapy.[7] However, this benefit is obtained at a 0.5% increased risk of life-threatening bleeding and a 0.3% increased risk of fatal bleeding. At present, prasugrel is approved for use in the ACS patient who is referred for PCI. In combination with aspirin, it is administered as a 60 mg oral loading dose followed by a 10 mg daily maintenance dose. Because prasugrel-associated bleeding complications are highest in patients with a previous stroke or transient ischemic attack, age older than 75 years, or a body weight of less than 60 kg, its use should be avoided in the patient with any of these features.

Glycoprotein IIb/IIIa inhibitors (Chapter 37) block platelet aggregation in response to all potential agonists and are the most potent antiplatelet agents available. Three glycoprotein IIb/IIIa inhibitors, each of which must be administered parenterally, are available: abciximab is the Fab fragment of a monoclonal antibody to the receptor; eptifibatide is a peptide; and tirofiban is a peptidomimetic molecule.

Glycoprotein IIb/IIIa inhibitors reduce the incidence of recurrent ischemic events in patients with NSTE-ACS who undergo PCI, but not in patients who are managed with medical therapy alone. If a glycoprotein IIb/IIIa inhibitor is administered, it should be initiated at the time of angiography because previously published studies have shown that its routine administration beforehand carries an increased bleeding risk and no improvement in outcomes.[8] The glycoprotein IIb/IIIa inhibitor infusion (see Table 72-3) typically is continued for 12 to 24 hours following PCI.

Anticoagulants

Anticoagulant therapy should be administered to all patients with ACS unless a contraindication, such as active bleeding, is present. For the patient in whom a noninvasive, ischemia-guided management strategy is selected, treatment with unfractionated heparin, low-molecular-weight heparin (LMWH), or fondaparinux is appropriate, with fondaparinux recommended for the patient at increased risk of bleeding. For the patient in whom an invasive management strategy is selected, unfractionated heparin and LMWH are the agents of choice. Bivalirudin may be preferred in the individual undergoing PCI, but it should not be used in the initial management of the patient with ACS.

Heparin

Unfractionated heparin (Chapter 37) exerts its anticoagulant effect by accelerating the action of circulating antithrombin and prevents thrombus propagation but does not lyse existing thrombi. In the patient with NSTE-ACS, the addition of heparin to aspirin reduces the rate of in-hospital ischemic events (i.e., death or MI) by 33%.[9]

Unfractionated heparin should be initiated with an intravenous bolus of 60 U/kg, followed by a continuous infusion of approximately 12 U/kg/hour (maximum, 1000 U/hour), adjusted to maintain the activated partial thromboplastin time (aPTT) at 1.5 to 2.5 times control (i.e., 50 to 70 seconds) or a heparin concentration at 0.3 to 0.7 U/mL (by anti–factor Xa determinations). The infusion should be continued for 48 hours or until revascularization is performed, whichever occurs sooner. Frequent monitoring of the aPTT or heparin concentration is necessary because the anticoagulant response to a standard dose of unfractionated heparin varies widely among individuals; even when a weight-based nomogram (see Table 81-4 in Chapter 81) is followed, the aPTT is outside the therapeutic range more than one third of the time.

Mild thrombocytopenia occurs in 10 to 20% of patients treated with unfractionated heparin. In 1 to 5% of patients, a more severe form of thrombocytopenia develops. This antibody-mediated response usually occurs 4 to 14 days after the initiation of treatment, although it may become manifest far more

quickly in the subject who received heparin within the preceding 6 months. Such antibody-mediated thrombocytopenia is associated with thromboembolic sequelae in 30 to 80% of subjects.

Low-Molecular-Weight Heparin

LMWHs (Chapter 37), which are fragments of unfractionated heparin, exert a more predictable anticoagulant effect, have a longer half-life, and are less likely to cause thrombocytopenia compared with unfractionated heparin. Because they provide predictable and sustained anticoagulation with once- or twice-daily subcutaneous administration, monitoring of their anticoagulant effect is not required.

LMWH is superior to unfractionated heparin in preventing MI or death during hospitalization in patients with NSTE-ACS who have elevated serum cardiac biomarkers as well as in those considered to be at high risk for recurrent ischemia (i.e., the subject with three or more TIMI risk factors).[10] In the low-risk subject, unfractionated heparin and LMWH have similar efficacy.[10] In the patient who is likely to undergo CABG surgery during the hospitalization, unfractionated heparin is preferred over LMWH because its anticoagulant effects can be more readily reversed with protamine.

Two LMWHs are approved for the treatment of the patient with NSTE-ACS, enoxaparin and dalteparin. The dose of enoxaparin is 1 mg/kg subcutaneously twice daily, and the dose of dalteparin is 120 IU/kg (maximum, 10,000 IU) subcutaneously twice daily. Therapy should be continued for the duration of the hospitalization, up to 8 days, or until revascularization is performed (whichever occurs first). In obese (>120 kg), thin (<60 kg), or renally impaired (creatinine clearance < 30 mL/minute) patients, the LMWH dose should be adjusted to achieve an anti–factor Xa concentration of 0.5 to 1.5 IU/mL 4 to 6 hours after drug administration.

LMWH should be avoided in the patient with a history of heparin-induced thrombocytopenia. In the patient with renal failure, treatment with LMWH has been associated with the development of hyperkalemia.

Fondaparinux

Fondaparinux (Chapter 37), which is a selective factor Xa inhibitor, does not require dose adjustment and monitoring. Fondaparinux does not cause thrombocytopenia. Fondaparinux is as effective as enoxaparin in preventing ischemic cardiac events but with 50% fewer major bleeding episodes (from 4.1% to 2.2%).[11] An increased incidence of catheter-related thrombosis has been reported following fondaparinux treatment, so it is not recommended for the patient who is likely to undergo coronary angiography. Thus, fondaparinux is a desirable anticoagulant for the patient with ACS who is managed with a noninvasive approach, especially if he or she is at higher risk of a bleeding complication with anticoagulant therapy, but not for other patients.

For the patient with ACS, fondaparinux is administered as a 2.5-mg subcutaneous injection once daily for up to 5 days or until hospital discharge. Its use is contraindicated in patients with severe renal impairment and in those who weigh 50 kg or less, and it should not be used as the sole anticoagulant during a PCI.

Bivalirudin

Bivalirudin, a direct thrombin inhibitor, is currently recommended as an alternative anticoagulant for patients undergoing PCI. It has not been tested in the patient with ACS who is managed with an ischemia-guided strategy. Hence, the administration of bivalirudin in a setting other than the cardiac catheterization laboratory is not recommended. In the patient undergoing PCI, bivalirudin (0.75 mg/kg intravenous bolus followed by an infusion of 1.75 mg/kg/hr for up to 4 hours after the PCI) is as effective as combination heparin and glycoprotein IIb/IIIa inhibitor therapy in preventing ischemic events, but it causes fewer major bleeding episodes.[12] Bivalirudin is the anticoagulant of choice for the patient with ACS who has heparin-induced thrombocytopenia.

Statins

Prompt initiation of statin therapy is recommended in all patients with NSTE-ACS to promote plaque stabilization and to restore endothelial function. Moreover, when statin therapy is initiated during the patient's hospitalization (rather than at hospital discharge), long-term medical compliance is substantially improved. In the absence of contraindications, high-dose atorvastatin (80 mg daily) should be given orally to the patient with NSTE-ACS, regardless of the baseline serum LDL cholesterol concentration; a lower dose is not as effective in reducing ischemic events.[13]

Recurrent or Refractory Unstable Angina

In most patients hospitalized with NSTE-ACS, symptoms do not recur after the institution of appropriate antianginal therapy. The occasional patient with continued or recurrent chest pain despite optimal medical therapy is at high risk for an MI. For the patient with refractory myocardial ischemia or hemodynamic instability despite optimal medical therapy, intraaortic balloon counterpulsation can reduce the ischemic episodes until revascularization can be performed. Intra-aortic balloon function is synchronized with the patient's ECG so that it inflates during diastole and deflates during systole, thereby augmenting coronary arterial blood flow and reducing myocardial oxygen demand by decreasing afterload. Intra-aortic balloon counterpulsation causes lower limb ischemia in approximately 3% of patients in whom the device is placed, but this complication usually resolves with its removal.

Coronary Revascularization

Coronary revascularization is performed to relieve angina that is persistent or recurrent despite optimal medical therapy, to prevent recurrent ischemia or MI in patients at high risk for a subsequent ischemic event, and to improve survival in patients with suitable anatomy.

Coronary revascularization is successful in relieving symptoms in 90% of the patients with angina refractory to medical therapy. Whether coronary bypass surgery or PCI is the more appropriate method of revascularization is determined by the location and severity of coronary arterial stenoses and the presence of comorbid medical conditions that may affect the performance or safety of the revascularization procedure.

The patient who has been rendered symptom free with optimal medical therapy should undergo an assessment to determine whether he or she is at high risk or relatively low risk of sustaining a cardiac ischemic event (death, MI, or recurrent ischemia) in the ensuing days, weeks, and months and a bleeding complication from intensive medical therapy or an invasive cardiac procedure. Patients who are at low risk of having an ischemic event (those with a normal serum troponin concentration, age less than 75 years, and zero, one, or two TIMI risk variables) should be evaluated noninvasively for inducible ischemia before hospital discharge. If the patient has spontaneous or provocable ischemia, coronary angiography and, if appropriate, revascularization should be performed.

The ACS patient with a detectable serum troponin concentration, age more than 75 years, or three or more TIMI risk variables is considered to be high risk and should be referred for routine coronary angiography and revascularization (if appropriate) during the hospitalization because this management strategy reduces the incidence of subsequent ischemic cardiac events.[3,14] In most subjects, early (within 24 hours of hospitalization) invasive therapy is no better at preventing death, MI, or stroke than somewhat delayed (median, 50 hours) invasive management, although it is associated with a modest decrease in the occurrence of recurrent ischemia.[3] In contrast, in the one third of subjects considered to be very high risk (GRACE risk score of >140, corresponding to an incidence of in-hospital death or MI of >20%), an early invasive management strategy is superior to a delayed strategy in reducing the incidence of death, MI, or stroke.[3]

The patient with clinical features or noninvasive test results suggestive of severe coronary artery disease (i.e., left ventricular dysfunction, hemodynamic instability, life-threatening ventricular arrhythmias, or extensive inducible ischemia) should be referred for coronary angiography to determine whether left main or three-vessel coronary arterial disease is present because patients with these coronary anatomic findings derive a survival benefit with coronary revascularization compared with medical therapy (Chapter 74).

Complications

Patients with NSTE-ACS can develop recurrent ischemic events or any of the complications associated with ST segment elevation MI, including arrhythmias, heart failure, and mechanical complications (Chapter 73). However, the acute complications other than recurrent ischemia occur less often in subjects with NSTE-ACS because the amount of myocardial damage usually is less.

Because intensive medical therapy in conjunction with invasive management can lead to life-threatening bleeding complications, the patient's risk of such should be assessed before these therapies are instituted. Female gender, older age, renal insufficiency, low body weight, tachycardia, systolic arterial pressure, hematocrit, and diabetes mellitus predict an increased risk of major bleeding, often due to excessive dosing of antiplatelet or anticoagulant agents. The bleeding risk can be estimated with the tool available at *www.crusadebleedingscore.org*.

Integrated Approach to Treatment

Although the treatment of the subject with NSTE-ACS should be individualized, taking into account the specific features of the disease and the particular circumstances of the patient, algorithms nonetheless provide a useful framework (Fig. 72-3).

NSTE-ACS is an acute episode related to one active culprit lesion, but the patient often has diffuse atherosclerosis. Smoking cessation (Chapter 31), cholesterol lowering (Chapter 213), control of blood pressure (Chapter 67), and diabetes mellitus (Chapters 236 and 237) are important long-term prevention strategies. Maintaining compliance long-term with medical therapy appears to reduce the risk of a future ischemic event by up to 80%.

PROGNOSIS

Because the number of ECG leads demonstrating ST segment depression and the magnitude of such depression are indicative of the extent and severity of myocardial ischemia and MI, it is not surprising that ST segment depression correlates with the patient's prognosis. Compared with subjects without

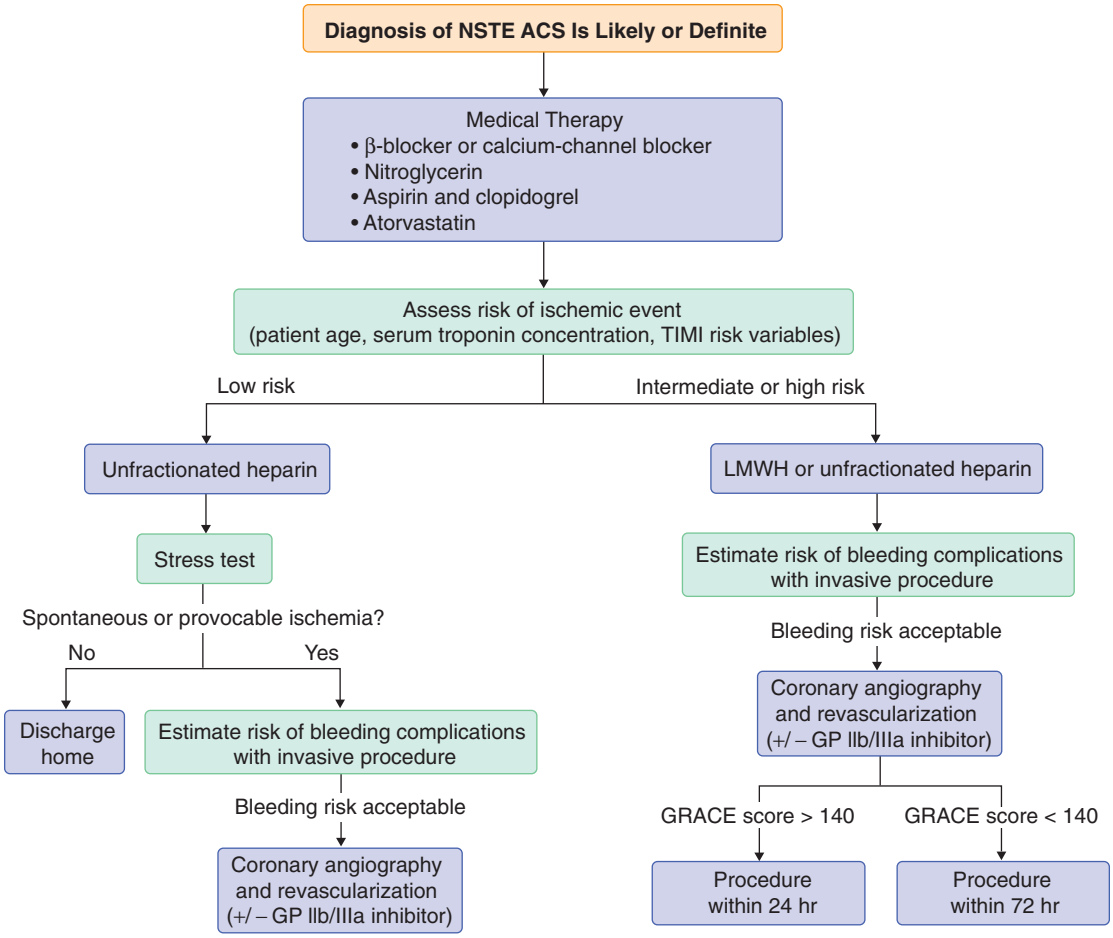

FIGURE 72-3. Approach to the patient with acute coronary syndrome (ACS). Low-risk patients have age < 75 years, no elevation in serum troponin concentration, and two or fewer Thrombolysis in Myocardial Infarction (TIMI) risk variables. Intermediate- or high-risk patients are those with age > 75 years, elevated serum troponin concentration, or three or more TIMI risk variables. The Global Registry of Acute Coronary Events (GRACE) score is available at *www.outcomes-umassmed.org/grace*. GP = glycoprotein; LMWH = low-molecular-weight heparin; NSTE = non–ST segment elevation.

ST segment depression, the patient with NSTE-ACS who has ST segment depression of 1 mm or greater in two or more leads is almost four times as likely to die within 1 year, and the patient with ST segment depression of 2 mm or greater in magnitude is almost six times as likely to die within 1 year. If ST segment depression of 2 mm or greater is present in more than one region of the ECG, the mortality is increased ten-fold. Even the 20% of patients with ACS who have only 0.5 to 1 mm of ST segment depression have an adverse prognosis. Patients with ST segment depression also have a higher risk for subsequent cardiac events compared with patients with only T wave inversion (>1 mm).

The magnitude of the serum troponin concentration predicts short-term (30 days) and long-term (1 year) risks of recurrent MI and death, independent of ECG abnormalities or markers of inflammatory activity. C-reactive protein measured with a highly sensitive assay, which is a widely used marker of inflammation, has no role in the diagnosis of ACS but is predictive of long-term (6 months) mortality among patients with troponin-negative NSTE-ACS. Elevated levels of natriuretic peptides (B-type natriuretic peptide [BNP] or its N-terminal prohormone [NT-proBNP]) are associated with a three- to five-fold increased mortality in patients with NSTE-ACS, although they have limited value for diagnosis, initial risk stratification, and selection of an initial management strategy. Natriuretic peptide concentrations measured a few days after the onset of symptoms have better predictive value than those measured at the time of hospitalization. In patients with NSTE-ACS, a simultaneous assessment of troponin, hsCRP, and BNP is superior to a single biomarker assessment at predicting short-term (in-hospital and 30-day) outcome.

During the past two decades, the prognosis of patients with ACS has improved dramatically with the introduction of more effective medical therapy and revascularization techniques. In contrast to individuals with ST segment elevation MI, in whom most events occur before or shortly after presentation to the hospital, patients with NSTE-ACS continue to have these events during the ensuing days, weeks, and months. Although in-hospital mortality is higher in patients with ST segment elevation MI than among those with NSTE-ACS (7 vs. 5%, respectively), the mortality rates at 6 months are similar for the two conditions (12 vs. 13%, respectively). During long-term follow-up of patients hospitalized with ACS, rates of death are actually higher in those with NSTE-ACS than in those with ST segment elevation MI, with a two-fold difference after 4 years. As a result, treatment strategies for NSTE-ACS should address the issues related to both the acute event and longer-term treatment.

ST SEGMENT ELEVATION ACUTE MYOCARDIAL INFARCTION AND COMPLICATIONS OF MYOCARDIAL INFARCTION

JEFFREY L. ANDERSON

DEFINITION

Conceptually, myocardial infarction (MI) is myocardial necrosis caused by ischemia. Practically, MI can be diagnosed and evaluated by clinical, electrocardiographic, biochemical, radiologic, and pathologic methods. Technologic advances in detecting much smaller amounts of myocardial necrosis than previously possible (e.g., by troponin determinations) have required a redefinition of MI. Given these developments, the term *MI* now should be qualified with regard to size, precipitating circumstance, and timing. This chapter focuses on acute MI associated with ST segment elevation on the electrocardiogram (ECG). This category of acute MI is characterized by profound ("transmural") acute myocardial ischemia affecting relatively large areas of myocardium. The underlying cause essentially always is *complete* interruption of regional myocardial blood flow (resulting from coronary occlusion, usually atherothrombotic) (Chapter 70). This clinical syndrome should be distinguished from non–ST segment elevation MI, in which the blockage of coronary flow is incomplete and for which different acute therapies are appropriate (Chapter 72).

EPIDEMIOLOGY

Cardiovascular disease is responsible for almost one half of all deaths in the United States and other developed countries and for one fourth of deaths in the developing world (Chapter 51). By 2020, cardiovascular disease will cause one of every three deaths worldwide. Cardiovascular disease causes almost 1 million deaths in the United States each year; it accounts for 37% of all deaths and contributes to 58% of deaths. Annually, an estimated 1.2 million U.S. residents suffer a fatal or nonfatal acute MI. Coronary heart disease, the leading cause of cardiovascular death, underlies or is a contributing cause of 650,000 deaths annually. Half of coronary heart disease deaths (250,000/year) are directly related to acute MI, and at least half of these acute MI–related deaths occur within 1 hour of onset of symptoms and before patients reach a hospital emergency department.

More than 5 million people visit emergency departments in the United States each year for evaluation of chest pain and related symptoms, and almost 1.5 million are hospitalized for an acute coronary syndrome (Chapter 50). The presence of ST segment elevation or new left bundle branch block (LBBB) on the ECG distinguishes patients with acute MI who require consideration of immediate recanalization therapy from other patients with an acute coronary syndrome (non–ST segment elevation MI/unstable angina; Chapter 72). Changing demographics, lifestyles, and medical therapies have led to a decrease in the ratio of ST segment elevation MI to non–ST segment elevation acute coronary syndromes over the past 10 to 15 years, so ST segment elevation MI now accounts for about 30% of all MIs. However, ST segment elevation MI is associated with greater in-hospital (but not post-hospital) mortality than non–ST segment elevation MI, and it remains an important contributor to total population mortality.

PATHOBIOLOGY

Erosion, fissuring, or rupture of vulnerable atherosclerotic plaques has been determined to be the initiating mechanism of coronary thrombotic occlusion, thereby precipitating intraplaque hemorrhage, coronary spasm, and occlusive luminal thrombosis (Chapter 70). Plaque rupture most frequently occurs in lipid-laden plaques with an endothelial cap weakened by internal collagenase (metalloproteinase) activity derived primarily from macrophages. These macrophages are recruited to the plaque from blood monocytes responding to inflammatory mediators and adhesion molecules.

With plaque rupture, elements of the blood stream are exposed to the highly thrombogenic plaque core and matrix containing lipid, tissue factor, and collagen. Platelets adhere, become activated, and aggregate; vasoconstrictive and thrombogenic mediators are secreted; vasospasm occurs; thrombin is generated and fibrin formed; and a partially or totally occlusive platelet- and fibrin-rich thrombus is generated. When coronary flow is occluded, electrocardiographic ST segment elevation occurs (ST segment elevation acute MI). Partial occlusion, occlusion in the presence of collateral circulation, and distal coronary embolization result in unstable angina or non–ST segment elevation MI (Chapter 72). Ischemia from impaired myocardial perfusion causes myocardial cell injury or death, ventricular dysfunction, and cardiac arrhythmias.

Although most MIs are caused by atherosclerosis, occasional patients can develop complete coronary occlusions owing to coronary emboli, in situ thrombosis, vasculitis, primary vasospasm, infiltrative or degenerative diseases, diseases of the aorta, congenital anomalies of a coronary artery, or trauma (Table 73-1). In a canine model of coronary occlusion and recanalization, myocardial cell death begins within 15 minutes of occlusion and proceeds rapidly in a wave front from endocardium to epicardium. Partial myocardial salvage can be achieved by releasing the occlusion within 3 to 6 hours; the degree of salvage is inversely proportional to the duration of ischemia and occurs in a reverse wave front from epicardium to endocardium. The extent of myocardial necrosis can also be altered by modification of metabolic demands and collateral blood supply. The temporal dynamic of infarction in human disease, although more complex, is generally similar.

CLINICAL MANIFESTATIONS

Traditionally, the diagnosis of acute MI has rested on the triad of ischemic-type chest discomfort, ECG abnormalities, and elevated serum cardiac markers. Acute MI was considered present when at least two of the three were present. With their increasing sensitivity and specificity, serum cardiac markers (e.g., troponin I [TnI] or troponin T [TnT]) have assumed a dominant role in confirming the diagnosis of acute MI in patients with suggestive clinical or ECG features.

History

Ischemic-type chest discomfort is the most prominent clinical symptom in most patients with acute MI (see Table 50-1 in Chapter 50). The discomfort is characterized by its quality, location, duration, radiation, and precipitating and relieving factors. The discomfort associated with acute MI is qualitatively similar to that of angina pectoris but more severe. It often is perceived as heavy, pressing, crushing, squeezing, bandlike, viselike, strangling, constricting, aching, or burning; it rarely is perceived as sharp pain and generally not as stabbing pain (Chapters 50 and 71).

The primary location of typical ischemic pain is most consistently retrosternal, but it also can present left parasternally, left precordially, or across the anterior chest (Chapter 50). Occasionally, discomfort is

TABLE 73-1 CONDITIONS OTHER THAN CORONARY ATHEROSCLEROSIS THAT CAN CAUSE ACUTE MYOCARDIAL INFARCTION

Coronary emboli	Causes include aortic or mitral valve lesions, left atrial or ventricular thrombi, prosthetic valves, fat emboli, intracardiac neoplasms, infective endocarditis, and paradoxical emboli
Thrombotic coronary artery disease	Can occur with oral contraceptive use, sickle cell anemia and other hemoglobinopathies, polycythemia vera, thrombocytosis, thrombotic thrombocytopenic purpura, disseminated intravascular coagulation, antithrombin III deficiency and other hypercoagulable states, macroglobulinemia and other hyperviscosity states, multiple myeloma, leukemia, malaria, and fibrinolytic system shutdown secondary to impaired plasminogen activation or excessive inhibition
Coronary vasculitis	Seen with Takayasu's disease, Kawasaki disease, polyarteritis nodosa, lupus erythematosus, scleroderma, rheumatoid arthritis, and immune-mediated vascular degeneration in cardiac allografts
Coronary vasospasm	Can be associated with variant angina, nitrate withdrawal, cocaine or amphetamine abuse, and angina with "normal" coronary arteries
Infiltrative and degenerative coronary vascular disease	Can result from amyloidosis, connective tissue disorders (e.g., pseudoxanthoma elasticum), lipid storage disorders and mucopolysaccharidoses, homocystinuria, diabetes mellitus, collagen vascular disease, muscular dystrophies, and Friedreich's ataxia
Coronary ostial occlusion	Associated with aortic dissection, luetic aortitis, aortic stenosis, and ankylosing spondylitis syndromes
Congenital coronary anomalies	Including Bland-White-Garland syndrome of anomalous origin of the left coronary artery from the pulmonary artery, left coronary artery origin from the anterior sinus of Valsalva, coronary arteriovenous fistula or aneurysms, and myocardial bridging with secondary vascular degeneration
Trauma	Associated with and responsible for coronary dissection, laceration, or thrombosis (with endothelial cell secondary to trauma such as angioplasty) and with radiation and cardiac contusion
Augmented myocardial oxygen requirements exceeding oxygen delivery	Encountered with aortic stenosis, aortic insufficiency, hypertension with severe left ventricular hypertrophy, pheochromocytoma, thyrotoxicosis, methemoglobinemia, carbon monoxide poisoning, shock, and hyperviscosity syndromes

predominantly perceived in the anterior neck, jaw, arms, or epigastrium. It generally is somewhat diffuse; highly localized pain (finger point) is rarely angina or acute MI. The most characteristic pattern of radiation is to the left arm, but the right arm or both arms can be involved. The shoulders, neck, jaw, teeth, epigastrium, and interscapular areas also are sites of radiation. Discomfort above the jaws or below the umbilicus is not typical of acute MI. Associated symptoms often include nausea, vomiting, diaphoresis, weakness, dyspnea, restlessness, and apprehension.

The discomfort of acute MI is more severe and lasts longer (typically 20 minutes to several hours) than angina, and it is not reliably relieved by rest or nitroglycerin. The onset of acute MI usually is unrelated to exercise or other apparent precipitating factors. Nevertheless, acute MI begins during physical or emotional stress and within a few hours of arising more frequently than explained by chance.

It is estimated that at least 20% of acute MIs are painless ("silent") or atypical (unrecognized). Elderly patients and patients with diabetes are particularly prone to painless or atypical MI, which occurs in as many as one third to one half of such patients. Because the prognosis is worse in elderly patients and in those patients with diabetes, diagnostic vigilance is required. In these patients, acute MI can present as sudden dyspnea (which can progress to pulmonary edema), weakness, lightheadedness, nausea, and vomiting. Confusional states, sudden loss of consciousness, a new rhythm disorder, and an unexplained fall in blood pressure are other uncommon presentations. The differential diagnosis of ischemic chest discomfort also should include gastrointestinal disorders (e.g., reflux esophagitis; Chapter 140), musculoskeletal pain (e.g., costochondritis), anxiety or panic attacks, pleurisy or pulmonary embolism (Chapter 98), and acute aortic dissection (see Table 50-2 in Chapter 50 and Chapter 78).

Physical Examination

No physical findings are diagnostic or pathognomonic of acute MI. The physical examination can be entirely normal or may reveal only nonspecific abnormalities. An S_4 gallop frequently is found if carefully sought. Blood pressure often is initially elevated, but it may be normal or low. Signs of sympathetic hyperactivity (tachycardia, hypertension, or both) often accompany anterior wall MI, whereas parasympathetic hyperactivity (bradycardia, hypotension, or both) is more common with inferior wall MI.

The examination is best focused on an overall assessment of cardiac function. Adequacy of vital signs and peripheral perfusion should be noted. Signs of cardiac failure, both left and right sided (e.g., S_3 gallop, pulmonary congestion, elevated neck veins) should be sought, and observation for arrhythmias and mechanical complications (e.g., new murmurs) is essential. If hypoperfusion is present, determination of its primary cause (e.g., hypovolemia, right heart failure, left heart failure) is critical to management.

DIAGNOSIS

Electrocardiogram

In patients with a possible acute MI, an ECG must be obtained immediately. Although the initial ECG is neither perfectly specific nor perfectly sensitive in all patients who develop acute ST segment elevation myocardial infarction (STEMI), it plays a critical role in initial stratification, triage, and management (Chapter 50). In an appropriate clinical setting, a pattern of regional ECG ST segment elevation suggests coronary occlusion causing marked myocardial ischemia; hospital admission is indicated with triage to the coronary care unit (CCU). An emergency recanalization strategy (primary angioplasty or fibrinolysis) should be used unless it is contraindicated. Other ECG patterns (ST segment depression, T wave inversion, nonspecific changes, normal ECG) in association with ischemic chest discomfort are consistent with a non–ST segment elevation acute coronary syndrome (non–ST segment elevation MI or unstable angina) and are treated with different triage and initial management strategies (Chapter 72).

Electrocardiographic Evolution

Serial ECG tracings improve the sensitivity and specificity of the ECG for the diagnosis of acute MI and assist in assessing the outcomes of therapy. When typical ST segment elevation persists for hours and is followed within hours to days by T wave inversions and Q waves, the diagnosis of acute MI can be made with virtual certainty. The ECG changes in ST segment elevation acute MI evolve through three overlapping phases: (1) hyperacute or early acute, (2) evolved acute, and (3) chronic (stabilized).

Early Acute Phase

This earliest phase begins within minutes, persists, and evolves over hours. T waves increase in amplitude and widen over the area of injury (hyperacute pattern). ST segments evolve from concave to a straightened to a convex upward pattern (acute pattern). When prominent, the acute injury pattern of blended ST-T waves can take on a tombstone appearance (Figs. 73-1 and 73-2). ST segment depressions that occur in leads opposite those with ST segment elevation are known as *reciprocal changes* and are associated with larger areas of injury and a worse prognosis but also with greater benefits from recanalization therapy.

Other causes of ST segment elevation must be considered and excluded. These conditions include pericarditis (Chapter 77), left ventricular (LV) hypertrophy with J point elevation, and normal variant early repolarization (Chapter 54). Pericarditis (or perimyocarditis) is of particular concern because it can mimic acute MI clinically, but fibrinolytic therapy is *not* indicated and can be hazardous.

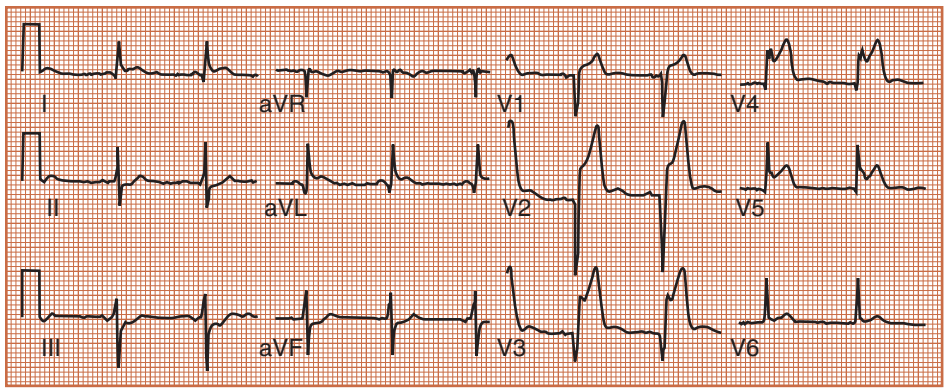

FIGURE 73-1. Electrocardiographic tracing shows an acute anterolateral myocardial infarction. Note ST segment elevation in leads I, L, and V_1 to V_6 with Q waves in V_1 to V_4.

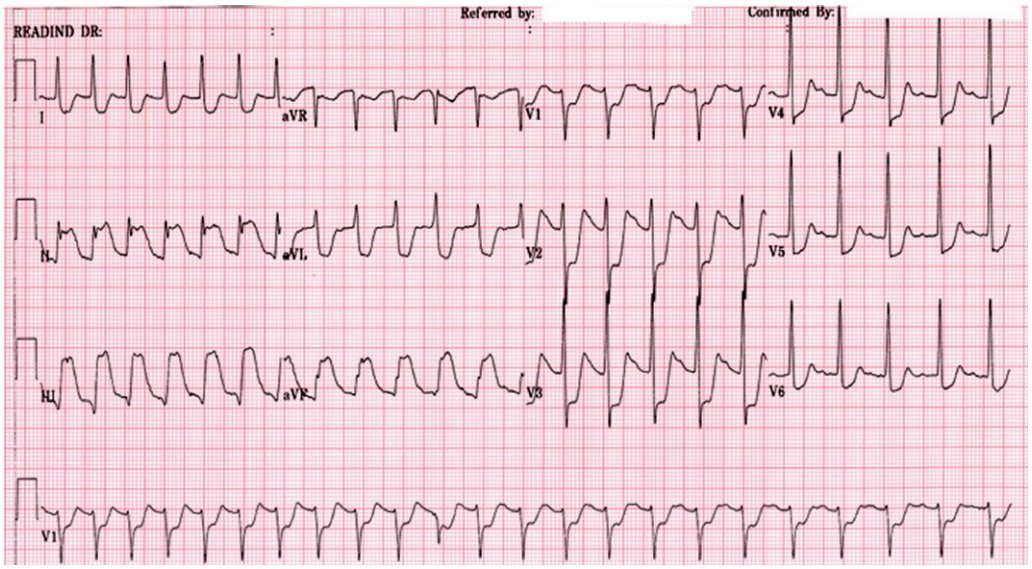

FIGURE 73-2. Electrocardiographic tracing shows an acute inferoposterior myocardial infarction.

Evolved Acute Phase

During the second phase, ST segment elevation begins to regress, T waves in leads with ST segment elevation become inverted, and pathologic Q or QS waves become fully developed (>0.03-second duration or depth >30% of R wave amplitude, or both).

Chronic Phase

Resolution of ST segment elevation is quite variable. It is usually complete within 2 weeks of inferior MI, but it can be delayed further after anterior MI. Persistent ST segment elevation, often seen with a large anterior MI, is indicative of a large area of akinesis, dyskinesis, or ventricular aneurysm. Symmetrical T wave inversions can resolve over weeks to months or can persist for an indefinite period; hence, the age of an MI in the presence of T wave inversions is often termed *indeterminate.* Q waves usually do not resolve after anterior MI but often disappear after inferior wall MI.

Early recanalization therapy accelerates the time course of ECG changes so that, on coronary recanalization, the pattern can evolve from acute to chronic over minutes to hours instead of days to weeks. ST segments recede rapidly, T wave inversions and losses of R wave occur earlier, and Q waves may not develop or progress and occasionally may regress. Indeed, failure of ST segment elevation to resolve by more than 50 to 70% within 1 to 2 hours suggests failure of fibrinolysis and should prompt urgent angiography for "rescue angioplasty."

True Posterior Myocardial Infarction and Left Circumflex Myocardial Infarction Patterns

"True posterior" MI presents a mirror-image pattern of ECG injury in leads V_1 to V_2 to V_4 (Fig. 73-2). Anatomically, the location of injury of "true posterior MI" by magnetic resonance imaging actually involves portions of the *lateral* left ventricular wall and is typically caused by occlusion of a nondominant left circumflex artery. The acute phase is characterized by ST segment depression, rather than ST segment elevation. The evolved and chronic phases show increased R wave amplitude and widening instead of Q waves. Recognition of a true posterior acute MI pattern is challenging but important because the diagnosis should lead to an immediate recanalization strategy. Extending the ECG to measure left posterior leads V_7 to V_9 increases sensitivity for detecting acute left circumflex–related injury patterns (i.e., ST segment elevation) with excellent specificity (Chapter 54). Other causes of prominent upright anteroseptal forces include right ventricular (RV) hypertrophy, ventricular preexcitation variants (Wolff-Parkinson-White syndrome; Chapter 64), and normal variants with early R wave progression. New appearance of these changes or the association with an acute or evolving inferior MI usually allows the diagnosis to be made.

Right Ventricular Infarction

Proximal occlusion of the right coronary artery before the acute marginal branch can cause RV as well as acute inferior MI in about 30% of cases. Because the prognosis and treatment of acute inferior MI differ in the presence of RV infarction, it is important to make this diagnosis. The diagnosis is assisted by obtaining right precordial ECG leads, which are routinely indicated for inferior acute MI (Chapter 54). Acute ST segment elevation of at least 1 mm (0.1 mV) in one or more of leads V_{4R} to V_{6R} is both sensitive and specific (>90%) for identifying acute RV injury, and Q or QS waves effectively identify RV infarction.

Diagnosis in the Presence of Bundle Branch Block

The presence of LBBB often obscures ST segment analysis in patients with suspected acute MI. The presence of a new (or presumed new) LBBB in association with clinical (and laboratory) findings suggesting acute MI is associated with high mortality; patients with new-onset LBBB benefit substantially from recanalization therapy and should undergo triage and treatment in the same way as patients with ST segment elevation MI. Certain ECG patterns, although relatively insensitive, suggest acute MI if present in

TABLE 73-2 CONDITIONS THAT CAN MIMIC ST SEGMENT ELEVATION MYOCARDIAL INFARCTION

Early repolarization with non-coronary chest pain
Myocarditis
Pericarditis
Takotsubo cardiomyopathy

the setting of LBBB: Q waves in two of leads I, aVL, V_5, V_6; R wave regression from V_1 to V_4; ST segment elevation of 1 mm or more in leads with a positive QRS complex; ST segment depression of 1 mm or more in leads V_1, V_2, or V_3; and ST segment elevation of 5 mm or more associated with a negative QRS complex. The presence of right bundle branch block (RBBB) usually does not mask typical ST-T wave or Q wave changes, except for rare cases of isolated true posterior acute MI, characterized by tall right precordial R waves and ST segment depressions.

Differential Diagnosis

Although ST-segment elevation MI is often an easy diagnosis to make based on the presentation and test results (see later), other considerations include acute pericarditis (Chapter 77), acute myocarditis (Chapter 60), stress-induced takotsubo syndrome (Chapter 60), and early repolarization (Table 73-2). All but early repolarization can be associated with abnormal biomarkers, but none is associated with a coronary occlusion. Early coronary angiography is advised when any of these conditions is suggested or when MI may be related to a cause other than atherosclerosis (see Table 73-1).

Serum Cardiac Markers

Ideal markers are not normally present in serum, become rapidly and markedly elevated during acute MI, and are not released from other injured tissues (see Table 73-2). The increasing sensitivity and specificity of serum cardiac markers, which are macromolecules (proteins) released from myocytes undergoing necrosis, have made them the "gold standard" for detection of myocardial necrosis. However, because of the 1- to 12-hour delay after the onset of symptoms before markers become detectable or diagnostic, and given laboratory delays even when markers are positive, the decision to proceed with an urgent recanalization strategy (primary angioplasty or fibrinolysis) must be based on the patient's clinical history and initial ECG (Chapter 50).

Troponins I and T

Troponins have replaced other markers because they are more specific in the setting of injuries to skeletal muscle or other organs and also are more sensitive in the setting of minimal myocardial injury. Cardiac-derived TnI (cTnI) and TnT (cTnT), proteins of the sarcomere, are not normally present in the blood with standard sensitivity assays and have amino acid sequences distinct from their skeletal muscle isoforms. With even small acute MIs, troponins increase to 20-fold or more above the lower limits of the assay, and elevations persist for several days.

The troponins generally are first detectable 2 to 4 hours after the onset of acute MI, are maximally sensitive at 8 to 12 hours, peak at 10 to 24 hours, and persist for 5 to 14 days. Their long persistence has allowed them to replace other markers for the diagnosis of acute MI in patients presenting late (>1 to 2 days) after symptoms. However, this persistence can obscure the diagnosis of an early recurrent MI, for which more rapidly cleared markers (i.e., CK-MB) are more useful. Clinically, cTnI and cTnT appear to be of approximately equivalent utility, except renal failure is more likely to be associated with false-positive elevations of cTnT than of cTnI.

Ultrasensitive troponin assays increase assay sensitivity and enable even earlier diagnosis. However, because troponins also may be present in low concentration in a number of nonischemic cardiovascular conditions, specificity for MI remains an issue.

Other Laboratory Tests

On admission, routine assessment of complete blood count and platelet count, standard blood chemistry studies, a lipid panel, and coagulation tests (prothrombin time, partial thromboplastin time) are useful. Results assist in assessing comorbid conditions and prognosis and in guiding therapy. Hematologic tests provide a useful baseline before initiation of antiplatelet, antithrombin, and fibrinolytic therapy or coronary angiography or angioplasty. Myocardial injury precipitates polymorphonuclear leukocytosis, commonly resulting in an elevation of white blood cell count of up to 12,000 to 15,000/μL, which appears within a few hours and peaks at 2 to 4 days. The metabolic panel provides a useful check on electrolytes, glucose, and renal function. On hospital admission or the next morning, a fasting lipid panel is recommended to assist in decision making for inpatient lipid lowering (e.g., statin therapy if low-density lipoprotein is greater than 70 mg/dL (Chapter 213). Unless carbon dioxide retention is suspected, finger oximetry is adequate to titrate oxygen therapy. The C-reactive protein level increases with acute MI, but its incremental prognostic value in the acute setting is unknown. B-type natriuretic peptide, which increases with ventricular wall stress and relative circulatory fluid overload, may provide useful incremental prognostic information in the setting of acute MI.

Imaging

A chest radiograph is the only imaging test *routinely* obtained on admission for acute MI. Although the chest radiograph is often normal, findings of pulmonary venous congestion, cardiomegaly, or widened mediastinum can contribute importantly to diagnosis and management decisions. For example, a history of severe, "tearing" chest and back pain in association with a widened mediastinum should raise the question of a dissecting aortic aneurysm (Chapter 78). In such cases, fibrinolytic therapy must be withheld pending more definitive diagnostic imaging of the aorta. Other noninvasive imaging (e.g., echocardiography [Chapter 55], cardiac nuclear scanning [Chapter 56], and other testing) is performed for evaluation of specific clinical issues, including suspected complications of acute MI. Coronary angiography (Chapter 57) is performed urgently as part of an interventional strategy for acute MI or later for risk stratification in higher-risk patients who are managed medically.

Echocardiography

Two-dimensional transthoracic echocardiography with color-flow Doppler imaging is the most generally useful noninvasive test obtained on admission or early in the hospital course (Chapter 55). Echocardiography efficiently assesses global and regional cardiac function and enables the clinician to evaluate suspected complications of acute MI. The sensitivity and specificity of echocardiography for regional wall motion assessment are high (>90%), although the age of the abnormality (new versus old) must be distinguished clinically or by ECG. Echocardiography is helpful in determining the cause of circulatory failure with hypotension (relative hypovolemia, LV failure, RV failure, or mechanical complication of acute MI). Echocardiography also can assist in differentiating pericarditis and perimyocarditis from acute MI. Doppler echocardiography is indicated to evaluate a new murmur and other suspected mechanical complications of acute MI (papillary muscle dysfunction or rupture, acute ventricular septal defect, LV free wall rupture with tamponade or pseudoaneurysm). Later in the course of acute MI, echocardiography may be used to assess the degree of recovery of stunned myocardium after recanalization therapy, the degree of residual cardiac dysfunction and indications for angiotensin-converting enzyme (ACE) inhibitors and other therapies for heart failure, and the presence of LV aneurysm and mural thrombus (requiring oral anticoagulants).

Radionuclide, Magnetic Resonance, and Other Imaging Studies

Radionuclide techniques generally are too time consuming and cumbersome for routine use in the acute setting. More commonly, they are used in risk stratification before or after hospital discharge to augment exercise or pharmacologic stress testing (Chapter 56). Thallium-201 and, increasingly, technetium-99m sestamibi (alone or together—dual isotope imaging) remain the most frequently used "cold spot" tracers to assess myocardial perfusion and viability, as well as infarct size, although additional tracers are becoming available. Infarct-avid tracers to identify, locate, and size recent myocardial necrosis are available but are rarely required for ST segment elevation MI. Computed tomography (Chapter 56) and magnetic resonance imaging (Chapter 56) can be useful to evaluate patients with a suspected dissecting aortic aneurysm and, together with positron emission tomography, for research purposes and in selected clinical applications such as for assessment of myocardial viability (infarct sizing). When the issue of a nonatherosclerotic cause of myocardial necrosis is raised (e.g., perimyocarditis simulating acute MI), contemporary multislice (e.g., 64-slice) coronary computed tomography (Chapter 56) can assess coronary artery disease qualitatively and semiquantitatively, and it can also distinguish other causes of chest pain syndromes (Chapters 50 and 56).

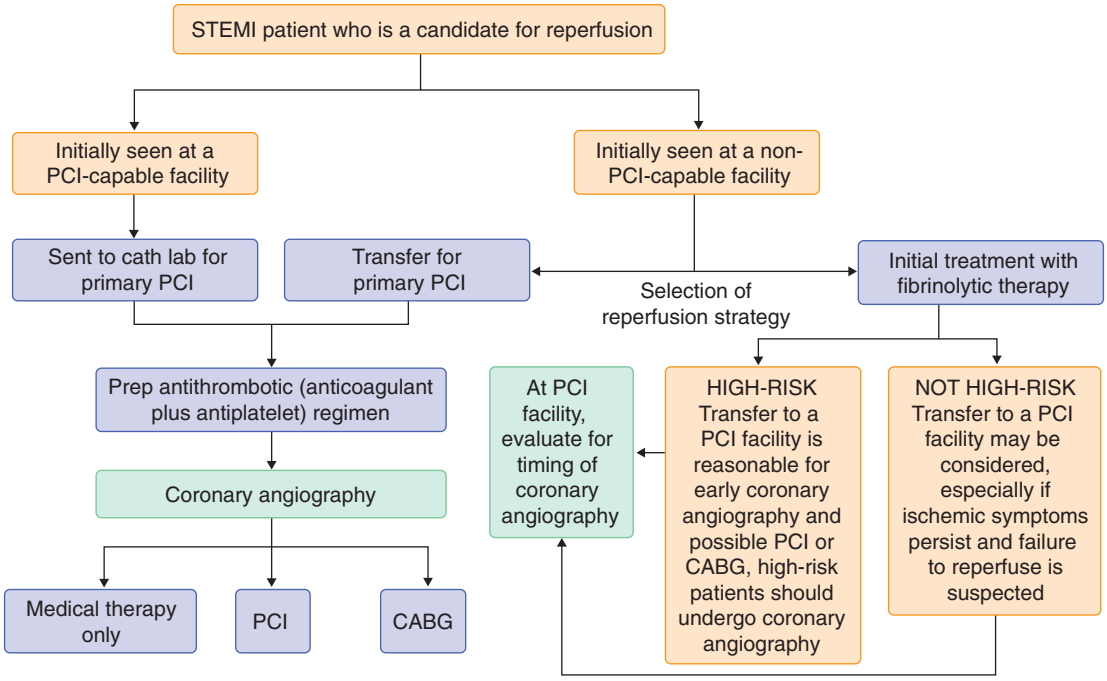

FIGURE 73-3. Evidence-based approach to percutaneous coronary intervention (PCI) and coronary artery bypass grafting (CABG) after ST segment elevation myocardial infarction (STEMI). (Adapted from Kushner FG, Hand M, Smith SC Jr, et al. 2009 Focused updates: ACC/AHA guidelines for the management of patients with ST-elevation myocardial infarction and the ACC/AHA/SCAI guidelines on percutaneous coronary intervention. *J Am Coll Cardiol.* 2009;54:2205-2241.)

TREATMENT

Rx

Assessment and Management

Prehospital Phase

More than one half of deaths related to acute MI occur within 1 hour of onset of symptoms and before the patient reaches a hospital emergency department. Most of these deaths are caused by ischemia-related ventricular fibrillation (VF) and can be reversed by defibrillation (Chapters 63 and 66). Rapid defibrillation allows resuscitation in 60% of patients when treatment is delivered by a bystander using an on-site automatic external defibrillator or by a first-responding medical rescuer (Chapter 63). Moreover, the first hour represents the best opportunity for myocardial salvage with recanalization therapy. Thus, the three goals of prehospital care are as follows: (1) to recognize symptoms promptly and seek medical attention; (2) to deploy an emergency medical system team capable of cardiac monitoring, defibrillation and resuscitation, and emergency medical therapy (e.g., nitroglycerin, lidocaine, atropine); and (3) to transport the patient expeditiously to a medical care facility staffed with personnel capable of providing expert coronary care, including recanalization therapy (primary angioplasty or fibrinolysis).

The greatest time lag to recanalization therapy is the patient's delay in calling for help. Public education efforts have yielded mixed results, and innovative approaches are needed. The feasibility of initiating fibrinolytic therapy by highly trained ambulance personnel in coordinated ambulance and emergency department systems has been shown. More recently, data indicate that high-dose prehospital tirofiban (25 µg/kg bolus, then 0.15 µg/kg/minute for 18 hours) can improve intermediate outcomes in patients with acute ST elevation MI who undergo percutaneous coronary intervention and is equivalent to abciximab.■ In coordinated systems and when transportation delays are substantial, initiation of fibrinolytic or other antithrombotic therapy in the field may be considered, thereby shortening the time to recanalization.

Hospital Phases

Emergency Department

The goals of emergency department care are to identify patients with acute myocardial ischemia rapidly, to stratify them into acute ST segment elevation MI as compared with other acute coronary syndromes (see Fig. 72-1 in Chapter 72 and Fig. 73-1), to initiate a recanalization strategy and other appropriate medical care in qualifying patients with acute ST segment elevation MI, and to prioritize by triage rapidly to inpatient care (CCU, step-down unit, observation unit) or outpatient care (patients without suspected ischemia) (see Fig. 72-2 in Chapter 72).

The evaluation of patients with chest pain and other suspected acute coronary syndromes begins with a 12-lead ECG even as the physician is beginning a focused history, including contraindications to fibrinolysis, and a targeted physical examination. Continuous ECG monitoring should be started, an intravenous line should be established, and admission blood tests should be drawn (including cardiac markers such as cTnI or cTnT). As rapidly as possible, the patient should be stratified as having a probable ST segment elevation acute MI, a non–ST segment elevation acute MI, probable or possible unstable angina, or likely noncardiac chest pain.

In patients with ST segment elevation acute MI by clinical and ECG criteria, a recanalization strategy must be selected: alternative choices are primary percutaneous coronary intervention (primary PCI; the patient is transferred directly to the cardiac catheterization laboratory with a goal of door-to-balloon time of less than 90 minutes) or fibrinolysis (begun immediately in the emergency department with a goal of door-to-needle time of less than 30 minutes) (Fig. 73-3).

Aspirin (162 to 325 mg) should be given to all patients unless it is contraindicated (see Fig. 73-3). A loading dose of a thienopyridine (e.g., clopidogrel, 600 mg, or prasugrel, 60 mg) also is recommended for STEMI patients for whom PCI is planned. In addition, it is reasonable to start treatment with a glycoprotein IIb/IIIa (GPIIb-IIIa) receptor antagonist (abciximab, 0.25 mg/kg IV bolus, then 0.125 µg/kg/minute [maximum, 10 µg/minute] for up to 12 hours), tirofiban (25 µg/kg IV bolus, then 0.15 µg/kg/minute for 12 to 18 hours; reduce infusion rate by 50% for estimated creatinine clearance less than 30 mL/minute) or eptifibatide (180 µg/kg IV bolus, second bolus after 10 minutes, then 2.0 µg/kg/minute for up to 18 hours; reduce infusion by 50% for estimated creatinine clearance less than 50 mL/minute) at the time of primary PCI for STEMI in selected patients, such as those with a large burden of thrombus or those who have not received adequate thienopyridine loading. It is uncertain whether there is any incremental usefulness of starting GPIIb-IIIa receptor antagonists "upstream," before arrival in the catheterization laboratory.

Intravenous heparin (initial bolus 60 IU/kg, maximum, 4000 IU, then 12 IU/kg/hour, maximum 1000 IU/hour, for patients >70 kg, adjusted to maintain activated partial thromboplastin time 1.5 to 2 times the control value) or low-molecular-weight heparin (LMWH; e.g., enoxaparin, 30 mg intravenous bolus, then 1 mg/kg subcutaneously twice daily, for patients <75 years old without renal insufficiency) or bivalirudin (for those undergoing a primary PCI strategy—0.75 mg/kg bolus, then 1.75 mg/kg/hour infusion) is appropriate in most patients. In STEMI patients who are undergoing PCI who are at higher risk for bleeding, evidence supports using bivalirudin anticoagulation with a thienopyridine but without a GPIIb-IIIa receptor antagonist.■

Patients with chest pain should be given sublingual nitroglycerin (0.4 mg every 5 minutes for up to three doses), after which an assessment should be made of the need for intravenous nitroglycerin. Persistent ischemic pain may be treated with titrated intravenous doses of morphine (i.e., 2 to 4 mg intravenously [IV], repeated every 5 to 15 minutes to relieve pain). Initiation of β-blocker therapy is usually indicated, especially in patients with hypertension, tachycardia, and ongoing pain; however, decompensated heart failure is a contraindication to the acute initiation of β-blocker therapy, particularly by the intravenous route. Oxygen should be used in doses sufficient to avoid

hypoxemia (e.g., initially at 2 to 4 L/minute by nasal cannula; fingertip oximetry may be used to monitor effect). The ideal systolic blood pressure is 100 to 140 mm Hg. Excessive hypertension usually responds to titrated nitroglycerin, β-blocker therapy, and morphine (also given for pain). Relative hypotension could require discontinuation of these medications, fluid administration, or other measures as appropriate to the hemodynamic subset (Table 73-3). Atropine (0.5 to 1.5 mg IV) should be available to treat symptomatic bradycardia and hypotension related to excessive vagotonia. Direct transfer to the catheterization laboratory or fibrinolysis followed by transfer to the CCU should occur as expeditiously as possible.

Early Hospital Phase: Coronary Care

Coronary care for early hospital management of acute MI has reduced in-hospital mortality by more than 50%. The goals of CCU care include (1) continuous ECG monitoring and antiarrhythmic therapy for serious arrhythmias (i.e., rapid defibrillation of VF), (2) initiation or continuation of a coronary recanalization strategy to achieve myocardial reperfusion, (3) initiation or continuation of other acute medical therapies, (4) hemodynamic monitoring and appropriate medical interventions for different hemodynamic subsets of patients, and (5) diagnosis and treatment of mechanical and physiologic complications of acute MI. General care and comfort measures also are instituted. A sample of CCU admission orders is given in Table 73-4.

General care measures include attention to activity, diet, and bowels, education, reassurance, and sedation. Bedrest is encouraged for the first 12 hours. In the absence of complications, dangling, bed to chair, and self-care activities can begin within 24 hours. When stabilization has occurred, usually within 1 to 3 days, patients may be transferred to a step-down unit where progressive reambulation occurs. The risk for emesis and aspiration or the anticipation of angiography or other procedures usually dictates nothing by mouth or clear liquids for the first 4 to 12 hours. Thereafter, a heart-healthy diet in small portions is recommended. In patients at high risk for bleeding gastric stress ulcers, a proton pump inhibitor or an H_2-antagonist is recommended for prophylaxis in patients receiving antithrombotic therapy. Many patients benefit from an analgesic (e.g., morphine sulfate, in 2- to 4-mg increments) to relieve ongoing pain and an anxiolytic or sedative during the CCU phase. A benzodiazepine is frequently selected. Sedatives should not be substituted for education and reassurance from concerned caregivers to relieve emotional distress and improve behavior; routine use of anxiolytics is neither necessary nor recommended. Constipation often occurs with bedrest and narcotics; stool softeners and a bedside commode are advised.

The ECG should be monitored continuously in the CCU (and usually in the step-down unit) to detect serious arrhythmias and to guide therapy. Measures to limit infarct size (i.e., coronary recanalization) and to optimize hemodynamics also stabilize the heart electrically. Routine antiarrhythmic prophylaxis (e.g., with lidocaine or amiodarone) is not indicated, but specific arrhythmias require treatment (see later text).

Hemodynamic evaluation is helpful in assessing prognosis and in guiding therapy (see Table 73-3). Clinical and noninvasive evaluation of vital signs is adequate for normotensive patients without pulmonary congestion. Patients with pulmonary venous congestion alone can usually be managed conservatively. Invasive monitoring is appropriate when the cause of circulatory failure is uncertain and when titration of intravenous therapies depends on hemodynamic measurements (e.g., pulmonary capillary wedge pressure and cardiac output). Similarly, an arterial line is not necessary in all patients and may be associated with local bleeding after fibrinolysis or potent antiplatelet and antithrombin therapy. Arterial catheters are appropriate and useful in clinically unstable, hypotensive patients who do not respond to intravenous fluids to replete or expand intravascular volume (see the later discussion of complications).

Later Hospital Phase

Transfer from the CCU to the step-down unit usually occurs within 1 to 3 days, when the cardiac rhythm and hemodynamics are stable. The duration of this late phase of hospital care is usually an additional 2 to 3 days in uncomplicated cases. Activity levels should be increased progressively under continuous ECG monitoring. Medical therapy should progress from parenteral and short-acting agents to oral medications appropriate and convenient for long-term outpatient use.

Risk stratification and functional evaluations are critical to assess prognosis and to guide therapy as the time for discharge approaches. Functional evaluation also can be extended to the early period after hospital discharge. Education must be provided about diet, activity, smoking, and other risk factors (e.g., lipids, hypertension, diabetes).

Specific Therapeutic Measures

Recanalization Therapy

Early reperfusion of ischemic, infarcting myocardium represents the most important conceptual and practical advance for ST segment elevation acute MI and is the primary therapeutic goal. Coronary recanalization is accomplished by using primary PCI with angioplasty and, commonly, stenting or with fibrinolytic (thrombolytic) therapy. With broad application of recanalization therapy, 30-day mortality rates from ST segment elevation acute MI have progressively declined over the past 3 decades (from 20 to 30% to 5 to 10%). Each community should develop and follow a multidisciplinary STEMI system of care that provides consistently optimal STEMI care within the resources available.

Fibrinolytic Therapy

Various fibrinolytic agents (Table 73-5) are useful in patients with ST segment elevation or new or presumed-new LBBB who present for treatment within 12 hours of the onset of symptoms and who have no contraindications to the use of these agents (Table 73-6). Compared with no recanalization therapy, older fibrinolytics such as streptokinase reduced mortality by 18% (from 11.5 to 9.8%) at 5 weeks. Patients with anterior ST segment elevation benefit more (37 lives saved per 1000) than those with inferior ST segment elevation only (8 lives saved per 1000), and younger patients benefit more than elderly (>75 years) patients. No benefit or a slight adverse effect is seen in patients presenting with normal ECGs or ST depression alone. Benefit is time dependent; it declines from about 40 lives or more saved per 1000 within the first hour, to 20 to 30 lives saved per 1000 for hours 2 to 12, to a nonsignificant 7 lives saved per 1000 for hours 13 to 24. An accelerated regimen of tissue plasminogen activator (t-PA plus intravenous heparin) further reduces mortality at 30 days (by 14%, from 7.3 to 6.3%), compared with streptokinase because the patency rate of the infarct-related artery at 90 minutes is higher with t-PA (81%) than with streptokinase (53 to 60%). Longer-acting variants of t-PA, given by single-bolus (tenecteplase) or double-bolus (reteplase) injections are now in widespread clinical use because they are more convenient to give, but they have not improved survival further.

The major risk of fibrinolytic therapy is bleeding. Intracerebral hemorrhage is the most serious and frequently fatal complication; its incidence rate is 0.5 to 1% with currently approved regimens. Older age (>70 to 75 years), female gender, hypertension, and higher relative doses of t-PA and heparin increase

TABLE 73-3 HEMODYNAMIC SUBSETS OF ACUTE MYOCARDIAL INFARCTION

	BLOOD PRESSURE (RELATIVE)	TYPICAL PHYSICAL FINDINGS	CARDIAC INDEX (L/min/m^2)	PA WEDGE PRESSURE (mm Hg)	SUGGESTED INTERVENTIONS
Normal	Normal	$\pm S_4$	>2.5	≤12	None required
Hyperdynamic	Normal or high	Anxious	>3	<12	Control pain, anxiety; β-blocker; treat SBP to <140 mm Hg
Hypovolemia	Low	Dry	≤2.7	≤9	Add fluids to maintain normal pressure; can develop pulmonary edema if hypotension caused by unrecognized LV failure
Mild LV failure	Low to high	Rales, $\pm S_3$	2-2.5	>15	Diuresis; nitrates, ACE inhibitor; consider low-dose β-blocker
Severe LV failure	Low to normal	Above $+S_3$, ± ↑ JVP, ± edema	<2	>20	Diuresis; nitrates; low-dose ACE inhibitor; avoid β-blockers; consider inotropes, urgent revascularization
Cardiogenic shock	Very low	Above + cool, clammy; ↓ mental or renal function	≤1.5	>25	Avoid hypotensive agents; place intra-aortic balloon pump; urgent revascularization if possible
RV infarct	Very low	↑ JVP with clear lungs	<2.5	≤12	Give IV fluids; avoid nitrates and hypotensive agents; dobutamine if refractory to fluids

↑ = increased; ↓ = decreased; ACE = angiotensin-converting enzyme; IV = intravenous; JVP = jugular venous pressure; LV = left ventricle; PA = pulmonary artery; RV = right ventricle; SBP = systolic blood pressure.

TABLE 73-4 SAMPLE ADMISSION ORDERS FOR ST SEGMENT ELEVATION ACUTE MYOCARDIAL INFARCTION

Diagnosis:	Acute ST segment elevation myocardial infarction
Admit:	Coronary care unit with telemetry
Condition:	Serious
Vital signs:	q½h until stable, then q1-4h and PRN; pulse oximetry × 24 hr; notify if heart rate <50 or >100; respiratory rate <8 or >20; SBP <90 or >150 mm Hg; O_2 saturation <90%
Activity:	Bedrest × 12 hr with bedside commode; thereafter, light activity if stable
Diet:	NPO except for sips of water until pain free and stable; then 2 g sodium, heart-healthy diet as tolerated, unless on call for catheterization (or other test requiring NPO)
Laboratory tests:*	Troponin I or T and CK/CK-MB q8h × 3; comprehensive blood chemistry, magnesium, CBC with platelets; PT/INR, aPTT; BNP; lipid profile (fasting in morning); portable CXR
IV therapy:	D_5W or NS to keep vein open (increase fluids for relative hypovolemia); second IV if IV medication given
Recanalization therapy:*	Emergency primary coronary angioplasty, or fibrinolysis (if appropriate) 1. Primary angioplasty (preferred if available within 90 min) 2. Tenecteplase, alteplase, reteplase, or streptokinase (see Table 73-5 for doses)
Medications:	1. Nasal O_2 at 2 L/min × 6 hr, then by order (titrate to keep O_2 saturation >90%) 2. Aspirin 162-325 mg chewed on admission, then 81-162 mg PO daily 3. IV heparin, 60 U/kg bolus (maximum, 4000 U) and 12 U/kg/hr (maximum, 1000 U/hr), titrate to target aPTT 1.5-2.0 × control (about 50-70 sec), OR enoxaparin (preferred with fibrinolytic), 30 mg IV, then 1 mg/kg SC q12h (maximum SC doses, 100 mg on day 1; reduce to 0.75 mg/kg for age ≥75, increase interval to q24h for CrCl <30 mL/min), OR bivalirudin (with primary PCI), 0.75 mg/kg IV bolus, then 1.75 mg/kg/hr (delay 30 min if heparin given) 4. Metoprolol, 12.5 PO q6h, incremented to 25-50 mg q6h as tolerated (hold for SBP < 100 mm Hg, pulse < 50 beats/min, asthma, heart failure); may consider IV metoprolol if immediate effect required (tachyarrhythmia, severe hypertension, unrelieved pain) in the absence of heart failure 5. Consider IV nitroglycerin drip × 24-48 hr (titrated to SBP 100-140 mm Hg) 6. Morphine sulfate, 2-4 mg IV and increment at 5-15 min PRN for unrelieved pain 7. Stool softener 8. Anxiolytic or hypnotic if needed 9. ACE inhibitor for hypertension, anterior acute MI, or LV dysfunction, in low oral dose (e.g., captopril, 6.25 mg q8h), begun within 24 hours or when stable (SBP > 100 mm Hg) and adjusted upward 10. Lipid-lowering therapy (i.e., statin) regardless of LDL: target LDL at least <100 mg/dL (<70 mg/dL reasonable); clopidogrel, 300-600 mg PO, then 75 mg PO daily, or prasugrel 60 mg PO, then 10 mg PO daily (with PCI strategy), begun immediately after PCI (if CABG not planned) 11. Specific treatments for hemodynamic subgroups (see Table 73-3)

*If not ordered in the emergency department.
ACE = angiotensin-converting enzyme; aPTT = activated partial thromboplastin time; BNP = brain natriuretic peptide; CABG = coronary artery bypass graft surgery; CBC = complete blood count; CK = creatine kinase; CrCl = creatinine clearance; CXR = chest radiograph; D_5W = 5% dextrose in water; GP = glycoprotein; INR = International Normalized Ratio; IV = intravenous; LDL = low-density lipoprotein; LV = left ventricle; MI = myocardial infarction; NPO = nothing by mouth; NS = normal saline; PCI = percutaneous coronary intervention; PO = orally; PRN = as needed; PT = prothrombin time; daily = once daily; SBP = systolic blood pressure; SC = subcutaneous.

TABLE 73-6 INDICATIONS AND CONTRAINDICATIONS TO FIBRINOLYTIC THERAPY

INDICATIONS
Ischemic-type chest discomfort or equivalent for 30 min-12 hr with new or presumed new ST segment elevation in two contiguous leads of ≥2 mm (≥0.2 mV) in leads V_1, V_2, or V_3 or ≥1 mm in other leads
New or presumed-new left bundle branch block with symptoms consistent with myocardial infarction
Absence of contraindications
CONTRAINDICATIONS, ABSOLUTE
Active bleeding or bleeding diathesis (menses excluded)
Prior hemorrhagic stroke, ischemic stroke within 3 months, except acute ischemic stroke within 3-4.5 hours
Intracranial or spinal cord neoplasm or arteriovenous malformation
Suspected or known aortic dissection
Closed head or facial trauma within 3 months
CONTRAINDICATIONS, RELATIVE
Severe, uncontrolled hypertension by history or on presentation (>180/110 mm Hg)
Anticoagulation with therapeutic or elevated international normalized ratio (>2-3)
Old ischemic stroke (>3 mo ago); intracerebral disease other than above
Recent (<3 wk) major trauma/surgery or prolonged (>10 min) cardiopulmonary resuscitation or internal bleeding
Active peptic ulcer
Recent noncompressible vascular punctures
Pregnancy
For streptokinase/anistreplase: prior exposure (especially if >5 days ago) or allergic reaction

TABLE 73-7 INDICATIONS FOR PRIMARY ANGIOPLASTY AND COMPARISON WITH FIBRINOLYTIC THERAPY

INDICATIONS
Alternative recanalization strategy for ST segment elevation or LBBB acute MI within 12 hr of symptom onset (or >12 hr if symptoms persist)
Cardiogenic shock developing within 36 hr of ST segment elevation/Q wave acute MI or LBBB acute MI in patients <75 yr old who can be revascularized within 18 hr of shock onset
Recommended only at centers performing >200 PCI/yr with backup cardiac surgery and for operators performing >75 PCI/yr
ADVANTAGES OF PRIMARY PCI
Higher initial recanalization rates
Reduced risk of intracerebral hemorrhage
Less residual stenosis; less recurrent ischemia or infarction
Usefulness when fibrinolysis contraindicated
Improvement in outcomes with cardiogenic shock
DISADVANTAGES OF PRIMARY PCI (COMPARED WITH FIBRINOLYTIC THERAPY)
Access, advantages restricted to high-volume centers, operators
Longer average time to treatment
Greater dependence on operators for results
Higher system complexity, costs

LBBB = left bundle branch block; MI = myocardial infarction; PCI = percutaneous coronary intervention (includes balloon angioplasty, stenting).

the risk for intracranial hemorrhage. The risk-to-benefit ratio should be assessed in each patient when fibrinolysis is considered and specific regimens are selected.

For failed fibrinolysis, rescue PCI is more effective than repeat fibrinolysis.[3] After fibrinolysis, regardless of its apparent success, the best strategy is to transfer all STEMI patients with high-risk features rapidly to a hospital with PCI facilities to undergo angiography, rather than to transfer only selected patients in whom fibrinolysis failed or recurrent ischemia developed.[4,5] This early transfer and angiography strategy at a median of 3 hours after fibrinolysis reduces the risk for recurrent ischemia, reinfarction, heart failure, cardiogenic shock or death by 36%.

Primary Percutaneous Coronary Intervention

Prompt PCI is the preferred recanalization strategy (Table 73-7).[3,6] PCI achieves mechanical recanalization by inflation of a catheter-based balloon centered within the thrombotic occlusion. Percutaneous transluminal coronary angioplasty (PTCA) is generally augmented by placing a stent at the site of occlusion as a scaffold to enlarge the lumen and to retain optimal postangioplasty expansion. Preference is often given to drug-eluting stents (e.g., sirolimus, paclitaxel), which markedly reduce the rates of restenosis but can increase the risk of late thrombosis (Chapter 74). Factors favoring a bare metal stent include inability to maintain at least 1 year of dual antiplatelet therapy because of an increased risk for bleeding, need for concomitant anticoagulation, risk for poor adherence or anticipated need for surgery requiring interruption of thienopyridine.

The relative benefits of primary PTCA or PCI over fibrinolysis are confirmed by a meta-analysis that found a significantly lower mortality rate (4.4 versus 6.5%; odds ratio, 0.66) and lower rates of nonfatal reinfarction (2.9 versus 5.3%; odds ratio, 0.53) and intracerebral hemorrhage with primary PTCA compared with fibrinolysis. PCI yields better outcomes than fibrinolysis across all age groups when it is performed within 1 to 2 hours of presentation to a health care facility.

Currently, a primary PCI strategy begins with initiation of a thienopyridine in the emergency department, together with aspirin and an anticoagulant (e.g., heparin or bivalirudin), followed by rapid application of coronary angioplasty with stenting. Augmented antiplatelet therapy with a GPIIb-IIIa inhibitor may be added in selected patients, generally at the time of catheterization. The addition of a reduced dose of a plasminogen activator to GPIIb-IIIa therapy in the field or emergency department may further improve outcomes only in selected patients who undergo early PCI, but this approach is generally not recommended.[8] Facilitated PCI, whereby patients at hospitals without PCI capabilities are given adjusted doses of fibrinolytic or GPIIb-IIIa inhibitors, or both, and then are transferred to other hospitals for emergent (i.e., within 1 to 2 hours) PCI, overall appears to be no better than rapid transfer for primary PCI within 1 to 2 hours.[8,9]

Operator and institutional experience is an issue more important to outcomes with primary PCI than fibrinolysis and has been incorporated into current recommendations (see Table 73-7). Primary PCI is feasible in community hospitals without surgical capability, but concerns about timing and safety remain. Current guidelines allow that primary PCI "might be considered" in hospitals without on-site cardiac surgery, provided (1) there is a proven plan for rapid and safe transport to a nearby hospital with cardiac surgery capability and availability, and (2) the PCI is done by a skilled operator (≥75 PCIs/year) in a hospital with adequate experience (≥36 primary PCIs/year).

Mechanical reperfusion, primarily with stenting and a GPIIb-IIIa receptor antagonist, for patients presenting more than 12 hours but less than 48 hours after the onset of symptoms, also can reduce infarct size and perhaps adverse events.[10] Extending PCI to ST segment elevation MI beyond 12 hours deserves further testing in larger studies.

An additional important indication is cardiogenic shock occurring within 36 hours of the onset of acute MI and treated within 18 hours of the onset of shock (Chapter 107). However, benefit was not established for patients older than 75 years, and benefit was greater with earlier PCI.

Increasing positive experience with PCI of the left main coronary artery with stents, especially drug-eluting stents, suggests that it may be an alternative to coronary artery bypass grafting (CABG) in patients with an amenable anatomy, a low risk of PCI procedural complications, and an increased risk of adverse surgical outcomes.

Mechanical thrombus aspiration at the time of angiography may improve outcomes of patients with STEMI undergoing primary PCI.[11] To reduce the risk for contrast-induced nephropathy, an isosmolar or a low-molecular-weight contrast medium together with preprocedure hydration is recommended in patients undergoing angiography.

Selecting a Recanalization Regimen

Whether to use PCI or fibrinolytic therapy depends on local resources and experience as well as on patient factors. Outcomes appear to be determined both by timing and by institutional and operator experience. In general, in experienced facilities (≥200 PCIs/center; surgical capability; ≥75 PCIs/operator annually; frequent primary PCI, e.g., ≥36/year/center; ≥4/operator/year) that are able to mobilize and treat patients quickly (<90 minutes to balloon inflation), primary PCI is considered the preferred strategy, with stenting preferred over balloon PTCA. PCI is particularly preferred for patients at higher risk for mortality (including shock), for later presentations (>3 hours), and for patients with greater risk of intracerebral hemorrhage (age >70 years, female gender, therapy with hypertensive agents). Ancillary antithrombotic therapy with primary PCI includes aspirin, unfractionated heparin or LMWH or bivalirudin, and a GPIIb-IIIa inhibitor (preferably initiated on admission before catheterization). Clopidogrel is begun directly after PCI and is continued after discharge.

For other situations, fibrinolytic therapy becomes the recommended recanalization strategy. If time since the onset of symptoms is within 3 hours and

the difference between expected time to PCI and fibrinolytic administration is more than 1 hour, fibrinolysis is often the preferred strategy. Fibrinolysis also is preferred in centers without sufficient PCI experience or capability. In hospitals with long ambulance transport times (>60 to 90 minutes), a strategy for initiating prehospital fibrinolysis may be considered. Very early or prehospital fibrinolysis followed by a routine emergent (i.e., within 1 to 2 hours) invasive strategy on hospital arrival, that is, "pharmacoinvasive therapy," although an appealing concept, appears to cause a *higher* rate of in-hospital mortality, cardiac ischemic events, and strokes compared with primary PCI alone or by a more delayed invasive approach after fibrinolysis in stabilized patients,[4,5,12] and its use cannot be recommended as a primary recanalization strategy. Whether fibrinolysis before PCI will be beneficial in selected subgroups with MI, such as patients seen within the first hour of symptoms and with an expected delay to PCI of 2 hours or more, deserves further testing. Currently, however, efforts should be made to provide primary PCI to a larger percentage of patients with acute MI.

The selection of a specific fibrinolytic regimen is based on the risk of complications of the acute MI, the risk of intracerebral hemorrhage, and a consideration of economic constraints. Using these factors, longer-acting variants of t-PA (i.e., tenecteplase and reteplase) have become dominant in the United States and other affluent medical markets; in other countries, less costly streptokinase is still widely used. A nonimmunogenic fibrinolytic agent is preferred for patients with a history of prior streptokinase use. Streptokinase is associated with a lower risk for intracerebral hemorrhage than other regimens if excessive heparin is avoided. Tenecteplase combined with enoxaparin was more effective than tenecteplase with standard heparin or with a GPIIb-IIIa inhibitor (abciximab) and heparin in one but not another trial. Reteplase with abciximab showed no mortality advantage when combined (in half-dose) with abciximab than with heparin alone; ischemic events decreased, but intracerebral hemorrhage increased, especially in elderly patients. Over the past decade, the application of recanalization therapy has remained relatively constant in the United States and other Western countries at 70 to 75% of "eligible" patients with acute MI. Primary PCI use has increased substantially over time, although fibrinolytic therapy continues to be more commonly applied, particularly in developing countries.

Ancillary and Other Therapies

Antiplatelet Therapy

Aspirin

Platelets form a critical component of coronary thrombi. Aspirin inhibits platelet aggregation by irreversibly blocking cyclooxygenase 1 activity by selective acetylation of serine at position 530. Cyclooxygenase 1 catalyzes the conversion of arachidonic acid to thromboxane-A_2, a potent platelet aggregator (Chapter 36).

Aspirin has been extensively tested to prevent coronary heart disease (Chapter 37). Aspirin trials in ST segment elevation acute MI have been more limited but positive. The most important trial of aspirin in ST segment elevation acute MI randomized more than 17,000 patients with "suspected acute MI" (representing mostly, but not entirely, ST segment elevation acute MI) to aspirin or control and to intravenous streptokinase or control. At 5 weeks, the relative risk for vascular death was reduced 21% by aspirin alone, 25% by streptokinase alone, and 40% by aspirin in combination with streptokinase. Since that time, aspirin has been included as standard therapy in most treatment regimens for ST segment elevation acute MI.

Current guidelines strongly recommend aspirin (class I indication) on admission in a dose of 162 to 325 mg, preferably chewed. Aspirin administration is continued throughout hospitalization and then indefinitely in a maintenance dose of 75 to 162 mg/day on an outpatient basis (enteric-coated forms are popular).

Adenosine Diphosphate Receptor Antagonists

The thienopyridine clopidogrel exerts potent antiplatelet effects by blocking the platelet membrane adenosine diphosphate receptor (Chapter 37). For patients allergic to aspirin, clopidogrel has become the alternative of choice for short- and long-term therapy of ST segment elevation acute MI. A single loading dose is given, usually 300 mg with fibrinolytic therapy but 600 mg with PCI. The maintenance dose is 75 mg/day.

In patients who can take aspirin, the addition of clopidogrel (300 mg followed by 75 mg/day) to aspirin and fibrinolytic therapy in patients 75 years or younger reduces predischarge occlusion rates of infarct-related arteries (by 41%) and reduces ischemic complications at 30 days (by 20%) without increasing rates of intracerebral hemorrhage.[13] When given without a loading dose but also without an upper age restriction, clopidogrel reduces 15-day ischemic complications by 9% and death from any cause by 7%.[14] Hence, clopidogrel appears to represent a beneficial initial adjunctive therapy in patients with STEMI who are treated with fibrinolytic agents. However, clopidogrel increases the risk for bleeding with CABG, so it is commonly initiated only after coronary angiography has been performed and early surgery has been excluded as a therapeutic choice; if CABG is planned, clopidogrel should be withheld for 5 to 7 days unless the urgency of surgery outweighs the risk of excessive bleeding.

Prasugrel, a new and more potent thienopyridine, may reduce ischemic events at the cost of a small increase in bleeding compared with clopidogrel after PCI in patients with acute STEMI.[15] Prasugrel is contraindicated in patients with a prior history of stroke or transient ischemia attack and should be used with caution (or in reduced doses) in older (≥75 years) and smaller (<60 kg) patients.

Clopidogrel added to aspirin on admission for patients with non–ST segment elevation acute MI or unstable angina (Chapter 72) or after a PCI reduces vascular events (by 22%) at 3 to 12 months compared with aspirin alone. Extrapolation of these findings led to the recommendations that clopidogrel be used for 3 to 12 months as an alternative antiplatelet agent in patients with ST segment elevation acute MI when aspirin is contraindicated and that it be considered routinely (in addition to aspirin) in patients after primary PCI.

Glycoprotein IIB/IIIA Inhibitors

Inhibitors of the platelet membrane GPIIb-IIIa receptor, a fibrinogen receptor, have been shown to benefit high-risk patients with non–ST segment elevation acute coronary syndrome (Chapters 37 and 72) on admission or after PCI. The benefit in STEMI is smaller when routine stenting is used and when GPIIb-IIIa therapy is administered only in the catheterization laboratory. Earlier ("upstream") glycoprotein inhibition before hospital admission or in the emergency department (precatheterization) is effective in improving coronary patency by the time of emergency angiography, but incremental benefit on clinical outcomes has not been established. If early CABG is a possibility after angiography, a shorter-acting inhibitor (eptifibatide, tirofiban) may impart a lower perioperative risk for bleeding than abciximab.

Antithrombin Therapy

Low-Molecular-Weight Heparins

Compared with unfractionated heparins, LMWHs have enhanced inhibitory activity for factor Xa (Chapter 37). They also have more reliable bioavailability and longer durations of action, thus permitting subcutaneous administration once or twice daily in fixed (weight-adjusted) doses. Evidence suggests that in patients with ST segment elevation acute MI who are treated with fibrinolytic therapy, LMWH can improve angiographic outcomes and can reduce reinfarction rates by 25% and mortality by about 10% compared with unfractionated heparin.[16] Enoxaparin may thus be preferred over unfractionated heparin as an antithrombotic agent for ST segment elevation acute MI in most patients treated with a fibrinolysis strategy. When used as ancillary therapy with a fibrinolytic agent, enoxaparin may be given to patients younger than 75 years who do not have renal insufficiency as a 30-mg intravenous bolus, followed by 1 mg/kg subcutaneously twice daily until hospital discharge, and to those 75 years and older as 0.75 mg/kg subcutaneously twice daily without a bolus.

Unfractionated Heparin

Unfractionated heparin can be used in patients undergoing primary PCI and in those receiving fibrin-specific lytic agents (i.e., alteplase, reteplase, or tenecteplase; see Fig. 73-3 and Table 73-4). It also can be used with intravenous streptokinase or anistreplase for patients at high risk for systemic emboli (e.g., large or anterior acute MI with LV thrombus, atrial fibrillation [AF]). Excessive bleeding when heparin is used in combination with antithrombotic regimens has led to reductions in heparin doses, with improved safety. When given with a fibrinolytic agent, intravenous heparin is begun concurrently and is given for 48 hours. Currently recommended doses include a 60 U/kg bolus (maximum, 4000 U), followed initially by a 12 U/kg/hour infusion (maximum, 1000 U/hour), with adjustment after 3 hours based on activated partial thromboplastin time (target of 50 to 70 seconds, 1.5 to 2 times control). Experimental regimens including a GPIIb-IIIa inhibitor and a fibrinolytic agent have used even lower heparin doses. During primary PCI, high-dose heparin is used (activated clotting time, 300 to 350 seconds). Given together with a GPIIb-IIIa inhibitor during PCI, the dose of heparin is adjusted to a lower activated clotting time range (150 to 300 seconds).

Factor Xa Inhibitors

Selective factor Xa inhibitors (e.g., fondaparinux, 2.5 mg subcutaneously once daily for up to 8 days during index hospitalization) reduce the end point of death or reinfarction at 30 days by 18 to 23% independent of heparin use in patients who receive fibrinolysis or no recanalization therapy but have no benefit in patients who have undergone PCI.[18] These results suggest that fondaparinux may be a preferred alternative to unfractionated heparin or no heparin (e.g., in patients who present later, in patients treated with streptokinase) in patients with STEMI who are not undergoing a primary PCI strategy.

Direct Antithrombins

Bivalirudin, a synthetic hirudin analogue with direct antithrombin activity (Chapter 37), compares favorably with heparin and a glycoprotein IIb/IIIa inhibitor for ST segment elevation acute MI managed by primary PCI, with better survival rates at 1 year.[19] However, an increased risk of ischemic events and stent thrombosis occurs in bivalirudin patients who do not receive upstream therapy with a 600-mg loading dose of clopidogrel. As a result, bivalirudin, together with early administration of clopidogrel, has become a

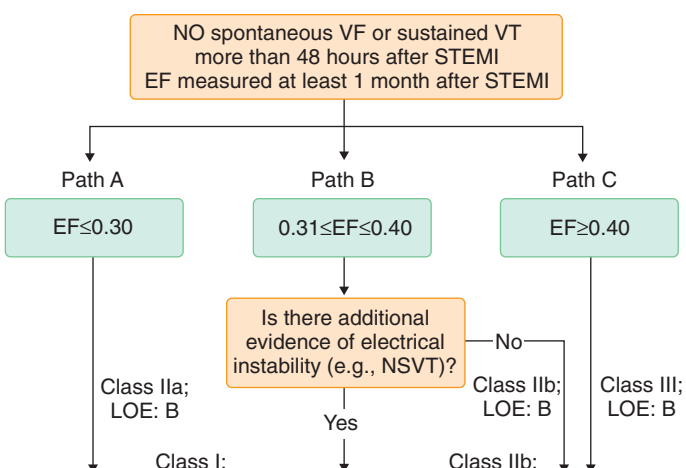

FIGURE 73-4. Algorithm to aid in selection of implantable cardioverter-defibrillator (ICD) in patients with ST segment elevation myocardial infarction (STEMI) and diminished ejection fraction (EF). The appropriate management path is selected based on left ventricular EF measured at least 1 month after STEMI. All patients, whether an ICD is implanted or not, should receive medical therapy. EPS = electrophysiologic studies; LOE = level of evidence; NSVT = nonsustained ventricular tachycardia; VF = ventricular fibrillation; VT = ventricular tachycardia. (Adapted from Antman EM, Anbe DT, Armstrong PW, et al. 2004 Update: ACC/AHA guidelines for the management of patients with ST-elevation myocardial infarction—executive summary. A Report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines. *Circulation.* 2004;110:588-536.)

widely used antithrombotic regimen in primary PCI for ST segment elevation acute MI.

Other Pharmacologic Therapies

Nitrates

Nitroglycerin and other organic nitrates (isosorbide dinitrate and isosorbide mononitrate) induce vascular smooth muscle relaxation by generating vascular endothelial nitric oxide. The resulting vasodilation of veins and peripheral and coronary arteries can beneficially reduce excessive cardiac preload and afterload, increase coronary caliber in responsive areas of stenosis, reverse distal small coronary arterial vasoconstriction, improve coronary collateral flow to ischemic myocardium, and inhibit platelet aggregation in acute MI (Chapter 71). The results are improved oxygen delivery and reduced oxygen consumption. Potential clinical benefits include relief of ischemia, limitation of infarct size, prevention of dilative remodeling, control of hypertension (afterload), and relief of congestion (preload).

In the era before reperfusion, nitrates appeared to confer a mortality benefit in acute MI. In the context of fibrinolytic therapy and aspirin, however, mortality benefits are modest, with a relative survival benefit of about 4 lives saved per 1000 patients treated. Nitroglycerin is definitely recommended for the first 24 to 48 hours for patients with acute MI and pulmonary congestion, large anterior MI, persistent ischemia, or hypertension. For other patients without contraindications, nitrates are possibly useful.

When nitrates are clearly indicated early in acute MI, intravenous nitroglycerin is preferred. Intravenous nitroglycerin may begin with a bolus injection of 12.5 to 25 μg followed by an infusion of 10 to 20 μg/minute. The infusion rate is increased by 5 to 10 μg every 5 to 10 minutes up to about 200 μg/minute during hemodynamic monitoring until clinical symptoms are controlled or blood pressure targets are reached (blood pressure decreased by 10% in normotensive patients or by 30% in hypertensive patients but not less than 80 mm Hg mean or 90 mm Hg systolic).

β-Blockers

β-Adrenoceptor blockers reduce heart rate, blood pressure, and myocardial contractility, and they stabilize the heart electrically. These actions provide clinical benefit to most patients with acute MI by limiting myocardial oxygen consumption, relieving ischemia, reducing infarct size, and preventing serious arrhythmias.

In the era before fibrinolysis, a meta-analysis of 28 randomized trials involving 27,500 patients found a modest early benefit on mortality (14% odds reduction), cardiac arrest (16% reduction), and nonfatal reinfarction (19% reduction). In patients with acute MI who are receiving fibrinolytic therapy, immediate (intravenous then oral) metoprolol reduces recurrent ischemic events and reinfarction compared with deferred oral therapy. Further experience has shown that moderate to severe heart failure should preclude the early use of intravenous β-blockers, but not predischarge and outpatient oral therapy initiated in small doses and carefully adjusted once stability is achieved.

Early (first-day) initiation of oral β-blockade is generally recommended for patients with acute MI who have ongoing or recurrent ischemic pain or tachyarrhythmias if they do not have heart failure or other contraindications (asthma, hypotension, severe bradycardia), regardless of concomitant fibrinolysis or PCI. Intravenous initiation (e.g., metoprolol, 5 mg over 2 minutes to a total of 15 mg over 10 to 15 minutes, or atenolol, 2.5 to 5 mg over 2 minutes to a total of 10 mg over 10 to 15 minutes) is reasonable in the absence of contraindications if an indication for immediate therapy is present, such as a tachyarrhythmia or hypertension. However, the routine, short-term initiation of intravenous β-blockade should be avoided because it is not associated with benefit and, indeed, causes a small excess of early death from cardiogenic shock, primarily in patients with preexisting heart failure.[18] All patients without contraindications or intolerance to β-blocker therapy should receive oral doses, titrated to tolerance or goal (e.g., metoprolol, 25 to 100 mg twice daily; atenolol, 50 to 100 mg/day; or carvedilol, 6.25 to 25 mg twice daily). β-Blocker therapy should begin promptly, in the absence of heart failure and if not otherwise contraindicated, and should be continued during the in-hospital convalescent phase of STEMI and beyond.

Renin-Angiotensin-Aldosterone System Inhibitors

The renin-angiotensin-aldosterone system is activated in acute MI and heart failure. Use of an ACE inhibitor has been shown to improve remodeling after acute MI (especially after large anterior MI). ACE inhibitors also have demonstrated efficacy in heart failure, wherein they prevent disease progression, hospitalization, and death (Chapter 59). A meta-analysis of three major trials and 11 smaller ones involving more than 100,000 patients showed an overall mortality reduction of 6.5%, representing about 5 lives saved per 1000 patients treated. Benefit is concentrated and greater in higher-risk patients with large or anterior MI and with LV dysfunction or heart failure, although patients with lesser degrees of LV dysfunction and only moderate cardiovascular risk can also benefit in the long term.

Oral *ACE inhibitor therapy* should begin within the first 24 hours in patients with anterior infarction, pulmonary congestion, or low ejection fraction (<0.40) in the absence of hypotension (systolic pressure <100 mm Hg or >30 mm Hg less than usual baseline) or known contraindications. An *angiotensin receptor blocker* (ARB) should be given to otherwise qualifying patients who are intolerant of ACE inhibitors. An ACE inhibitor or an ARB also should be considered for other patients with STEMI, especially those with a relative indication (e.g., hypertension, diabetes, or mild renal insufficiency), with the expectation of a smaller but worthwhile benefit. All patients without contraindications or intolerance to initial ACE inhibitor or ARB therapy also should receive these drugs during the in-hospital convalescent phase. ACE inhibitor therapy should begin with low oral doses and should be progressively adjusted to full dose as tolerated. For example, the short-acting agent captopril may be started in a dose of 6.25 mg or less and adjusted over 1 to 2 days to 50 mg twice daily. Before discharge, a transition may be made in graded dose schedules to longer-acting agents such as ramipril (2.5 mg titrated to 10 mg/day), lisinopril (2.5 to 5 mg titrated to 10 mg/day), or enalapril (2.5 mg, titrated to up to 20 mg twice daily). In patients who cannot tolerate ACE inhibitors (e.g., because of cough), graded doses of an ARB may be substituted (e.g., valsartan, 80 to 160 mg twice daily, or losartan, 50 to 100 mg/day).

Selective *aldosterone receptor blockade* with eplerenone (25 to 50 mg/day) reduces total and cardiovascular mortality (including sudden death) as well as cardiovascular hospitalizations in post-MI patients who have an ejection fraction of 0.40 or less and heart failure or diabetes and who are already receiving other optimal therapies, including ACE inhibitors.[19] Spironolactone also benefits patients with advanced heart failure, including those in whom it is caused by a remote MI. Hence, aldosterone receptor blockade should be added to other standard therapies during convalescence in patients with these characteristics. Hyperkalemia, which is the most common side effect, requires monitoring (Chapter 59).

Antiarrhythmic Agents

Antiarrhythmic therapy is reserved for treatment of, or short-term prevention after, symptomatic or life-threatening ventricular arrhythmias, together with other appropriate measures (cardioversion, treatment of ischemia and metabolic disturbances). An implantable cardioverter-defibrillator (ICD) is indicated in patients with VF or hemodynamically significant sustained ventricular tachycardia (VT) occurring more than 2 days after STEMI or in patients with inducible VT or VF at electrophysiologic study and a depressed ejection fraction (≤0.40) at least 1 month after STEMI (Chapter 65). An ICD also may be considered for patients with severe LV dysfunction (ejection fraction ≤0.30) at least 1 month after STEMI and 3 months after CABG without spontaneous or induced VT or VF.[20] These differences reflect an apparent time dependence, in which the benefit of an ICD appears to be delayed until the early post-MI and post-revascularization periods (Chapter 66). By comparison, early ICD implantation is not beneficial in a broader group of patients because its usefulness in preventing similar deaths is offset by the high rate of nonsudden deaths.[21]

Inotropes

Digitalis and intravenous inotropes can increase oxygen demand, provoke serious arrhythmias, and extend infarction. Current recommendations support the use of digoxin in selected patients recovering from acute MI who develop

supraventricular tachyarrhythmias (e.g., AF) or heart failure refractory to ACE inhibitors and diuretics. Intravenous inotropes (e.g., dobutamine, dopamine, milrinone, and norepinephrine) are reserved for temporary support of patients with hypotension and circulatory failure that is unresponsive to volume replacement (Chapters 59 and 107). Other treatment measures for these patients (e.g., intra-aortic balloon pump, early revascularization) are discussed herein.

Lipid-Lowering Therapy

Lipid lowering, particularly with hydroxymethylglutaryl–coenzyme A reductase inhibitors (statins), reduces event rates in patients with coronary disease, and a more aggressive approach appears to provide superior benefits (Chapter 213).[23] A fasting lipid profile should be obtained on admission, so a statin can be started promptly in the hospital with a low-density lipoprotein cholesterol goal of less than 70 mg/dL.

Other Medical Therapies

Calcium channel blockers, although anti-ischemic, also are negatively inotropic and have not been shown to reduce mortality after ST segment elevation acute MI. With certain agents and in specific groups of patients, harm has been suggested. For example, short-acting nifedipine has been reported to cause reflex sympathetic activation, tachycardia, hypotension, and increased mortality. Verapamil or diltiazem (heart rate–slowing drugs) may be given to patients in whom β-blockers are ineffective or contraindicated for control of rapid ventricular response with AF or relief of ongoing ischemia *in the absence of heart failure, LV dysfunction, or atrioventricular (AV) block.*

Magnesium is of no benefit in patients with acute MI who are treated with fibrinolysis. Supplementation is recommended if the magnesium level is lower than normal or in patients with torsades de pointes–type VT associated with a prolonged QT interval.

Glucose-insulin-potassium affords no benefit on mortality, cardiac arrest, or cardiogenic shock when this combination is added to usual care in patients with acute STEMI. However, *glucose control,* using an insulin-based regimen to achieve and maintain glucose levels less than 180 mg/dL while avoiding hypoglycemia, is recommended in the acute phase of STEMI. After the acute phase, individualized treatment is indicated using agents or combinations of agents that best achieve glycemic control and are well tolerated (Chapters 236 and 237).

Management of Complications

Recurrent Chest Pain

When chest pain recurs after acute MI, the diagnostic possibilities include post-infarction ischemia, pericarditis, infarct extension, and infarct expansion. Characterization of the pain, physical examination, ECG, echocardiography, and cardiac marker determinations assist in the differential diagnosis. CK-MB often discriminates reinfarction better than cTnI or cTnT.

Post-infarction angina developing spontaneously during hospitalization for acute MI despite medical therapy usually merits coronary angiography. β-blockers (IV, then orally) and nitroglycerin (IV, then orally or topically) are recommended medical therapies. Pain with recurrent ST segment elevation or recurrent elevation of cardiac markers may be treated with (re)administration of t-PA or, possibly, a GPIIb-IIIa inhibitor, together with nitroglycerin, β-blockade, and heparin. Streptokinase, which induces neutralizing antibodies, generally should not be readministered after the first few days. If facilities for angiography, PCI, and surgery are available, an invasive approach is recommended to relieve discomfort occurring hours to days after an acute MI that is associated with objective signs of ischemia. Radionuclide perfusion stress testing can be helpful in patients with discomfort that is transient or of uncertain ischemic origin. For lesions with questionable degrees of stenosis at angiography, coronary pressure (fractional flow reserve) or Doppler velocimetry can determine whether PCI is warranted.

Infarct expansion implies circumferential slippage with thinning of the infarcted myocardium. Infarct expansion can be associated with chest pain but without recurrent elevation of cardiac markers. Expansive remodeling can lead to an LV aneurysm. The risk for remodeling is reduced with early recanalization therapy and administration of ACE inhibitors.

Acute pericarditis most commonly manifests on days 2 to 4 in association with large, "transmural" infarctions causing pericardial inflammation. Occasionally, hemorrhagic effusion with tamponade develops; thus, excessive anticoagulation should be avoided. Pericarditis developing later (2 to 10 weeks) after acute MI could represent Dressler's syndrome, which is believed to be immune mediated. The incidence of this post-MI syndrome has decreased dramatically in the modern reperfusion era. Pericardial pain is treated with aspirin (preferred, especially in the acute setting) or other nonsteroidal agents (e.g., indomethacin); patients with severe symptoms could require corticosteroids.

Rhythm Disturbances

Ventricular Arrhythmias

Acute MI is associated with a proarrhythmic environment that includes heterogeneous myocardial ischemia, heightened adrenergic tone, intracellular electrolyte disturbance, lipolysis and free fatty acid production, and oxygen free radical production on recanalization. Arrhythmias thus are common early during acute MI. Micro-re-entry is likely the most common electrophysiologic mechanism of early-phase arrhythmias, although enhanced automaticity and triggered activity also are observed in experimental models.

Primary VF, the most serious MI-related arrhythmia, contributes importantly to mortality within the first 24 hours. It occurs with an incidence of 3 to 5% during the first 4 hours and then declines rapidly over 24 to 48 hours. Polymorphic VT and, less commonly, monomorphic VT are associated life-threatening arrhythmias that can occur in this setting. Clinical features (including warning arrhythmias) are not adequately specific or sensitive to identify patients at risk for sustained ventricular tachyarrhythmias, so all patients should be continuously monitored. Prophylactic lidocaine, which reduces primary VF but does not decrease (and may increase) mortality, is not recommended. Primary VF is associated with a higher rate of in-hospital mortality, but long-term prognosis is unaffected in survivors.

Accelerated idioventricular rhythm (60 to 100 beats per minute) frequently occurs within the first 12 hours and is generally benign (i.e., is not a risk factor for VF). Indeed, accelerated idioventricular rhythm frequently heralds recanalization after fibrinolytic therapy. Antiarrhythmic therapy is not indicated except for sustained, hemodynamically compromising accelerated idioventricular rhythm.

Late VF, which is defined as VF developing more than 48 hours after the onset of acute MI, often occurs in patients with larger MIs or heart failure, portends a worse prognosis for survival, and is an indication for aggressive measures (e.g., consideration of an ICD). Monomorphic VT resulting from re-entry in the context of a recent or old MI also can appear late after MI, and patients may require long-term therapy (e.g., an ICD).

Electrical cardioversion is required for VF and sustained polymorphic VT (unsynchronized shock) and for sustained monomorphic VT that causes hemodynamic compromise (synchronized shock) (Chapters 65 and 66). Brief intravenous sedation is given to conscious, "stable" patients. For slower, stable VT and nonsustained VT requiring therapy, intravenous amiodarone or intravenous lidocaine is commonly recommended. After episodes of VT or VF, infusions of antiarrhythmic drugs may be given for 6 to 24 hours; the ongoing risk for arrhythmia then is reassessed. Electrolyte and acid-base imbalance and hypoxia should be corrected. β-Blockade is useful in patients with frequent polymorphic VT associated with adrenergic activation ("electrical storm"). Additional, aggressive measures should be considered to reduce cardiac ischemia (e.g., emergency PCI or CABG) and LV dysfunction (intra-aortic balloon pump) in patients with recurrent polymorphic VT despite the use of β-blockers or amiodarone, or both.

Patients with sustained VT or VF occurring late in the hospital course should be considered for long-term prevention and therapy. An ICD provides greater survival benefit than antiarrhythmic drugs in patients with ventricular arrhythmias and can improve survival after acute MI for patients with an ejection fraction of 30% or less, regardless of their rhythm status.[28]

Atrial Fibrillation and Other Supraventricular Tachyarrhythmias

AF occurs in up to 10 to 15% of patients after an acute MI, usually within the first 24 hours (Chapter 64). The incidence of atrial flutter or another supraventricular tachycardia is much lower. The risk for AF increases with age, larger MIs, heart failure, pericarditis, atrial infarction, hypokalemia, hypomagnesemia, hypoxia, pulmonary disease, and hyperadrenergic states. The incidence of AF is reduced by effective early recanalization. Hemodynamic compromise with rapid rates and systemic embolism (in ~2%) are adverse consequences of AF. Systemic embolism can occur on the first day, so prompt anticoagulation with heparin is indicated.

Recommendations for management of AF include the following: electrical cardioversion for patients with severe hemodynamic compromise or ischemia; rate control with intravenous digoxin for patients with ventricular dysfunction (i.e., give 1.0 mg, one half initially and one half in 4 hours), with an intravenous β-blocker (e.g., metoprolol, 5 mg over 2 minutes to a total of 15 mg over 10 to 15 minutes) in those without clinical ventricular dysfunction, or with intravenous diltiazem or verapamil in hemodynamically compensated patients with a contraindication to β-blockers; and anticoagulation with heparin (or LMWH). Amiodarone, which is generally reserved for patients with or at high risk for recurrence, may be continued for 6 weeks if sinus rhythm is restored and maintained.

Bradycardias, Conduction Delays, and Heart Block

Sinus and AV nodal dysfunction is common during acute MI. Sinus bradycardia, a result of increased parasympathetic tone often in association with inferior acute MI, occurs in 30 to 40% of patients. Sinus bradycardia is particularly common during the first hour of acute MI and with recanalization of the right coronary artery (Bezold-Jarisch reflex). Vagally mediated AV block also can occur in this setting. Anticholinergic therapy (atropine, 0.5 to 1.5 mg IV) is indicated for *symptomatic* sinus bradycardia (heart rate generally <50 beats per minute associated with hypotension, ischemia, or escape ventricular arrhythmia), including ventricular asystole, and *symptomatic* second-degree (Wenckebach) or third-degree block at the AV nodal level (narrow QRS complex escape rhythm). Atropine is not indicated and can worsen infranodal AV block (anterior MI, wide complex escape rhythm).

New-onset infranodal AV block and intraventricular conduction delays or bundle branch blocks (BBBs) predict substantially increased in-hospital mortality. Fortunately, their incidence has declined in the recanalization era (from 10 to 20% to ~4%). Mortality is related more to extensive myocardial damage than to heart block itself, so cardiac pacing only modestly improves survival. Prophylactic placement of multifunctional patch electrodes, which allow for immediate transcutaneous pacing (and defibrillation) if needed, is indicated for symptomatic sinus bradycardia refractory to drug therapy, infranodal second-degree (Mobitz II) or third-degree AV block, and new or indeterminate-age bifascicular (LBBB; RBBB with left anterior or left posterior fascicular block) or trifascicular block (bilateral or alternating BBB [any age], BBB with first-degree AV block). Transcutaneous pacing is uncomfortable and is intended for prophylactic and temporary use only. In patients who require a pacemaker to maintain a rhythm or who are at very high risk (>30%) of requiring pacing (including patients with alternating, bilateral BBB, with new or indeterminate-age bifascicular block with first-degree AV block, and with infranodal second-degree AV block) should have a transvenous pacing electrode inserted as soon as possible.

Indications for permanent pacing after acute MI depend on the prognosis of the AV block and not solely on symptoms. Class I indications include even transient second- or third-degree AV block in association with BBB and symptomatic AV block at any level. Advanced block at the AV nodal level (Wenckebach) rarely is persistent or symptomatic enough to warrant permanent pacing.

Heart Failure and Other Low-Output States

Cardiac pump failure is the leading cause of circulatory failure and in-hospital death from acute MI. Manifestations of circulatory failure can include a weak pulse, low blood pressure, cool extremities, a third heart sound, pulmonary congestion, oliguria, and obtundation. However, several distinct mechanisms, hemodynamic patterns, and clinical syndromes characterize the spectrum of circulatory failure in acute MI. Each requires a specific approach to diagnosis, monitoring, and therapy (see Table 73-3).

Left Ventricular Dysfunction

The degree of LV dysfunction correlates well with the extent of acute ischemia or infarction. Hemodynamic compromise becomes evident when impairment involves 20 to 25% of the left ventricle, and cardiogenic shock or death occurs with involvement of 40% or more (Chapter 107). Pulmonary congestion and S_3 and S_4 gallops are the most common physical findings. Early recanalization (with fibrinolytic agents, PCI, or CABG) is the most effective therapy to reduce infarct size, ventricular dysfunction, and associated heart failure. Medical treatment of heart failure related to the ventricular dysfunction of acute MI is otherwise generally similar to that of heart failure in other settings (Chapter 59) and includes adequate oxygenation and diuresis (begun early, blood pressure permitting, and continued on a long-term basis if needed). Morphine sulfate (i.e., 2 to 4 mg IV, with increments as needed after 5 to 15 minutes or more) is useful for patients with pulmonary congestion. Nitroglycerin also reduces preload and effectively relieves congestive symptoms. Titrated oral ACE inhibitor therapy (e.g., captopril, incremented from 3.125 to 6.25 mg three times daily to 50 mg twice daily as tolerated) also is indicated for heart failure and pulmonary edema unless excessive hypotension (systolic blood pressure <100 mm Hg) is present. Treatment can be begun sublingually (0.4 mg every 5 minutes three times), and then the transition can be made to intravenous therapy (initially 5 to 10 µg/minute, incrementing by 5 to 20 µg/minute until symptoms are relieved or until mean arterial pressure falls by 10% in normotensive or 30% in hypertensive patients but not <90 mm Hg or >30 mm Hg lower than baseline). Intravenous vasodilator therapy to reduce preload and afterload, inotropic support, and intra-aortic balloon counterpulsation (IABP), together with urgent recanalization, are indicated in cardiogenic shock (Chapter 107).

Volume Depletion

Relative or absolute hypovolemia is a frequent cause of hypotension and circulatory failure and is easily corrected if it is recognized and treated promptly. Poor hydration, vomiting, diuresis, and disease- or drug-induced peripheral vasodilation can contribute to this condition. Hypovolemia should be identified and corrected with intravenous fluids before more aggressive therapies are considered. An empirical fluid challenge may be tried in the appropriate clinical setting (e.g., for hypotension in the absence of congestion, for inferior or RV infarction, and for hypervagotonia). If filling pressures are measured, cautious fluid administration to a pulmonary capillary wedge pressure of up to about 18 mm Hg may optimize cardiac output and blood pressure without impairing oxygenation.

Right Ventricular Infarction

RV ischemia and infarction occur with proximal occlusion of the right coronary artery (before the take-off of the RV branches). Ten to 15% of inferior acute STEMIs show classic hemodynamic features, and these patients form the highest-risk subgroup for morbidity and mortality (25 to 30% versus <6% hospital mortality). Improvement in RV function commonly occurs over time, a finding suggesting reversal of ischemic stunning and other favorable accommodations, if short-term management is successful.

Hypotension in patients with clear lung fields and elevated jugular venous pressure in the setting of inferior or inferoposterior acute MI should raise the suspicion of RV infarction. Kussmaul's sign (distention of the jugular vein on inspiration) is relatively specific and sensitive in this setting. Right-sided ECG leads show ST segment elevation, particularly in V_{4R} (Chapter 54), in the first 24 hours of RV infarction. Echocardiography is helpful in confirming the diagnosis (RV dilation and dysfunction are observed). When right-sided heart pressures are measured, a right atrial pressure of 10 mm Hg or greater and 80% or more of the pulmonary capillary wedge pressure are relatively sensitive and specific for RV ischemic dysfunction.

Management of RV infarction consists of early maintenance of RV preload with intravenous fluids, reduction of RV afterload (i.e., afterload-only reducing drugs as for LV dysfunction; consider intra-aortic balloon pump), early recanalization, short-term inotropic support if needed, and avoidance of venodilators (e.g., nitrates) and diuretics used for LV failure (they may cause marked hypotension). Volume loading with normal saline solution alone is often effective. If the cardiac output fails to improve after 0.5 to 1 L fluid, inotropic support with intravenous dobutamine (starting at 2 µg/kg/minute and titrating to hemodynamic effect or tolerance, up to 20 µg/kg/minute) is recommended. High-grade AV block is common, and restoration of AV synchrony with temporary AV sequential pacing can lead to substantial improvement in cardiac output. The onset of AF (in up to one third of RV infarcts) can cause severe hemodynamic compromise requiring prompt cardioversion. Early coronary recanalization with fibrinolysis or PCI markedly improves outcomes.

Cardiogenic Shock

Cardiogenic shock (Chapter 107) is a form of severe LV failure characterized by marked hypotension (systolic pressures <80 mm Hg) and reductions in cardiac index (to <1.8 L/minute/m^2) despite high LV filling pressure (pulmonary capillary wedge pressure >18 mm Hg). The cause is loss of a critical functional mass (>40%) of the left ventricle. Cardiogenic shock is associated with mortality rates of more than 70 to 80% despite aggressive medical therapy. Risk factors include age, large (usually anterior) acute MI, previous MI, and diabetes. In patients with suspected shock, hemodynamic monitoring and IABP are indicated. Intubation often is necessary. Vasopressors are often needed. Early urgent mechanical revascularization (PCI or CABG), if feasible, affords the best chance for survival, especially in patients younger than 75 years (Chapter 107).

IABP remains useful for patients with medically refractory unstable ischemic syndromes and for cardiogenic shock. The deflated balloon catheter is introduced into the femoral artery and is advanced into the aorta. The ECG triggers balloon inflation during early diastole, thereby augmenting coronary blood flow; deflation then occurs in early systole, thereby reducing LV afterload. Primary IABP therapy for cardiogenic shock associated with acute MI provides temporary stabilization but does not reduce mortality (>80%). IABP is currently recommended in the setting of acute MI as a stabilizing measure for patients undergoing angiography and subsequent PCI or surgery for (1) cardiogenic shock, (2) mechanical complications (acute mitral regurgitation, acute ventricular septal defect), (3) refractory post-MI ischemia, or (4) recurrent intractable VT or VF associated with hemodynamic instability. IABP is not useful in patients with significant aortic insufficiency or severe peripheral vascular disease.

Mechanical Complications

Mechanical complications usually occur within the first weeks and account for approximately 15% of MI-related deaths. Such complications include acute mitral valve regurgitation, ventricular septal defect, free wall rupture, and LV aneurysm. Suspicion and investigation of a mechanical defect should be prompted by a new murmur or sudden, progressive hemodynamic deterioration with pulmonary edema or a low output state. Transthoracic or transesophageal Doppler echocardiography usually establishes the diagnosis. A balloon flotation catheter can be helpful in confirming the diagnosis. Arteriography to identify correctable coronary artery disease is warranted in most cases. Surgical consultation should be requested promptly, and urgent repair is usually indicated.

Acute mitral valve regurgitation (Chapter 75) results from infarct-related rupture or dysfunction of a papillary muscle. Total rupture leads to death in 75% of patients within 24 hours. Medical therapy is initiated with nitroprusside (beginning with 0.1 µg/kg/minute and titrating upward every 3 to 5 minutes to the desired effect, as tolerated by blood pressure response, up to 5 µg/kg/minute), to lower preload and to improve peripheral perfusion, and inotropic support (e.g., dobutamine, titrated from 2 up to 20 µg/kg/minute in normotensive patients; dopamine, titrated from 2 up to 20 µg/kg/minute in hypotensive patients; or combined dobutamine and dopamine). An IABP is used to maintain hemodynamic stability. Emergency surgical repair (if possible) or replacement is then undertaken. Surgery is associated with high mortality (≥25 to 50%), but it leads to better functional and survival outcomes than medical therapy alone.

Post-infarction septal rupture with *ventricular septal defect,* which occurs with increased frequency in elderly patients, in patients with hypertension, and possibly after fibrinolysis, also warrants urgent surgical repair. Because a small post-MI ventricular septal defect can suddenly enlarge and cause rapid hemodynamic collapse, all septal perforations should be repaired. On

diagnosis, invasive monitoring is recommended, together with vasodilators (e.g., nitroprusside, initially 0.1 µg/kg/minute, titrated upward every 3 to 5 minutes to desired effect, as tolerated by blood pressure response, up to 5 µg/kg/minute) and, if needed, judicious use of inotropic agents (e.g., dobutamine, titrated from 2 up to 20 µg/kg/minute in normotensive patients; dopamine, titrated from 2 up to 20 µg/kg/minute in hypotensive patients; or combined dobutamine and dopamine). An IABP should be inserted, a surgical consultation promptly obtained, and surgical repair undertaken as soon as feasible.

LV free wall rupture usually causes acute cardiac tamponade with sudden death. In a small percentage of cases, however, resealing or localized containment ("pseudoaneurysm") can allow medical stabilization, usually with inotropic support or an IABP, followed by emergency surgical repair.

An *LV aneurysm* can develop after a large, usually anterior, acute MI. If refractory heart failure, VT, or systemic embolization occurs despite medical therapy and PCI, aneurysmectomy with CABG is indicated.

Thromboembolic Complications

Thromboembolism has been described in approximately 10% of clinical series and 20% of autopsy series, a finding suggesting a high rate of undiagnosed events. Thromboembolism contributed to up to 25% of hospital deaths from acute MI in the past, but the incidence has declined in the recanalization era in association with greater use of antithrombotics, reductions of infarct size, and earlier ambulation. Systemic arterial emboli (including cerebrovascular emboli) typically arise from an LV mural thrombus, whereas pulmonary emboli commonly arise from thrombi in leg veins. Arterial embolism can cause dramatic clinical events, such as hemiparesis, loss of a pulse, ischemic bowel, or sudden hypertension, depending on the regional circulation involved.

Mural thrombosis with embolism typically occurs in the setting of a large (especially anterior) ST segment elevation acute MI and heart failure. The risk for embolism is particularly high when a mural thrombus is detected by echocardiography. Thus, in patients with anterior ST segment elevation acute MI and in other high-risk patients, echocardiography should be performed during hospitalization; if results are positive, anticoagulation should be started (with an antithrombin), if not already initiated, and continued (with warfarin) for 6 months.

Deep vein thrombosis can be prevented by lower extremity compression therapy, by limiting the duration of bedrest, and by the use of subcutaneous unfractionated heparin or LMWH (in patients at risk not receiving intravenous heparin) until patients are fully ambulatory (Chapter 81). Patients with pulmonary embolism are treated with intravenous heparin, then oral anticoagulation for 6 months (Chapter 98).

Risk Stratification after Myocardial Infarction

The goal of risk stratification before and early after discharge for acute MI is to assess ventricular and clinical function, latent ischemia, and arrhythmic risk, to use this information for patient education and prognostic assessment, and to guide therapeutic strategies (see Fig. 73-3).

Cardiac Catheterization and Noninvasive Stress Testing

Risk stratification generally involves functional assessment by one of three strategies: cardiac catheterization, submaximal exercise stress ECG before discharge (at 4 to 6 days), or symptom-limited stress testing at 2 to 6 weeks after discharge. Many or most patients with ST segment elevation acute MI undergo invasive evaluation for primary PCI or after fibrinolytic therapy. Catheterization generally is performed during hospitalization for patients at high risk. In others, predischarge submaximal exercise testing (to peak heart rate of 120 to 130 beats per minute or 70% of the predicted maximum) appears safe when it is performed in patients who are ambulating without symptoms; it should be avoided within 2 to 3 days of acute MI and in patients with unstable post-MI angina, uncompensated heart failure, or serious cardiac arrhythmias. Alternatively or in addition, patients may undergo symptom-limited stress testing at 2 to 6 weeks before they return to work or resume other increased physical activities. Abnormal test results include not only ST segment depression but also low functional capacity, exertional hypotension, and serious arrhythmias. Patients with positive test results should be considered for coronary angiography.

The sensitivity of stress testing can be augmented with radionuclide perfusion imaging (thallium-201 or technetium-99m sestamibi, or both; Chapter 56) or echocardiography (Chapter 55). Supplemental imaging also can quantify the LV ejection fraction and size the area of infarction or ischemia (e.g., by cardiac magnetic resonance imaging; Chapter 56). For patients taking digoxin or for those with ST segment changes that preclude accurate ECG interpretation (e.g., baseline LBBB or LV hypertrophy), an imaging study is recommended with initial stress testing. In others, an imaging study may be performed selectively for those in whom the exercise ECG test result is positive or equivocal. For patients unable to exercise, pharmacologic stress testing can be performed using adenosine, a long-acting bolus analogue of adenosine (e.g., regadenoson) or dipyridamole scintigraphy or using dobutamine echocardiography.

Electrocardiographic Monitoring

Modern telemetry systems capture complete rhythm information during hospital observations and allow for identification of patients with serious arrhythmias, so routine 24- to 48-hour ambulatory ECG (Holter) monitoring before or after hospital discharge is not recommended. Patients with sustained VT or VF occurring late during hospitalization or provoked during electrophysiologic study with nonsustained VT on monitoring are candidates for an ICD, especially if the ejection fraction is less than 40% (Fig. 73-4) (Chapters 65 and 66). Prophylactic ICD placement at least 1 month after acute MI prevents sudden death for patients with severely depressed function (ejection fraction ≤ 0.30) regardless of the rhythm status.[2]

Secondary Prevention, Patient Education, and Rehabilitation

Secondary Prevention

Advances in secondary prevention have resulted in increasingly effective measures to reduce recurrent MI and cardiovascular death. Secondary prevention should be conscientiously applied after acute MI (Table 73-8).

A fasting *lipid profile* is recommended on admission, and *lipid-lowering therapy,* typically with a statin, is begun in the hospital, generally with an LDL cholesterol goal of less than 70 mg/dL (Chapter 213). Continued smoking doubles the subsequent mortality risk after acute MI, and *smoking cessation* reduces the risk for reinfarction and death within 1 year (Chapter 31). An individualized smoking cessation plan should be formulated, including pharmacologic aids (nicotine gum and patches, bupropion, or varenicline).

Antiplatelet therapy (Chapter 37; Fig. 73-5) should consist of aspirin, given on a long-term basis to all patients without contraindications (maintenance dose, 75 to 162 mg/day). Clopidogrel (75 mg/day) or prasugrel (10 mg/day) is given to patients who received PCI with stenting, and clopidogrel is also appropriate for others at higher risk for recurrent vascular events. Therapy is recommended for a minimum of 1 month after a bare metal stent, for at least 3 months for sirolimus-eluting stents, and for at least 6 months for paclitaxel-eluting stents. If patients are not at high risk for bleeding, therapy is continued for up to 1 year or more.

Anticoagulant therapy (i.e., warfarin, with an international normalized ratio goal of 2.0 to 3.0) is indicated after acute MI for patients unable to take antiplatelet therapy (aspirin or clopidogrel), for those with persistent or paroxysmal AF, for those with LV thrombus, and for those who have suffered a systemic or pulmonary embolism. Anticoagulants also may be considered for patients with extensive wall motion abnormalities and markedly depressed ejection fraction with or without heart failure. Data on the benefits and risks of warfarin added to antiplatelet therapy (Fig. 73-5) are sparse.

ACE inhibitor therapy can prevent adverse myocardial remodeling after acute MI and can reduce heart failure and death; it is clearly indicated for long-term use in patients with anterior acute MI or an LV ejection fraction of less than 40%. ACE inhibitors also reduce recurrent MI in higher-risk patients with an ejection fraction greater than 40%. In contrast, ACE inhibition, when added to other contemporary therapies, provides little additional benefit in reducing cardiovascular events in patients who have stable coronary disease and a low risk (<5%/year) for a coronary event. These data suggest a rationale for the long-term use of ACE inhibitors (e.g., ramipril, 2.5 mg titrated to 10 mg/day, or lisinopril, 2.5 to 5 mg titrated to 10 mg/day) in all patients after MI, except perhaps those at lowest risk (i.e., without heart failure, hypertension, glucose intolerance, or reduced ejection fraction). An ARB (e.g., valsartan, 80 to 160 mg twice daily, or losartan, 50 to 100 mg/day) should be substituted in patients who cannot tolerate an ACE inhibitor; in patients with advanced heart failure, both an ACE inhibitor and an ARB may be complementary (Chapter 59). An aldosterone receptor blocker (e.g., eplerenone, 25 mg/day orally, increased to 50 mg/day after 4 weeks if tolerated, with monitoring of serum potassium levels) also should be added to the ACE inhibitor or ARB (but not both) regimen on a long-term basis in patients with depressed ejection fraction (≤0.40) and clinical heart failure or diabetes, unless this approach is contraindicated.

Long-term β-blocker therapy is strongly recommended for all MI survivors without uncompensated heart failure or other contraindications. Options include metoprolol, 20 to 200 mg per day, or carvedilol, 6.25 to 25 mg twice daily. Long-term therapy in patients at low risk (normal ventricular function, successful recanalization, absence of arrhythmias) is reasonable but not mandatory.

Nitroglycerin (0.4 mg) is prescribed routinely for sublingual or buccal administration for acute anginal attacks. Longer-acting oral therapy (isosorbide mononitrate, 30 to 60 mg orally every morning, or dinitrate, 10 to 40 mg orally two to three times daily) or topical nitroglycerin (e.g., start 0.5 inch, can titrate up to 2 inches, every 6 hours for 2 days) may be added to treatment regimens for angina or heart failure in selected patients.

Calcium-channel blockers are negatively inotropic and are *not* routinely given on a long-term basis; however, they may be given to selected patients without LV dysfunction (ejection fraction > 0.40) who are intolerant of β-blockers and who require these drugs for antianginal therapy (e.g., amlodipine, 5 to 10 mg/day orally, or diltiazem, 120 to 480 mg/day orally as sustained release or divided doses) or for control of heart rate in AF (e.g., diltiazem, 120 to 480 mg/day orally, or verapamil, 180 to 480 mg/day orally, as sustained release or in divided doses). Short-acting nifedipine should be avoided.

Hormone therapy with estrogen with or without progestin is not begun after an acute MI because it increases thromboembolic risk and does not prevent reinfarction. For women already receiving hormone replacement, therapy

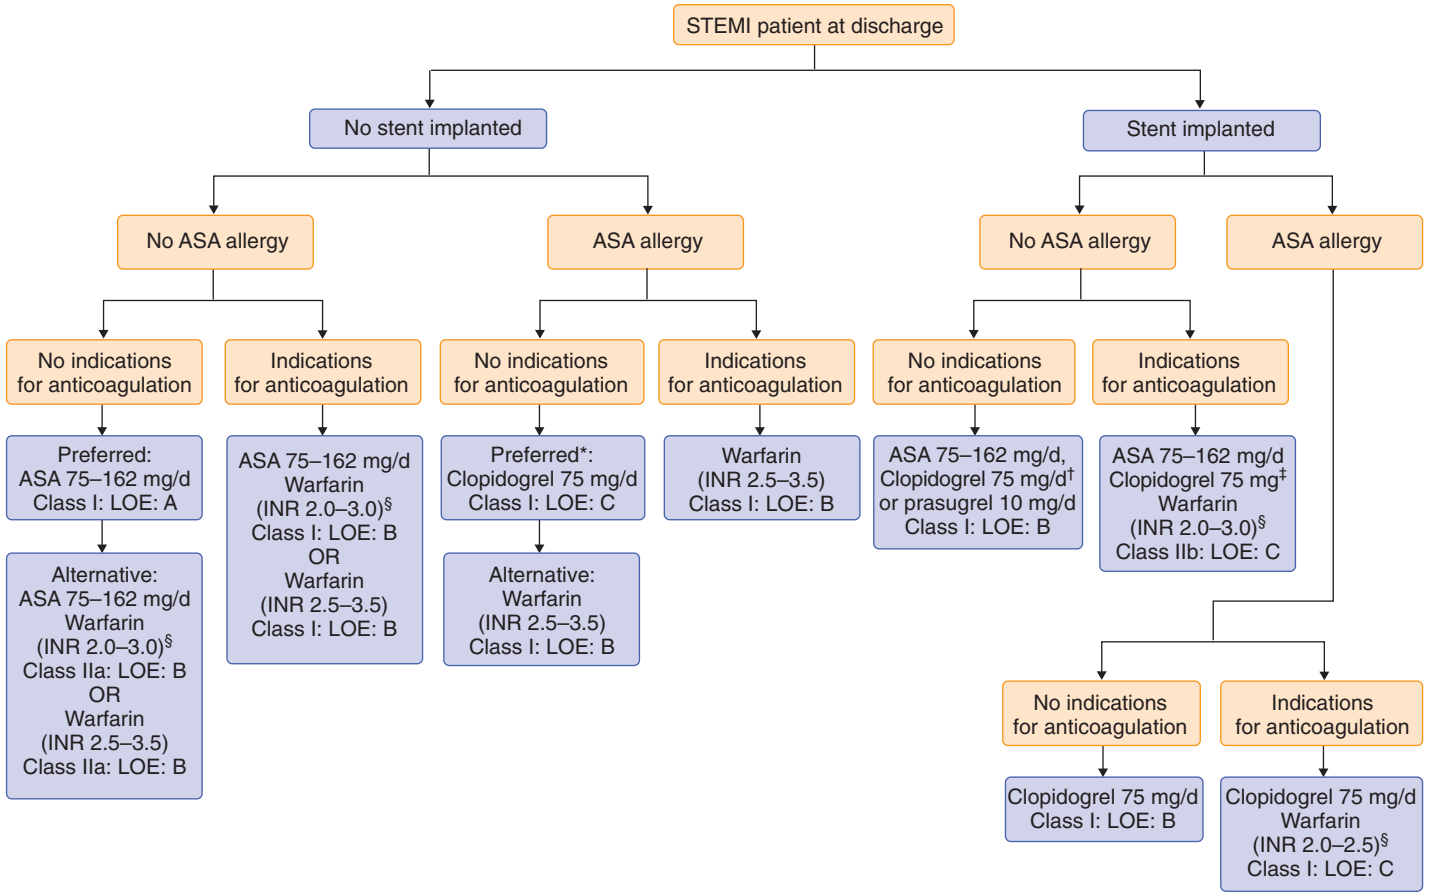

FIGURE 73-5. Long-term antithrombotic therapy at hospital discharge after ST segment elevation myocardial infarction (STEMI). *Clopidogrel is preferred over warfarin because of increased risk of bleeding and low patient compliance in warfarin trials. †For 12 months. ‡Discontinue clopidogrel 1 month after implantation of a bare metal stent or several months after implantation of a drug-eluting stent (3 months after sirolimus and 6 months after paclitaxel) because of the potentially increased risk of bleeding with warfarin and two antiplatelet agents. Continue aspirin (ASA) and warfarin on a long-term basis if warfarin is indicated for other reasons such as atrial fibrillation, left ventricular thrombus, cerebral emboli, or extensive regional wall motion abnormality. §An International Normalized Ratio (INR) of 2.0 to 3.0 is acceptable with tight control, but the lower end of this range is preferable. The combination of antiplatelet therapy and warfarin may be considered in patients younger than 75 years who have a low bleeding risk and who can be monitored reliably. LOE = level of evidence. (Adapted from Antman EM, Anbe DT, Armstrong PW, et al. ACC/AHA guidelines for the management of patients with ST-elevation myocardial infarction—executive summary. A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines [Writing Committee to Revise the 1999 Guidelines for the Management of Patients with Acute Myocardial Infarction]. *Circulation.* 2004;110:588-636.)

TABLE 73-8 DISCHARGE MEDICATION CHECKLIST AFTER MYOCARDIAL INFARCTION*

MEDICATION	DOSES	REASONS NOT TO USE	COMMENTS
Aspirin	Initial: 162-325 mg Maintenance: 75-162 mg daily	High bleeding risk	Reduces mortality, reinfarction, and stroke
Clopidogrel	Initial dose: 300-600 mg (75-150 mg after fibrinolysis in patients >75 years old) Maintenance: 75 mg daily	High bleeding risk; suboptimal antiplatelet response	Indicated after PCI for at least 1 yr (shorter time for BMS if high bleeding risk); also reduces vascular events when added to aspirin in non–ST segment elevation acute MI (also useful based on recent clinical trials after ST segment elevation acute MI) Genetic variants (CYP2C19) may reduce response Controversial interaction with PPIs (e.g., omeprazole)
Prasugrel	Initial dose: 60 mg Maintenance: 10 mg daily	High bleeding risk	Avoid with history of prior stroke/TIA Consider 5 mg daily in patients >75 years old or <60 kg
β-Blocker (e.g., metoprolol, carvedilol)	Metoprolol: 25-200 mg daily Carvedilol: 6.25-25 mg bid	Asthma, bradycardia, heart failure	Reduces mortality, reinfarction, sudden death, arrhythmia, hypertension, angina, atherosclerosis progression
ACE inhibitor (e.g., ramipril, lisinopril) or ARB (e.g., valsartan, losartan)	Ramipril: 2.5-10 mg daily Lisinopril: 5-10 mg daily Valsartan: 80-160 mg daily-bid Losartan: 50-100 mg daily	Hypotension, allergy, hyperkalemia	Reduces mortality, reinfarction, stroke, heart failure, diabetes, atherosclerosis progression
Lipid-lowering agent (e.g., a statin) (e.g., atorvastatin, simvastatin)	Atorvastatin: 10-80 mg daily Simvastatin: 20-40 mg daily	Myopathy, rhabdomyolysis, hepatitis	Goal = LDL <100 and preferably <70 (statins also can benefit patients with lower LDL†); consider addition of niacin or fibrate for high non-HDL cholesterol, low HDL
Nitroglycerin sublingual	0.4 mg SL PRN for angina	Aortic stenosis; sildenafil (Viagra) use	Instruct on PRN use and appropriate need for medical attention

*Medications given at hospital discharge improve long-term compliance.
†Heart Protection Study (*Lancet*. 2002;360:7); and PROVE-IT Study (*N Engl J Med*. 2004;350:1495).
ACE, angiotensin-converting enzyme; ARB = angiotensin receptor blocker; bid = twice daily; BMS = bare metal stent; HDL = high-density lipoprotein; LDL = low-density lipoprotein; MI = myocardial infarction; PCI = percutaneous coronary intervention; PRN = as needed; daily = once daily, SL = sublingual; TIA, transient ischemic attack.

should be discontinued unless it is being given for another compelling indication.

Hypertension (Chapter 67) and diabetes mellitus (Chapter 236) must be assessed and tightly controlled in patients after acute MI. ACE inhibitors or β-blockers as described earlier are usually the first-choice therapies for hypertension, with ARBs indicated when ACE inhibitors are not tolerated. ACE inhibitors and ARBs also can reduce the long-term complications of diabetes.

Antioxidant supplementation (e.g., vitamin E, vitamin C) does not benefit patients after acute MI and is *not* recommended. Folate therapy reduces homocyst(e)ine levels, but it has not been effective in reducing clinical events in large secondary prevention trials. Fish oil supplements showed no benefit in the best randomized trial.

Antiarrhythmic drugs are *not* generally recommended after acute MI, and class I antiarrhythmic agents can increase the risk for sudden death. Class III drugs (amiodarone, sotalol, dofetilide) may be used as part of the management strategy for specific arrhythmias (e.g., AF, VT) (Chapters 64 and 65).

The intracoronary infusion of stem cells has been proposed as a mechanism to reduce infarct size. To date, however, trials have been inconclusive.

Patient Education and Rehabilitation

The hospital stay provides an important opportunity to educate patients about their MI and its treatment, coronary risk factors, and behavioral modification. Education should begin on admission and should continue after discharge. However, the time before hospital discharge is particularly opportune. Many hospitals use case managers and prevention specialists to augment physicians and nurses, to provide educational materials, to review important concepts, to assist in formulating and actualizing individual risk-reduction plans, and to ensure proper and timely outpatient follow-up. This follow-up should include early return appointments with the patient's physician (within a few weeks). Instructions on activities also should be given before discharge. Many hospitals have cardiac rehabilitation programs that provide supervised, progressive exercise.

INTERVENTIONAL AND SURGICAL TREATMENT OF CORONARY ARTERY DISEASE

PAUL S. TEIRSTEIN AND BRUCE W. LYTLE

Percutaneous coronary intervention (PCI) and coronary artery bypass graft (CABG) surgery represent alternative and sometimes complementary approaches to coronary revascularization. Each has its relative indications, advantages, disadvantages, and contraindications.

PERCUTANEOUS CORONARY INTERVENTION

PCI is applicable to most forms of coronary artery disease, including multivessel disease, total occlusions, saphenous vein graft disease, unstable angina (Chapter 72), and acute myocardial infarction (MI) (Chapter 73). An estimated 2 million PCIs are performed worldwide each year, making it one of the most widely used medical procedures. Its popularity is based largely on its simplicity, the need for only local anesthesia, a short (approximately 1 day) hospitalization, and negligible postprocedure recovery time.

Mechanisms and Technical Considerations

Under local anesthesia, a hollow-bore needle is inserted percutaneously into a peripheral artery (usually the femoral or radial artery). A guidewire (approximately 0.038 inch) is placed through this needle and advanced into the aorta. The needle is removed, leaving the guidewire, over which a small-caliber (approximately 3 mm), specially shaped catheter (called a guiding catheter) is advanced under fluoroscope guidance into the ostium of the obstructed coronary artery. By use of radiographic contrast injections that provide fluoroscopic visualization of the coronary artery lumen, a thin (approximately 0.014 inch), highly steerable guidewire is directed down the coronary artery and across the stenotic lesion. This guidewire becomes a "rail" over which therapeutic tools such as inflatable balloons, stents, and atherectomy catheters are passed to the diseased segment (Fig. 74-1).

Balloon catheters (Fig. 74-2) typically have two lumens, one to allow passage over the guidewire and another to carry a mixture of saline and radiographic contrast material to inflate a balloon at the distal catheter tip. Under fluoroscopy, the balloon is centered across the lesion and inflated to 3 to 20 atmospheres of pressure. Balloon inflation widens the narrowed lumen by stretching the vessel and, in most cases, causing a tear (a therapeutic dissection) at the edges of the plaque, where the atheroma meets the nondiseased media. Atherectomy catheters, which also are passed over a guidewire to the diseased segment, remove plaque by a shaving, grinding, slicing, or suction mechanism. Coronary stents are metallic scaffolding devices that are crimped onto a deflated balloon catheter before insertion into the diseased vessel. During balloon inflation, the collapsed stent expands to support the vessel lumen (Fig. 74-3). Whereas balloons and atherectomy devices create an adequate, albeit rough channel through diseased arteries, the supporting structure of the stent can widen the lumen to near its predisease dimensions.

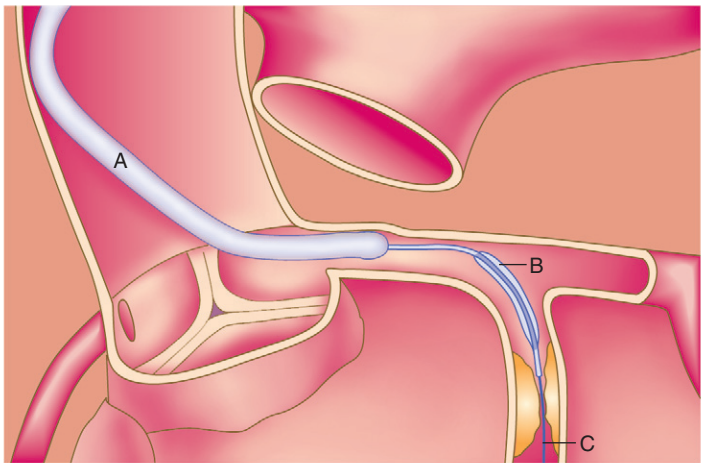

FIGURE 74-1. Schematic view of coronary angioplasty technique. A guide catheter (A) is inserted into the orifice of the coronary artery (in this figure, the left main); a balloon catheter (B) is advanced over a thin guidewire (C) into the lesion. Balloon inflation dilates the stenotic region. (Modified from Baim DS. Percutaneous balloon angioplasty and general coronary intervention. In: Baim DS, ed. *Grossman's Cardiac Catheterization, Angiography, and Intervention,* 7th ed. Philadelphia: Lippincott Williams & Wilkins; 2005.)

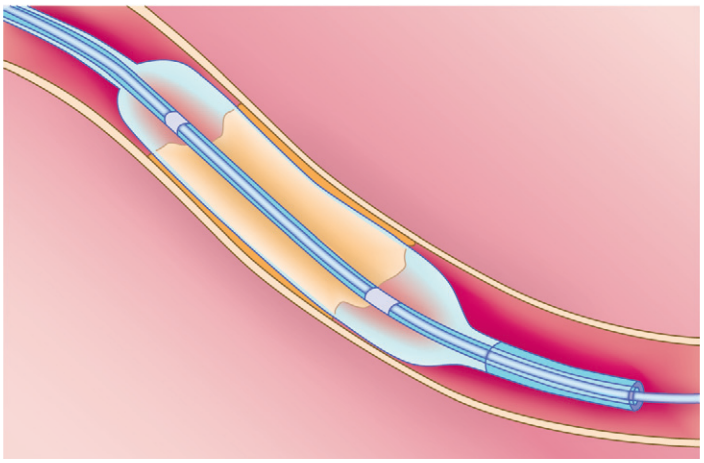

FIGURE 74-2. Balloon angioplasty catheter. The catheter consists of two lumens, an inflation lumen and a guidewire lumen. Two radiopaque markers, indicating the lateral balloon margins, aid in positioning of the balloon before inflation.

With a stent, tissue flaps are "pinned" against the wall, and recoil is limited. Most stents are designed so that the metallic struts compose only about 20% of the surface area to allow a rapid endothelialization (during about 2 weeks) and a reduced risk of thrombosis. Because coronary stents are able to obtain a larger and more secure lumen, some resist restenosis, and some elute beneficial medications, they are now used in more than 95% of PCIs.

During the PCI procedure, the interventional cardiologist is able to assess the target vessel fluoroscopically by injections of contrast material through the guiding catheter (Fig. 74-4). When the coronary artery has been opened successfully, all catheters are withdrawn, and the arterial access site is sealed by mechanical pressure, an absorbable plug, or a remote suturing device. Patients without comorbidity ambulate in 3 to 6 hours. Discharge from the hospital usually occurs on the morning after the procedure, after stability of the arterial access site, cardiac biomarkers, and electrocardiogram is confirmed. Selected patients in some medical centers are treated as outpatients and released 6 to 12 hours after the procedure without an overnight stay.

Selection of Patients

Any decision to perform PCI must include a review of the coronary angiogram (Chapter 57) by an experienced interventional cardiologist to assess the lesion's technical suitability for the procedure. The disease must narrow the coronary artery lumen by at least 60%, and the quantity of myocardium subtended by the vessel should not be trivial. High-risk lesion characteristics, such as longer lesion length, vessel tortuosity, lesion calcification, or the presence of thrombus, must be taken into consideration. Subtle angiographic findings, such as the presence of collateral vessels that supply a different myocardial territory and that originate distal to the target, should be appreciated. For each patient, the benefits of PCI must be weighed against the procedural risk. Characteristics of the patient conveying increased risk include advanced age (i.e., >75 years), diabetes, smaller vessels that are often found in women, prior MI, significant impairment of left ventricular function, and renal insufficiency.

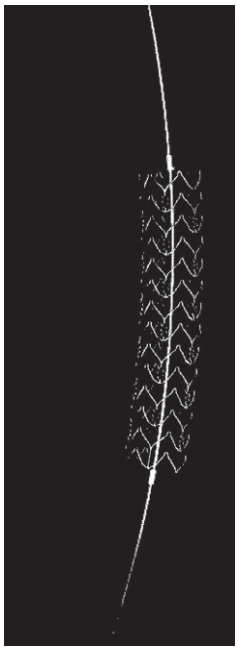

FIGURE 74-3. Balloon-expandable coronary stent. The stainless steel stent is crimped onto a balloon catheter to allow low-profile passage through the coronary artery. When it is positioned across the lesion, the balloon is inflated, expanding the stent. After balloon deflation and removal, the stent remains, providing a scaffold that supports the vessel lumen.

Procedural Success and Complications

With use of modern techniques in appropriately selected patients, most PCI procedures have a greater than 95% success rate. The single exception is a chronic total coronary occlusion (100% obstruction of the lumen), in which the interventional cardiologist's ability to negotiate a guidewire through the blockage is only about 50 to 80%. With the increased use of coronary stents and adjunctive antiplatelet agents (thienopyridines and platelet glycoprotein IIb/IIIa inhibitors), abrupt coronary artery closure is rarely encountered. When PCI is performed by an experienced interventional cardiologist in appropriately selected patients, the risk of in-hospital death is less than 1%; MI (usually small, non–ST segment elevation MI) is approximately 5%; the need for urgent or emergent CABG surgery is less than 1%; the risk of stroke is less than 0.1%; the chance of coronary perforation is less than 1%; and morbidity at the arterial access site (i.e., hematoma, pseudoaneurysm, or arteriovenous fistula) occurs in less than 5%. Balloons and filters deployed within a coronary vessel beyond the target lesion to limit distal embolization of plaque, platelet aggregates, and other "debris" can further reduce ischemic complications in selected, high-risk patients.

Restenosis and Thrombosis

Restenosis is a renarrowing of an artery after a PCI procedure, usually resulting from one of two general mechanisms. The first mechanism, unfavorable remodeling and elastic recoil, is a mechanical renarrowing caused by adventitial constriction and shrinkage of the vessel lumen. The second mechanism, neointimal hyperplasia, is due to the proliferation of smooth muscle cells and matrix in response to the injury caused by balloons, stents, or atherectomy devices. Restenosis occurs in 10 to 50% of PCI patients after balloon angioplasty without stenting, usually within the first 6 months after the procedure. Characteristics associated with higher risk of restenosis include longer lesions, small-diameter vessels, diabetes, and multivessel disease. Treatment with either balloon angioplasty or atherectomy devices results in similar rates of restenosis. Coronary stents provide a semirigid scaffolding within the lumen and reduce restenosis by eliminating the mechanical renarrowing

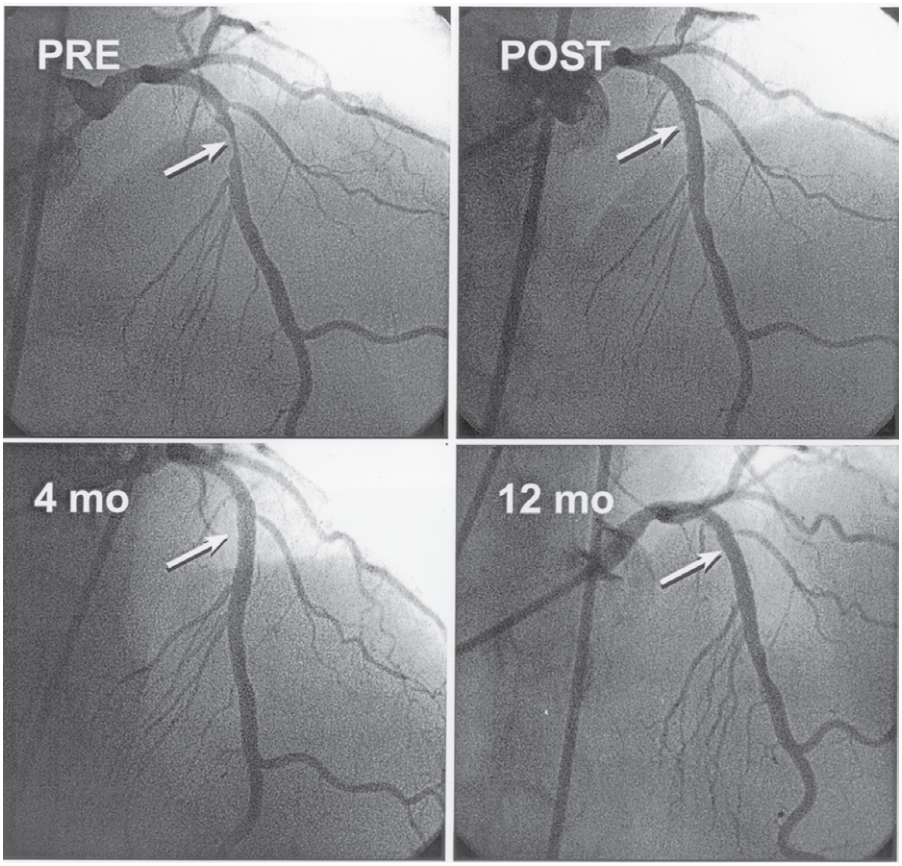

FIGURE 74-4. Angiographic images before, after, and at late follow-up after placement of a sirolimus-eluting stent. The left anterior descending artery contains a tight stenosis *(arrow, upper left panel)*. After stent implantation *(upper right panel)*, the stenosis is abolished *(arrow)*. Follow-up at 4 and 12 months *(bottom panels)* reveals a completely open lumen, with no evidence of restenosis *(arrows)*.

caused by unfavorable remodeling and elastic recoil. In randomized trials, bare metal stents reduce restenosis by about one third, from approximately 30 to 40% in patients randomized to balloon angioplasty to 20 to 30% in patients receiving stents.[1]

Although bare metal stents reduce restenosis, they do not eliminate restenosis because the stent struts that embed into the vessel wall increase the intimal proliferative response to injury. With bare metal stents, the mechanical component of restenosis is eliminated, but the proliferative component is enhanced. Smooth muscle cell division and matrix formation can migrate through the stent struts to renarrow the vessel lumen. Antiproliferative drugs that are embedded into a polymer stent coating are extremely effective for the control of restenosis. However, drug-eluting stents carry a slightly higher risk of thrombosis later (>1 year), especially if patients cannot or do not continue with aspirin plus a thienopyridine. As a result, trials of stents that release the cell cycle inhibitors sirolimus, everolimus, zotarolimus, and paclitaxel have demonstrated a reduced need for early repeated procedures,[2] but have not always found improved long-term outcome compared with bare metal stents.[3,4] Among the drug-eluting stents, the most favorable current data are for everolimus and sirolimus.[5,6]

Choices Related to Stenting

Based on long-term follow-up data, the choice between a bare metal stent and a drug-eluting stent remains controversial. Patients receiving drug-eluting stents must continue dual antiplatelet therapy with aspirin and a thienopyridine for a minimum of 12 months. If a patient is unlikely to be able to adhere to such therapy because of bleeding risks or the need for an invasive or surgical procedure, a bare metal stent is preferable. Atherectomy is rarely used, with the exception of the Rotablator (Boston Scientific, Maple Grove, MN), which pulverizes plaque into microparticles that pass through the coronary microcirculation and is particularly helpful for the treatment of heavily calcified lesions. After plaque debulking with the Rotablator, a drug-eluting stent is usually implanted.

Discharge Issues

Discharge planning after PCI represents an important opportunity to emphasize evidence-based medical treatment of atherothrombotic disease and coronary risk factor modification. All patients should receive aspirin (81 to 325 mg/day) indefinitely. For patients receiving bare metal stents, a minimum 2-week course of a thienopyridine (i.e., clopidogrel 75 mg daily or prasugrel 10 mg daily) is mandatory. If a drug-eluting stent is deployed, this dual antiplatelet therapy must be extended for at least 12 months, and then either aspirin alone or dual antiplatelet therapy must be continued indefinitely if possible.[7] Prolonged use of aspirin, clopidogrel, angiotensin-converting enzyme inhibitors, β-blockers, and lipid-lowering agents should be considered on the basis of randomized trials showing improved long-term outcome, particularly in patients who present with unstable angina syndromes (Chapters 71, 72, and 73). Smoking cessation (Chapter 31), blood pressure control (Chapter 67), stress management, exercise, weight loss, changes in dietary habits, and strict blood glucose control for diabetic patients (Chapter 237) also are important elements of the discharge plan.

Activity restrictions after PCI are modest. If the femoral artery was instrumented, heavy lifting is discouraged for several days. Intense aerobic exercise is usually discouraged for 2 to 4 weeks (especially after stent implantation) because exercise can activate platelets and lead to formation of thrombus at the angioplasty site. Patients may return to work 1 or 2 days after the procedure if their occupation does not include heavy lifting or excessive physical exercise. There is usually no restriction on driving an automobile.

CORONARY ANGIOPLASTY VERSUS MEDICAL THERAPY

PCI reduces angina and commonly leads to better treadmill exercise performance and improved quality-of-life measurements. However, PCI has not been shown to reduce the risks of death, MI, or other major cardiovascular events compared with modern optimal medical therapy in patients with stable angina (Chapter 71).[8] PCI reduces symptoms for the first 24 months, especially in patients with more severe angina, but symptoms were similarly improved over baseline with both intensive medical therapy and PCI at 36 months.[9] In truly asymptomatic patients, significant ischemia first should be documented by functional testing, or a large quantity of myocardium should be supplied by the stenotic coronary artery. Patients experiencing acute ST elevation MI (Chapter 73) represent an important subgroup in whom PCI has proved beneficial compared with medical therapy (Fig. 74-5). In ST elevation MI, randomized trials consistently have reported a reduction in

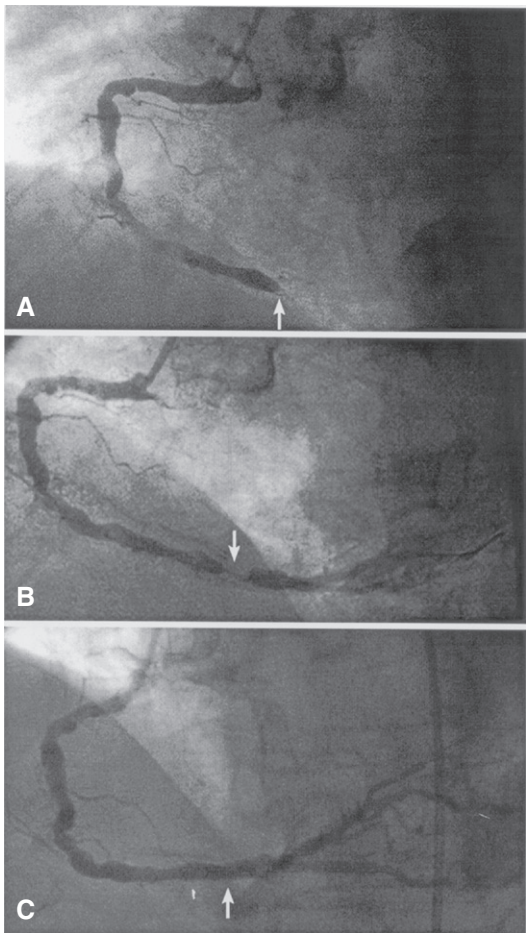

FIGURE 74-5. Primary coronary angioplasty for acute myocardial infarction. This 50-year-old man presented at midnight with 70 minutes of crushing substernal chest pressure accompanied by inferior ST segment elevation. Emergency angiography performed 45 minutes after arrival found 100% occlusion of the right coronary artery (**A,** *arrow*). Within 10 minutes, a guidewire was negotiated through the obstruction (presumably caused by fresh thrombus), allowing perfusion into the distal vessel and uncovering a high-grade stenotic lesion (**B,** *arrow*). After deployment of a coronary stent (**C,** *arrow*), the stenosis was abolished and significant myocardial damage aborted.

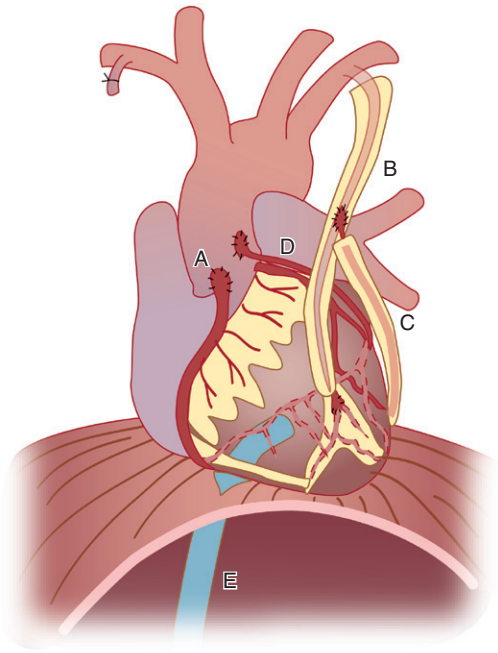

FIGURE 74-6. Types of bypass grafts. Bypass grafts include reversed saphenous vein graft from aorta to right coronary artery (A), in situ left internal mammary artery graft to anterior descending coronary artery (B), Y graft of right internal mammary artery from left internal mammary artery to circumflex coronary artery (C), radial artery graft from aorta to circumflex coronary artery (D), and in situ gastroepiploic graft to posterior descending branch of the right coronary artery (E).

mortality, stroke, subsequent MI, and recurrent ischemia with immediate PCI compared with thrombolytic therapy[10] or with initial thrombolytic therapy followed by rescue PCI as needed,[11] even if immediate PCI requires transfer to another hospital. For non–ST elevation MI and many patients with unstable angina, an early aggressive approach that includes either PCI or CABG in angiographically suitable patients is generally preferable to a conservative strategy,[12,13] except in lower-risk patients (Chapter 72).

CORONARY ARTERY SURGERY

CABG is based on the premise that the morbidity and mortality associated with coronary atherosclerosis are largely related to atherosclerotic coronary stenoses that can be demonstrated by coronary angiography (Chapter 57) and that if grafts are constructed to route blood flow around these stenoses, myocardial blood supply can be improved or preserved, cardiac symptoms relieved, cardiac events diminished, and survival prolonged. Over time, the fundamentals of that concept have been shown to be correct.

The most common types of grafts for coronary artery bypass have been reversed segments of saphenous vein and the internal thoracic arteries. Saphenous vein grafts are anastomosed to the aorta (proximal anastomosis) and to the coronary artery distal to the major obstruction (Fig. 74-6). Saphenous vein grafts have the advantages of availability, larger size than most coronary arteries, and favorable handling characteristics. However, with time, saphenous vein grafts may develop intrinsic pathologic changes, intimal fibroplasia, and vein graft atherosclerosis, each of which may lead to narrowing or occlusions. By 10 years after surgery, approximately 30% of saphenous vein grafts become occluded, and 30 to 35% of those remaining exhibit angiographic evidence of vein graft atherosclerosis. Treatment with platelet inhibitors and statins (Chapter 213) decreases the risk of vein graft failure but does not eliminate it.

Internal thoracic artery grafts, on the other hand, are resistant to the development of late atherosclerosis. When it is used as an in situ (subclavian origin intact) graft to the left anterior descending (LAD) coronary artery, the left internal thoracic artery graft has a more than 90% patency rate up to 20 years after operation. Because the LAD coronary artery has a strong prognostic influence, the left internal thoracic artery to LAD graft is a clinically important part of myocardial revascularization. Patients who receive a left internal thoracic artery to LAD graft with or without saphenous vein grafts have a better long-term survival rate, fewer reoperations, and fewer cardiac events compared with patients receiving only saphenous vein grafts. The right internal thoracic artery may also be used for revascularization as an in situ graft, as an aorta to coronary artery graft, or as a composite arterial graft from the left internal thoracic artery to a coronary artery. Use of both internal thoracic arteries as grafts provides incremental benefit over a single internal thoracic artery graft strategy and produces an improved survival with a lower risk for reoperation. By comparison, radial artery grafts provide outcomes that are essentially equivalent to those with saphenous vein grafts.[14]

Most CABG operations have been performed with a full median sternotomy incision, historically with the aid of cardiopulmonary bypass, aortic cross-clamping, and cardioplegic solution—techniques that allow exposure and arrest of the heart such that detailed microsurgical anastomoses can be constructed while myocardial function is effectively protected. By comparison, strategies for performing operations through smaller incisions (minimally invasive surgery) have had limited application for coronary revascularizations. Although beating heart ("off-pump") surgery without cardiopulmonary bypass has been widely advocated to avoid neurologic complications, it apparently does not provide such protection and leads to lower rates of graft patency compared with traditional on-pump CABG.[15]

Perioperative Risks

The risk of mortality associated with CABG correlates with ischemia at the time of operation, left ventricular function, extent of coronary stenoses, noncardiac atherosclerosis, and comorbid conditions and with the experience, skill, and judgment of the surgeon. Effective myocardial protection has diminished much of the incremental risk based on the severity of cardiac disease. For patients younger than 70 years without serious comorbid conditions, the mortality risk of primary CABG surgery is less than 1% in experienced hands regardless of the number of coronary arteries that are stenotic, and left ventricular dysfunction only slightly increases risk. Nevertheless, CABG surgery in the presence of ongoing myocardial ischemia due to acute

myocardial infarction, unstable angina, or acute vessel closure after PCI is still associated with increased risk. National data on primary CABG operations show a 1.7% mortality rate for elective operations, a 2.6% rate for "urgent" operations, a 6% rate for "emergency" procedures, and a 23% rate for "salvage" operations. Noncardiac comorbid conditions (aortic atherosclerosis, renal function, chronic obstructive pulmonary disease, and coagulation system disorders) increase perioperative risk when these conditions are severe.

The most serious postoperative morbidity after CABG is stroke, often related to aortic or cerebrovascular atherosclerosis and atherosclerotic embolization. Heightened awareness of the importance of aortic and carotid atherosclerosis and improved management strategies appear to have decreased the risk of focal stroke in patients previously at high risk. Serious wound complications of median sternotomy are uncommon (1 to 2%). Obesity, diabetes, and bilateral internal thoracic artery grafting (particularly in combination with diabetes) are associated with higher rates of wound complications.

Late Outcomes

The late outcomes after CABG are related to age, severity of cardiac disease before operation, noncardiac comorbid conditions, progression of atherosclerosis, and the operation itself. Many of these factors can be influenced by treatment choices. CABG tends to diminish but not to eliminate long-term survival differences based on the number of diseased coronary vessels, left main stenosis, and different levels of left ventricular function. The achievement of complete revascularization (bypass grafts to all stenotic coronary vessels) and the use of internal thoracic artery grafts improve long-term survival rates and symptomatic status.

Patients often have prolonged survival after CABG; more than 80% of patients are alive more than 10 years after operation. Over the long term, control of the progression of atherosclerosis by lifestyle modifications, pharmacologic treatment of hypertension (Chapter 67) and lipids (Chapter 213), and platelet inhibitors (Chapter 37) appears to extend the benefits of CABG.

INDICATIONS FOR BYPASS SURGERY

The goals of CABG are to relieve symptoms and to prolong life expectancy. On the basis of randomized trials and the emergence of alternative medical treatments and PCI, the surgical population has evolved toward patients with complex conditions, often involving left main or triple-vessel disease, diffuse coronary stenoses, totally obstructed vessels, abnormal left ventricular function, and diabetes. Surgically treated patients with single-vessel disease usually have LAD stenoses or have failed alternative treatments.

Symptom Relief

If patients who experience angina have severe stenoses in graftable coronary arteries that supply areas of myocardium ischemic at rest or with stress, CABG will reliably relieve angina. Randomized trials have shown that the relief of angina after CABG is more consistent than that achieved with alternative treatments. When intermittent heart failure symptoms represent an "anginal equivalent" that is also caused by ischemia, such symptoms also respond well to relief of that ischemia by CABG. Patients with symptoms of heart failure at rest are more complex, but dobutamine echocardiography (Chapter 55) and positron emission tomography (Chapter 56) can identify segments of viable but hibernating myocardium (ischemic at rest) that may improve with bypass grafting, thus reducing symptoms of heart failure.

Survival

Chronic Stable Angina

In randomized trials of patients with mild to moderate chronic stable angina, an improved survival rate has been documented for patients treated with initial CABG compared with initial medical treatment in the presence of a left main stenosis of more than 50% of the diameter, triple-vessel disease, double-vessel disease with a proximal LAD lesion, abnormal left ventricular function, or a strongly positive exercise test result (Chapter 71). Meta-analysis of these randomized trials also suggests a survival benefit of CABG for any patient with a proximal LAD lesion and myocardial ischemia. These are subgroups of patients for whom bypass surgery should be strongly considered even in the absence of severe symptoms. During these trials, patients with severe angina were not randomized but were included in observational studies that noted improved survival rates with CABG for patients with double- and triple-vessel disease and normal or abnormal left ventricular function. Medical, interventional, and surgical treatments have all advanced substantially since these trials were completed.

Unstable Angina or Non–ST Elevation Myocardial Infarction

Current data suggest an aggressive strategy, including CABG when indicated, in patients with unstable angina or non–ST elevation acute myocardial infarction (Chapter 72).[12]

Ischemic Syndromes without Randomized Trials

ST Elevation Acute Myocardial Infarction

For patients with ST segment elevation acute myocardial infarction, CABG may be indicated in the acute setting when thrombolytic therapy or PCI has not been effective, ischemia is ongoing, and large areas of myocardium remain jeopardized. CABG after a completed MI may be indicated in patients in whom persistent ischemia in noninfarcted areas of myocardium produces post-infarction angina or hemodynamic instability. Mechanical complications of myocardial necrosis, including papillary muscle rupture, ventricular septal rupture, and myocardial free wall rupture, are acute life-threatening situations that usually require urgent operation for repair of the defect, often combined with CABG (Chapter 73).

Failed Percutaneous Coronary Intervention

The availability of intracoronary stents has decreased the need for emergency CABG to treat acute failure of PCIs. Current indications for emergency CABG include closure or threatened closure of a vessel supplying a significant amount of myocardium.

Coronary Bypass Reoperations

Patients in whom new stenoses develop in native arteries or in bypass grafts may have recurrent ischemic syndromes. Observational study of patients with severe vein graft atherosclerosis indicate that this is an unstable lesion often leading to serious cardiac events, particularly if the LAD or multiple vessels are jeopardized; reoperation appears to improve the survival rate of these patients. Reoperations are more difficult and dangerous than primary procedures, but the risk now approaches that for primary procedures in institutions performing a large number of reoperations. PCI is sometimes an alternative for the treatment of vein graft disease.

Coexisting Cardiac Disease

During cardiac operations performed for valvular (Chapter 75) or aortic (Chapter 78) disease, the standard treatment is to perform bypass grafts to major coronary arteries with angiographic stenoses of more than 50% of the luminal diameter. No randomized trials have addressed this issue, and these indications, although logical given the natural history of atherosclerosis, remain practice patterns based on consensus but not on definitive data.

PERCUTANEOUS CORONARY INTERVENTION VERSUS CORONARY ARTERY BYPASS GRAFTING

The decision between PCI and CABG surgery is largely determined by clinical status and anatomic features but remains controversial. For patients with acute coronary syndromes, PCI is the preferred initial approach and is known to improve the survival rate of patients with ST elevation M. CABG is reserved for patients with failed acute PCI or residual myocardial ischemia. For patients with chronic coronary syndromes, there are currently no data to confirm that PCI prolongs life regardless of anatomy, whereas randomized trials, albeit older trials, demonstrate that CABG prolongs the life expectancy of patients with severe coronary artery disease, particularly patients with left ventricular dysfunction or severe ischemia. Surgery, therefore, is often the initial approach to these patient subsets.

For patients in whom the survival benefit of revascularization is less clear, the decision is often related to anatomic features. For low-risk patients followed for 1 year after revascularization, repeat revascularization is more frequent after PCI (14%) than CABG (6%), stroke is more common after CABG (2.2%) than PCI (0.6%), and the rates of death and MI are similar (Fig. 74-7). Patients with extensive and diffuse coronary stenoses appear to benefit most from surgery, whereas patients with more limited coronary stenoses, including some with left main stenosis, have equivalent outcomes with PCI.[18]

The need for repeated revascularization procedures is consistently higher in patients randomized to PCI.[17] In several randomized trials, diabetic patients with multivessel coronary disease have better outcomes with CABG surgery.[18,19]

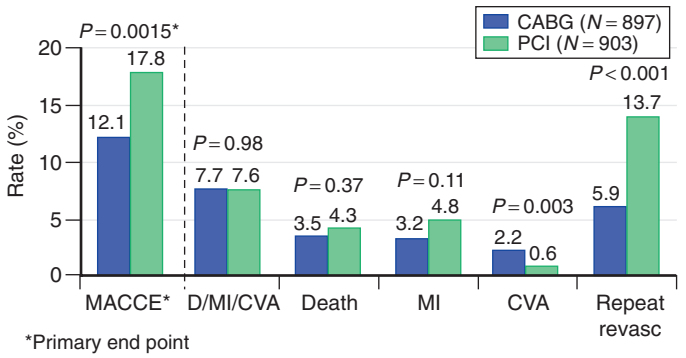

FIGURE 74-7. The SYNTAX trial randomized patients with left main vessel or three-vessel coronary artery disease to coronary artery bypass grafting (CABG) versus percutaneous coronary intervention (PCI). At 12 months, rates of death and myocardial infarction were similar, CABG increased stroke risk (2.2% vs. 0.6%), and PCI resulted in more repeat revascularizations. CVA = cerebrovascular accident, or stroke; MACCE = death, MI, CVA, and repeat revascularization; MI = myocardial infarction; repeat revasc = repeat revascularization. VALVULAR HEART DISEASE

BLASE A. CARABELLO

The cardiac valves permit unobstructed forward blood flow through the heart when they are open while preventing backward flow when they are closed. Most valvular heart diseases cause either valvular stenosis with obstruction to forward flow or valvular regurgitation with backward flow. Valvular stenosis imparts a pressure overload on the left or right ventricle because these chambers must generate higher than normal pressure to overcome the obstruction to pump blood forward. Valvular regurgitation imparts a volume overload on the heart, which now must pump additional volume to compensate for what is regurgitated. When valve disease is severe, these hemodynamic burdens can lead to ventricular dysfunction, heart failure, and sudden death (Table 75-1). In almost every instance, definitive therapy for severe valvular heart disease is mechanical restoration of valve function.

AORTIC STENOSIS

EPIDEMIOLOGY

Bicuspid and Other Congenitally Abnormal Aortic Valves

Approximately 1% of the population is born with a bicuspid aortic valve, with a male preponderance (Chapter 69). Although this abnormality does not usually cause a hemodynamic disturbance at birth, bicuspid aortic valves tend to deteriorate with age. Approximately one third of these valves become stenotic, another third become regurgitant, and the remainder cause only minor hemodynamic abnormalities. When stenosis develops, it usually occurs when patients are in their 40s, 50s, and 60s.

Sometimes, congenital aortic stenosis from a unicuspid, bicuspid, or even abnormal tricuspid valve causes symptoms during childhood and requires correction by adolescence. Occasionally, these congenitally stenotic aortic valves escape detection until adulthood.

Tricuspid Aortic Valve Stenosis

In some patients born with apparently normal tricuspid aortic valves, thickening and calcification develop similar to what occurs in bicuspid valves. When aortic stenosis develops in previously normal tricuspid aortic valves, it usually does so in the 60s to 80s. Although stenosis and calcifications of bicuspid and tricuspid aortic valves were formerly considered to be degenerative processes, it is clear that this type of aortic stenosis arises from an active inflammatory process similar to that of coronary heart disease. This concept is supported by many pieces of evidence. First, the initial lesion of aortic stenosis is similar to the plaque of coronary disease. Second, both diseases have hypertension and hyperlipidemia as risk factors. Third, there is excellent correlation between calcification of the aortic valve and calcification of the coronary arteries. Fourth, patients with the most severe aortic stenosis have the highest levels of C-reactive protein. However, statins, which are so effective in treating coronary disease, have been ineffective in retarding the progression of moderately advanced aortic stenosis.

Rheumatic Valvular Heart Disease

Rheumatic valve disease is now a rare cause of aortic stenosis in developed countries. In virtually every case, the mitral valve is also detectably abnormal.

PATHOBIOLOGY

The normal aortic valve area is 3 to 4 cm^2, and little hemodynamic disturbance occurs until the orifice is reduced to about one third of normal, at which point a systolic gradient develops between the left ventricle and aorta. Left ventricular (LV) and aortic pressures are normally nearly equal during systole. In aortic stenosis, intracavitary LV pressure must increase above aortic pressure, however, to produce forward flow across the stenotic valve and to achieve acceptable downstream pressure (see Fig. 57-2 in Chapter 57). There is a geometric progression in the magnitude of the gradient as the valve area narrows. Given a normal cardiac output, the gradient rises rapidly from 10 to 15 mm Hg at valve areas of 1.5 to 1.3 cm^2 to about 25 mm Hg at 1.0 cm^2, 50 mm Hg at 0.8 cm^2, 70 mm Hg at 0.6 cm^2, and 100 mm Hg at

TABLE 75-1 SUMMARY OF SEVERE VALVAR HEART DISEASE

	AORTIC STENOSIS	MITRAL STENOSIS	MITRAL REGURGITATION	AORTIC REGURGITATION
Etiology	Idiopathic calcification of a bicuspid or tricuspid valve Congenital Rheumatic	Rheumatic fever Annular calcification	Mitral valve prolapse Ruptured chordae Endocarditis Ischemic papillary muscle dysfunction or rupture Collagen vascular diseases and syndromes Secondary to LV myocardial diseases	Annuloaortic ectasia Hypertension Endocarditis Marfan syndrome Ankylosing spondylitis Aortic dissection Syphilis Collagen vascular disease
Pathophysiology	Pressure overload on the LV with compensation by LV hypertrophy As disease advances, reduced coronary flow reserve causes angina. Hypertrophy and afterload excess lead to systolic and diastolic LV dysfunction.	Obstruction to LV inflow increases left atrial pressure and limits cardiac output, thus mimicking LV failure. Mitral valve obstruction increases the pressure work of the right ventricle Right ventricular pressure overload is augmented further when pulmonary hypertension develops.	Places volume overload on the LV. Ventricle responds with eccentric hypertrophy and dilation, which allow increased ventricular stroke volume. Eventually, however, LV dysfunction develops if volume overload is uncorrected.	*Chronic:* Total stroke volume causes hyperdynamic circulation, induces systolic hypertension and causes pressure and volume overload. Compensation is by concentric and eccentric hypertrophy. *Acute:* Because cardiac dilation has not developed, hyperdynamic findings are absent. High diastolic LV pressure causes mitral valve preclosure and potentiates LV ischemia and failure.
Symptoms	Angina Syncope Heart failure	Dyspnea Orthopnea PND Hemoptysis Hoarseness Edema Ascites	Dyspnea Orthopnea PND	Dyspnea Orthopnea PND Angina Syncope
Signs	Systolic ejection murmur radiating to the neck Delayed carotid upstroke S_4, soft or paradoxical S_2	Diastolic rumble after an opening snap Loud S_1 Right ventricular lift Loud P_2	Holosystolic apical murmur radiating to the axilla, S_3 Displaced PMI	*Chronic:* Diastolic blowing murmur Hyperdynamic circulation Displaced PMI Quincke pulse de Musset's sign *Acute:* Short diastolic blowing murmur Soft S_1
Electrocardiogram	LAA LVH	LAA RVH	LAA LVH	LAA LVH
Chest radiograph	Boot-shaped heart Aortic valve calcification on lateral view	Straightening of left heart border Double density at right heart border Kerley B lines Enlarged pulmonary arteries	Cardiac enlargement	*Chronic:* Cardiac enlargement Uncoiling of the aorta *Acute:* Pulmonary congestion with normal heart size
Echocardiographic findings	Concentric LVH Reduced aortic valve cusp separation Doppler shows mean gradient ≥40 mm Hg in most severe cases	Restricted mitral leaflet motion Valve area ≤1 cm^2 in most severe cases Tricuspid Doppler may reveal pulmonary hypertension	LV and LAA in chronic severe disease Doppler: large regurgitant jet	*Chronic:* LV enlargement Large Doppler jet PHT <400 msec *Acute:* Small LV Mitral valve preclosure
Catheterization findings	Increased LVEDP Transaortic gradient 50 mm Hg AVA ≤0.7 in most severe cases	Elevated pulmonary capillary wedge pressure Transmitral gradient usually >10 mm Hg in severe cases MVA <1 cm^2	Elevated pulmonary capillary wedge pressure Ventriculography shows regurgitation of dye into LV	Wide pulse pressure Aortography shows regurgitation of dye into LV Usually unnecessary
Medical therapy	Avoid vasodilators Digitalis, diuretics, and nitroglycerin in inoperable cases	Diuretics for mild symptoms Anticoagulation in atrial fibrillation Digitalis, β-blockers, verapamil, or diltiazem for rate control	Vasodilators in acute disease No proven therapy in chronic disease	*Chronic:* Vasodilators may help in chronic asymptomatic disease with normal left ventricular function. *Acute:* Vasodilators
Indications for surgery	Appearance of symptoms in patients with severe disease (see text)	Appearance of more than mild symptoms Development of pulmonary hypertension Appearance of persistent atrial fibrillation	Appearance of symptoms EF <0.60 ESD ≥40 mm	*Chronic:* Appearance of symptoms EF <0.55 ESD ≥55 mm *Acute:* Even mild heart failure Mitral valve preclosure

AVA = aortic valve area; EF = ejection fraction; ESD = end-systolic diameter; LAA = left atrial enlargement; LV = left ventricle; LVEDP = left ventricular end-diastolic pressure; LVH = left ventricular hypertrophy; MVA = mitral valve area; PHT = pressure half-time; PMI = point of maximal impulse; PND = paroxysmal nocturnal dyspnea; RVH = right ventricular hypertrophy.

0.5 cm^2. The rate of progression of aortic stenosis varies widely from patient to patient; it may remain stable for many years or increase by more than 15 mm Hg per year.

A major compensatory response to the increased LV pressure associated with aortic stenosis is the development of concentric LV hypertrophy. The Laplace equation—stress (s) = pressure (p) × radius (r)/2 × thickness (th)—indicates that the force on any unit of LV myocardium (afterload) varies directly with ventricular pressure and radius and inversely with wall thickness. As pressure increases, it can be offset by increased LV wall thickness (concentric hypertrophy). The determinants of LV ejection fraction are contractility, preload, and afterload. By normalizing afterload, the development of concentric hypertrophy helps preserve ejection fraction and cardiac output despite the pressure overload. Although hypertrophy clearly serves a compensatory function, it also has a pathologic role and is in part responsible for the classic symptoms of aortic stenosis.

Angina

In general, angina (Chapter 71) results from myocardial ischemia when LV oxygen (and other nutrient) demand exceeds supply, which is predicated on coronary blood flow. In normal subjects, coronary blood flow can increase five- to eight-fold under maximum metabolic demand, but in patients with aortic stenosis, this reserve is limited. Reduced coronary blood flow reserve may be caused by a relative diminution in capillary ingrowth to serve the needs of the hypertrophied left ventricle or by a reduced transcoronary gradient for coronary blood flow because of the elevated LV end-diastolic pressure. Restricted coronary blood flow reserve appears to be responsible for angina in many patients who have aortic stenosis despite normal epicardial coronary arteries. In other patients, angina is due to increased oxygen demand when inadequate hypertrophy allows wall stress, a key determinant of myocardial oxygen consumption, to increase.

Syncope

Syncope (Chapters 50 and 62) generally occurs because of inadequate cerebral perfusion. In aortic stenosis, syncope is usually related to exertion. It may result when exertion causes a fall in total peripheral resistance that cannot be compensated by increased cardiac output because output is limited by the obstruction to LV outflow; this combination reduces systemic blood pressure and cerebral perfusion. In addition, high LV pressure during exercise may trigger a systemic vasodepressor response that lowers blood pressure and produces syncope. Cardiac arrhythmias, possibly caused by exertional ischemia, also cause hypotension and syncope.

Heart Failure

In aortic stenosis, contractile dysfunction (systolic failure) and failure of normal relaxation (diastolic failure) occur and cause symptoms (Chapter 58). The extent of ventricular contraction is governed by contractility and afterload. In aortic stenosis, contractility (the ability to generate force) is often reduced. The mechanisms of contractile dysfunction may include abnormal calcium handling, microtubular hyperpolymerization causing an internal viscous load on the myocyte, and myocardial ischemia. In some cases, contractile function is normal, but the hypertrophy is inadequate to normalize wall stress and excessive afterload results. Excessive afterload inhibits ejection, reduces forward output, and leads to heart failure.

The increased wall thickness that helps normalize stress increases diastolic stiffness. Even if muscle properties remain normal, higher filling pressure is required to distend a thicker ventricle. As aortic stenosis advances, collagen deposition also stiffens the myocardium and adds to the diastolic dysfunction.

CLINICAL MANIFESTATIONS

The diagnosis of aortic stenosis is usually first suspected when the classic systolic ejection murmur is heard during physical examination (Chapter 50). The murmur is loudest in the aortic area and radiates to the neck. In some cases, the murmur may disappear over the sternum and reappear over the LV apex, thereby giving the false impression that a murmur of mitral regurgitation is also present (Gallavardin's phenomenon). The intensity of the murmur increases with cycle length because longer cycles are associated with greater aortic flow. In mild disease, the murmur peaks in intensity in early systole or mid-systole. As the severity of stenosis worsens, the murmur peaks progressively later in systole. Perhaps the most helpful clue to the severity of aortic stenosis by physical examination is the characteristic delay in the carotid pulse with a diminution in its volume (see Fig. 50-5 in Chapter 50); in elderly patients, however, increasing carotid stiffness may pseudonormalize the carotid upstrokes. The LV apical impulse in aortic stenosis is not displaced but is enlarged and forceful. The simultaneous palpation of a forceful LV apex beat and a delayed and weakened carotid pulse is a persuasive clue that severe aortic stenosis is present. S_1 in aortic stenosis is generally normal. In congenital aortic stenosis when the valve is not calcified, S_1 may be followed by a systolic ejection click. In calcific disease, S_2 may be single and soft when the aortic component is lost because the valve neither opens nor closes well. In some cases, delayed LV emptying secondary to LV dysfunction may create paradoxical splitting of S_2. An S_4 gallop is common. In advanced disease, pulmonary hypertension and signs of right-sided failure are common.

Because of the dire consequences of missing the diagnosis of aortic stenosis, the physician must have a low threshold for obtaining an echocardiogram whenever aortic stenosis cannot be excluded by physical examination, especially in patients with a history of angina, syncope, or heart failure. In asymptomatic patients with suspicious murmurs, early diagnosis allows the patient and physician to be more vigilant regarding possible early signs and symptoms.

DIAGNOSIS

The electrocardiogram (ECG) in patients with aortic stenosis usually shows LV hypertrophy (Chapter 54). In some cases of even severe aortic stenosis, however, LV hypertrophy is absent on the ECG, possibly because of the lack of LV dilation. Left atrial abnormality is common because the stiff left ventricle increases left atrial afterload and causes the left atrium to dilate.

The chest radiograph in aortic stenosis is generally nondiagnostic. The cardiac silhouette is not usually enlarged but may assume a boot-shaped configuration. In advanced cases, there may be signs of cardiomegaly and pulmonary congestion; aortic valve calcification may be seen in the lateral view.

Echocardiography (Chapter 55) is indispensable to assess the extent of LV hypertrophy, systolic ejection performance, and aortic valve anatomy (Fig. 75-1). Doppler interrogation of the aortic valve makes use of the modified Bernoulli equation (gradient = 4 × velocity^2) to assess the severity of the stenosis (Chapter 55). As blood flows from the body of the left ventricle across the stenotic valve, the flow rate must accelerate for the volume to remain constant. Doppler interrogation of the valve can be performed to detect this increase in velocity for estimation of the valve gradient. The peak aortic flow velocity in patients with preserved LV systolic function is a useful clinical guide to prognosis. In patients with a flow velocity of 3.0 mL/second or less, symptoms are unlikely to develop in the next 5 years; by comparison, in patients with a flow velocity of 4.0 mL/second or greater, symptoms usually develop within 2 years.

Although exercise testing is contraindicated in symptomatic patients with aortic stenosis because of the high risk for complications, cautious exercise

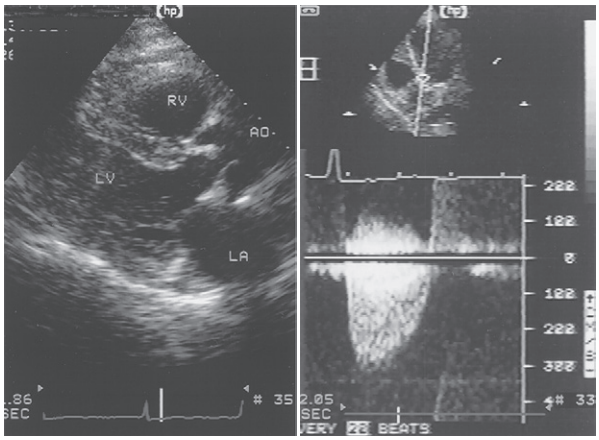

FIGURE 75-1. Doppler echocardiogram from a patient with aortic stenosis. The *left panel* shows thickened aortic valve leaflets that dome into the aorta with restricted opening in systole. The *top right panel* shows a miniaturized apical four-chamber view at the top with a Doppler cursor through the aorta, whereas the *bottom right panel* shows a continuous-wave spectral Doppler signal with a peak velocity of 3 m/sec. The peak valve gradient can be calculated as 4 × 3^2, or 36 mm Hg. AO = aorta; LA = left atrium; LV = left ventricle; RV = right ventricle. (Courtesy of Dr. Anthony DeMaria.)

testing is gaining favor in asymptomatic patients. Such testing often reveals latent symptoms or hemodynamic instability that have gone unrecognized during the patient's normal daily activities. Exercise-induced hypotension or symptoms are indications for aortic valve replacement in patients with severe aortic stenosis; in patients with mild to moderate aortic stenosis, another source of exercise limitation should be sought.

Brain natriuretic peptide levels may be higher in patients who will become symptomatic in a short time span. Levels exceeding 550 pg/mL portend a poor prognosis, but use of this biomarker to indicate the need for valve replacement is still premature.

Cardiac catheterization for performance of coronary arteriography is usually undertaken before surgery because most patients with aortic stenosis are of the age at which coronary disease is common. When echocardiography shows severe aortic stenosis and the patient has one or more of the classic symptoms of the disease, formal invasive documentation of the severity of the stenosis is not necessary, and coronary angiography need not be performed in young adults. When the hemodynamic diagnosis is unclear, however, right-sided and left-sided heart catheterization should be performed to determine the transaortic valvular pressure gradient and cardiac output, which are used to calculate the aortic valve area by the Gorlin formula:

$$A = \frac{CO/SEP \times HR}{44.3\sqrt{h}}$$

where CO is cardiac output (mL/min), SEP is the systolic ejection period (seconds), HR is the heart rate, and h is the mean gradient.

TREATMENT

Medical Therapy

In asymptomatic patients, no treatment is indicated, nor is any known to be beneficial. Even statins are not useful, despite the similar pathobiology between aortic stenosis and coronary disease.

There also is no accepted effective medical therapy for symptomatic aortic stenosis. In patients with heart failure awaiting surgery, diuretics can be used cautiously to relieve pulmonary congestion. Nitrates may also be used cautiously to treat angina pectoris. Although vasodilators, especially angiotensin-converting enzyme inhibitors, have become a cornerstone of therapy for heart failure, they are not recommended for aortic stenosis. With fixed valvular obstruction to outflow, vasodilation reduces pressure distal to the obstruction without increasing cardiac output and may cause syncope. Statins do not slow the progression of calcific aortic stenosis. When surgery and valvoplasty are unsuccessful or impossible, digitalis and diuretics can be used to improve symptoms with the understanding that they will not improve life expectancy.

Invasive Therapy

Valve Replacement Surgery

The only proven effective therapy for aortic stenosis is aortic valve replacement. Even octogenarians benefit from valve replacement unless other comorbid factors preclude surgery, so aortic valve replacement should not be denied simply on the basis of age. Valve replacement should also not be denied because the ejection fraction is reduced; the excess afterload imposed by the stenotic valve is relieved with valve replacement, and a depressed ejection fraction usually improves dramatically after surgery. The exception to this rule is a severely reduced ejection fraction in the face of only a small aortic valve gradient; in this case, the severity of the aortic stenosis may be overestimated because the failing left ventricle has difficulty opening a mildly to moderately stenotic valve. In such patients, LV muscle dysfunction either has another cause or is often so severe that it does not recover after valve replacement. Evidence indicates, however, that even some well-selected patients in this category, such as patients who demonstrate increased cardiac output during dobutamine infusion, may benefit from aortic valve replacement.

Percutaneous Aortic Valve Replacement

Percutaneous transcatheter aortic valve implantation reduces 1-year mortality by 45% (from 51 to 31%) in patients who have severe aortic stenosis and are too ill to undergo surgery.■ It also is not inferior to standard valve replacement in high-risk adults.■ In this procedure, the native valve is dilated, and then a stented valve is inserted over a balloon into the aortic annulus (Fig. 75-2). The balloon is expanded to secure the valve and its stent, which is intended to help prevent restenosis. Two such valves have been approved in Europe, where thousands of patients have already received successful implants.

Balloon Aortic Valvotomy

In acquired calcific aortic stenosis, leaflet restriction results from heavy calcium deposition in the leaflets themselves and is not due to commissural fusion. Balloon aortic valvotomy is relatively ineffective in improving aortic stenosis; it generally results in a residual gradient of 30 to 50 mm Hg and a valve area of 1.0 cm^2. Mortality after this procedure is similar to that in untreated patients. The only occasional indication for balloon aortic valvotomy is palliative in cases in which aortic valve replacement is impossible because of comorbidity or is impractical when immediate temporary relief is required because of the demands of other noncardiac conditions.

PROGNOSIS

In asymptomatic patients with normally functioning or minimally dysfunctional bicuspid aortic valves, survival is similar to age-matched controls, and sudden death is rare, occurring in less than 1% of asymptomatic patients. However, 27% of patients require surgery by 20 years after diagnosis. In adults with asymptomatic but hemodynamically significant aortic stenosis, symptoms typically develop within 5 years. A higher peak aortic-jet velocity and high β-type natriuretic peptide levels predict a worse prognosis.

The progression of mild to moderate aortic stenosis to severe disease is the key to the natural history of the disease and is quite variable. Aortic stenosis may remain mild for a decade or more in some patients, whereas in others, it may progress to severe disease in as little as 5 years.

When symptoms develop, survival declines precipitously. Approximately 35% of patients with aortic stenosis are initially evaluated for angina. Of these, 50% are dead in 5 years unless aortic valve replacement is performed. Approximately 15% have syncope; of these, 50% are dead in only 3 years unless the aortic valve is replaced. Of the 50% with symptoms of heart failure, 50% are dead in 2 years without aortic valve replacement. In all, only 25% of patients with symptomatic aortic stenosis survive 3 years in the absence of valve replacement, and the annual risk for sudden death ranges from 10% in patients with angina to 15% with syncope to 25% with heart failure.

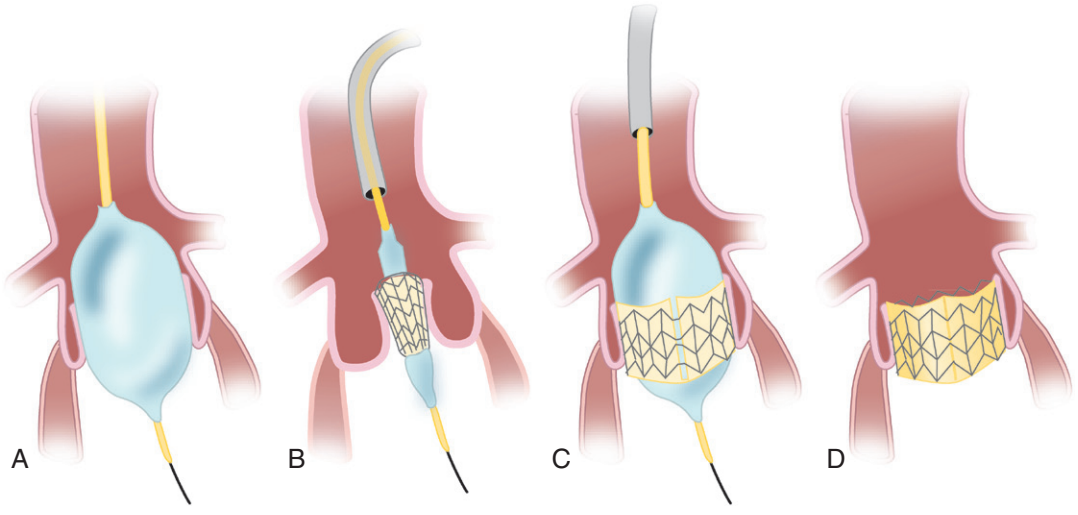

FIGURE 75-2. Steps for percutaneous balloon valvotomy. A, Dilation of the native stenotic valve. **B,** A crimped stented valve has been inserted over a guidewire into the aortic annulus. **C,** Inflation of the balloon deploys the valve. **D,** The balloon is deflated and removed with the aortic valve replaced. (Modified from http://my.clevelandclinic.org/heart/percutaneous/percutaneousValve.aspx.)

After valve replacement surgery, prognosis improves to near normal, especially for patients older than 65 years at the time of valve implantation, presumably because older patients have fewer years at risk for valve-related complications.

MITRAL STENOSIS

EPIDEMIOLOGY

In almost all cases of acquired mitral stenosis, the cause is rheumatic heart disease. Occasionally, severe calcification of the mitral annulus can lead to mitral stenosis in the absence of rheumatic involvement. Mitral stenosis is three times more common in women and usually develops in the 40s and 50s. Although the disease has become rare in developed countries because of the waning incidence of rheumatic fever, mitral stenosis is still prevalent in developing nations, where rheumatic fever is common.

PATHOBIOLOGY

At the beginning of diastole, a transient gradient between the left atrium and left ventricle normally initiates LV filling. After early filling, left atrial and LV pressures equilibrate. In mitral stenosis, obstruction to LV filling increases left atrial pressure and produces a persistent gradient between the left atrium and the left ventricle (see Fig. 57-2 in Chapter 57). The combination of elevated left atrial pressure (and pulmonary venous pressure) and restriction of inflow into the left ventricle limits cardiac output. Although myocardial involvement from the rheumatic process occasionally affects LV muscle function, the muscle itself is normal in most patients with mitral stenosis. However, in approximately one third of patients with mitral stenosis, LV ejection performance is reduced despite normal muscle function because of reduced preload (from inflow obstruction) and increased afterload as a result of reflex vasoconstriction caused by reduced cardiac output.

Because the right ventricle generates most of the force that propels blood across the mitral valve, the right ventricle incurs the pressure overload of the transmitral gradient. In addition, secondary but reversible pulmonary vasoconstriction develops, thus further increasing pulmonary artery pressure and the burden on the right ventricle. As mitral stenosis worsens, right ventricular (RV) failure develops.

CLINICAL MANIFESTATIONS

Patients with mitral stenosis usually remain asymptomatic until the valve area is reduced to about one third its normal size of 4 to 5 cm^2. Then the symptoms typical of left-sided failure—dyspnea on exertion, orthopnea, and paroxysmal nocturnal dyspnea—develop. As the disease progresses and RV failure occurs, ascites and edema are common. Hemoptysis, which is common in mitral stenosis but uncommon in other causes of left atrial hypertension, develops when high left atrial pressure ruptures the anastomoses of small bronchial veins. In some cases, a large left atrium may impinge on the left recurrent laryngeal nerve and cause hoarseness (Ortner's syndrome) or may impinge on the esophagus and cause dysphagia.

Physical Examination

Although mitral stenosis produces typical and diagnostic findings on physical examination, the diagnosis is missed frequently because the auscultatory findings may be subtle. Palpation of the precordium finds a quiet apical impulse. If pulmonary hypertension and RV hypertrophy have developed, the examiner notes a parasternal lift. S_1 is typically loud and may be the most prominent physical finding of the disease. A loud S_1 is present because the transmitral gradient holds the mitral valve open throughout diastole until ventricular systole closes the fully opened valve with a loud closing sound. In far-advanced disease, the mitral valve may be so damaged, however, that it neither opens nor closes well, so S_1 may become soft. S_2 is normally split; the pulmonic component is increased in intensity if pulmonary hypertension has developed. Left-sided S_3 and S_4 gallop sounds, which represent the ventricular and atrial components of rapid LV filling, are exceedingly rare in mitral stenosis because obstruction at the mitral valve prevents rapid filling. S_2 is usually followed by an opening snap. The distance between S_2 and the opening snap provides a reasonable estimation of left atrial pressure and the severity of the mitral stenosis. The higher the left atrial pressure, the sooner the left atrial pressure and the falling LV pressure of early ventricular relaxation equilibrate. At this equilibration point, the mitral valve opens, and the opening snap occurs. When left atrial pressure is high, the opening snap closely (0.06 second) follows S_2. Conversely, when left atrial pressure is relatively normal, the snap occurs later (0.12 second) and may mimic the cadence of an S_3 gallop. The opening snap is followed by the classic low-pitched early diastolic mitral stenosis rumble, which increases in length as the mitral stenosis worsens. This murmur may be inaudible if the patient has a relatively low resting cardiac output. Modest exercise, such as isometric handgrip, may accentuate the murmur's intensity. If the patient is in sinus rhythm, atrial systole may produce a presystolic accentuation of the murmur. If pulmonary hypertension has developed, the pulmonic component of S_2 increases in intensity to become as loud or louder than the aortic component. With pulmonary hypertension, a diastolic blowing murmur of pulmonary insufficiency (Graham Steell's murmur) is often heard, although in many cases, a coexistent murmur of mild aortic insufficiency is mistaken for this murmur. Neck vein elevation, ascites, and edema are present if RV failure has developed.

DIAGNOSIS

If the patient is in sinus rhythm, left atrial abnormality is generally present on the ECG. Atrial fibrillation is common, however. If pulmonary hypertension has developed, there is often evidence of RV hypertrophy.

On the chest radiograph, left atrial enlargement produces straightening of the left heart border and a double density at the right heart border as a result of the combined silhouettes of the right atrium and left atrium. Pulmonary venous hypertension produces increased vascularity. Kerley B lines, which represent thickening of the pulmonary septa secondary to chronic venous engorgement, may also be seen.

The echocardiogram produces excellent images of the mitral valve and is the most important diagnostic tool in confirming the diagnosis (Fig. 75-3). Transthoracic echocardiography or, if necessary, transesophageal echocardiography makes the diagnosis in nearly 100% of cases and accurately assesses severity. Mitral stenosis, similar to aortic stenosis, can be quantified by assessing the transvalvular gradient with the modified Bernoulli principle. The stenosis is considered mild when the calculated or planimetered valve area is more than 1.75 cm^2, moderate at 1.25 to 1.75 cm^2, moderately severe at 1.0 to 1.25 cm^2, and severe at less than 1.0 cm^2.

During echocardiography, the suitability of the valve for balloon valvotomy can also be assessed (see later). If even mild tricuspid regurgitation is present, the systolic gradient across the tricuspid valve can be used to gauge pulmonary artery pressure, which is an important prognostic factor in mitral stenosis because the prognosis worsens as pulmonary pressure increases.

Invasive Evaluation

Cardiac Catheterization

Cardiac catheterization is usually unnecessary to assess the severity of mitral stenosis. Because many patients with mitral stenosis are of an age when coronary disease might be present, however, coronary arteriography is generally performed if cardiac surgery is anticipated or if the patient has coexistent angina. In these cases, it is common to perform left-sided and right-sided heart catheterization to confirm the transmitral gradient and to calculate the valve area from the Gorlin formula (see earlier).

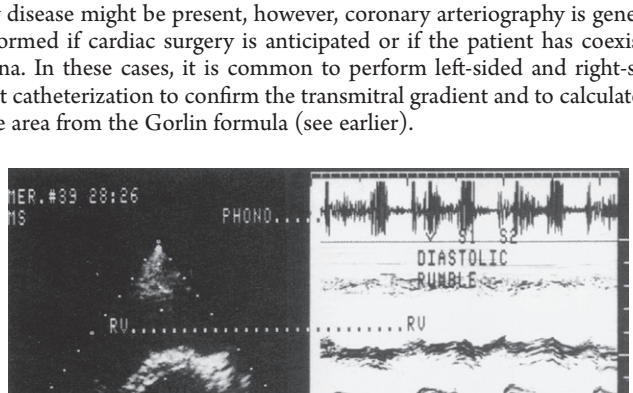

FIGURE 75-3. Mitral stenosis. An en face view of a stenotic mitral valve in the short-axis view of the left ventricle is shown on the *left*. Planimetry for the mitral valve orifice yielded an area of 1.09 cm^2. The M-mode echocardiogram on the *right* has been aligned with the appropriate structures on the *left*. It shows the restricted opening of the mitral valve in diastole associated with the classic diastolic rumbling murmur. RV = right ventricle. (From Assey ME, Usher BW, Carabello BA. The patient with valvular heart disease. In: Pepine CJ, Hill JA, Lambert CR, eds. *Diagnostic and Therapeutic Cardiac Catheterization,* 3rd ed. Baltimore: Williams & Wilkins; 1998:709.)

PREVENTION, TREATMENT, AND PROGNOSIS Rx

Mitral stenosis can be prevented by appropriate antibiotic treatment of β-hemolytic streptococcal infections (Chapter 298).

Medical Therapy

Asymptomatic patients with mitral stenosis and sinus rhythm require no therapy. Symptoms of mild dyspnea and orthopnea can be treated with diuretics alone. When symptoms worsen to more than mild or if pulmonary hypertension develops, mechanical correction of the stenosis is preferable to medical therapy because it improves longevity in severely symptomatic patients.

Patients with mitral stenosis in whom atrial fibrillation develops usually decompensate because the rapid heart rate reduces diastolic filling time, increases left atrial pressure, and decreases cardiac output. The heart rate must be controlled promptly, preferably with an infusion of diltiazem or esmolol for acute atrial fibrillation or with a β-blocker, a calcium-channel blocker, or oral digoxin in chronic atrial fibrillation (Chapter 64).

Conversion to sinus rhythm is routinely recommended either pharmacologically or with direct-current countershock (Chapter 64) after anticoagulation is therapeutic. It should be noted that patients with rheumatic atrial fibrillation have been excluded from trials of echocardiogram-guided cardioversion without anticoagulation and trials of rate control versus rhythm control for the chronic management of atrial fibrillation. If sinus rhythm cannot be maintained, mechanical therapy for the mitral stenosis is generally recommended in the hope that sinus rhythm can be restored after the obstruction to atrial outflow is corrected. However, the cause of atrial fibrillation in patients with mitral stenosis probably includes atrial rheumatic inflammation, so restoration of sinus rhythm is unpredictable even after mechanical intervention.

Because patients with concomitant mitral stenosis and atrial fibrillation have an extraordinarily high risk for systemic embolism, they should undergo chronic anticoagulation with warfarin at an international normalized ratio (INR) target of 2.5 to 3.5. Anticoagulation is warranted in all patients unless there is a serious contraindication to its use.

Mechanical Therapy

When symptoms progress past early functional class II, that is, symptoms with more than ordinary activity, or if pulmonary hypertension develops, the prognosis is worse unless the mitral stenosis is relieved. In most instances, an excellent result can be achieved with percutaneous balloon valvotomy. In contrast to aortic stenosis, in mitral stenosis there is fusion of the valve leaflets at the commissures. Balloon dilation produces a commissurotomy and a substantial increase in valve area that appears to persist for at least a decade and provides improvement comparable to that of closed or open commissurotomy in suitable patients. Suitability for balloon valvotomy is determined partially during echocardiography. Patients with pliable valves, little valvular calcification, little involvement of the subvalvular apparatus, and less than moderate mitral regurgitation are ideal candidates. Even when valve anatomy is not ideal, however, valvotomy may be attempted in patients with advanced age or in situations in which comorbid risk factors increase surgical risk. In otherwise healthy patients with unfavorable valve anatomy, surgery to perform an open commissurotomy or valve replacement is undertaken.

MITRAL REGURGITATION

EPIDEMIOLOGY

The mitral valve is composed of the mitral annulus, the leaflets, the chordae tendineae, and the papillary muscles. Abnormalities in any of these structures may lead to mitral regurgitation. The most common cause of mitral regurgitation in the United States is mitral valve prolapse, which is responsible for approximately two thirds of all cases and comprises many diseases, including myxomatous degeneration of the valve. Myocardial ischemia leading to papillary muscle dysfunction or infarction is the next most common cause and accounts for approximately a fourth of all cases. Annular calcification, endocarditis, collagen vascular disease, and rheumatic heart disease are less common causes. Use of the weight loss agents dexfenfluramine and fenfluramine has been implicated in causing valve damage in a few patients who received these drugs.

Mitral regurgitation can be subdivided on the basis of chronicity. Common causes of severe acute mitral regurgitation include ruptured chordae tendineae, ischemic papillary muscle dysfunction or rupture, and infective endocarditis. Chronic severe mitral regurgitation is more likely to be due to myxomatous degeneration of the valve, rheumatic heart disease, or annular calcification.

PATHOBIOLOGY

The pathophysiology of mitral regurgitation can be divided into three phases (Fig. 75-4). In acute mitral regurgitation of any cause, the sudden option for ejection of blood into the left atrium "wastes" a portion of the LV stroke volume as backward rather than forward flow. The combined regurgitant and forward flow causes volume overload of the left ventricle and stretches the existing sarcomeres toward their maximum length. Use of the Frank-Starling mechanism is maximized, and end-diastolic volume increases concomitantly. The regurgitant pathway unloads the left ventricle in systole because it allows ejection into the relatively low-impedance left atrium and thereby reduces end-systolic volume. Although increased end-diastolic volume and decreased

	Preload SL (μ)	Afterload ESS (kdyne/cm²)	CF	EF	RF	FSV (mL)
N	2.07	90	N	.67	.0	100
AMR	2.25	60	N	.82	.50	70
CCMR	2.19	90	N	.79	.5	95
CDMR	2.19	120	↓	.58	.57	65

FIGURE 75-4. Mitral regurgitation. A and **B,** Normal physiology (N) **(A)** is compared with the physiology of acute mitral regurgitation (AMR) **(B).** Acutely, the volume overload increases preload (sarcomere length [SL]), and end-diastolic volume (EDV) increases from 150 to 170 mL. Unloading of the left ventricle by the presence of the regurgitant pathway decreases afterload (end-systolic stress [ESS]), and end-systolic volume (ESV) falls from 50 to 30 mL. These changes result in an increase in the ejection fraction (EF). Because 50% of the total left ventricular (LV) stroke volume (regurgitant fraction [RF]) is ejected into the left atrium (LA), however, forward stroke volume (FSV) falls from 100 to 70 mL. At this stage, contractile function (CF) is normal. **C,** Chronic compensated mitral regurgitation (CCMR). In CCMR, eccentric cardiac hypertrophy has developed, and EDV has increased substantially. Increased EDV, combined with normal contractile function, permits ejection of a larger total stroke volume and a larger forward stroke volume than in the acute phase. Left atrial enlargement permits lower left atrial pressure. Because the radius term in the Laplace equation has increased with increasing LV volume, afterload and ESV return to normal. **D,** Chronic decompensated mitral regurgitation (CDMR). In this stage, contractile dysfunction causes a large increase in ESV with a fall in total and forward stroke volume. Additional LV enlargement leads to worsening mitral regurgitation. The relatively favorable loading conditions in this phase still permit a normal EF, however, despite contractile dysfunction. (From Carabello BA. Mitral regurgitation: basic pathophysiologic principles. *Mod Concepts Cardiovasc Dis.* 1988;57:53-57.)

end-systolic volume act in concert to increase total stroke volume, forward stroke volume is subnormal because a large portion of the total stroke volume is regurgitated into the left atrium. This regurgitant volume increases left atrial pressure, so the patient experiences heart failure with low cardiac output and pulmonary congestion despite normal LV contractile function.

In many cases, severe acute mitral regurgitation necessitates emergency surgical correction. Patients who can be managed through the acute phase may enter the phase of compensation. In this phase, eccentric LV hypertrophy and increased end-diastolic volume, combined with normal contractile function, allow ejection of a sufficiently large total stroke volume to permit forward stroke volume to return toward normal. Left atrial enlargement allows accommodation of the regurgitant volume at a lower filling pressure. In this phase, the patient may be relatively asymptomatic even during strenuous exercise.

Although severe mitral regurgitation may be tolerated for many years, the lesion often causes LV dysfunction, atrial fibrillation, or heart failure within 5 years of the detection of severe mitral regurgitation. The now damaged ventricle has impaired ejection performance, and end-systolic volume increases. Greater LV residual volume at end systole increases end-diastolic volume and end-diastolic pressure, and the symptoms of pulmonary congestion may reappear. Additional LV dilation may worsen the amount of regurgitation by causing further enlargement of the mitral annulus and malalignment of the papillary muscles. Although there is substantial contractile dysfunction, the increased preload and the presence of the regurgitant pathway, which tends to normalize afterload despite ventricular enlargement, augment the ejection fraction and may maintain it in a relatively normal range.

The causes of LV contractile dysfunction in patients with mitral regurgitation may relate to loss of contractile proteins and abnormalities in calcium handling. In at least some cases, contractile dysfunction is reversible by timely mitral valve replacement.

CLINICAL MANIFESTATIONS

In the medical history, the standard symptoms of left-sided heart failure should be sought (Chapter 58). An attempt to discover potential causes should be made by questioning for a prior history of a heart murmur or abnormal findings on cardiac examination (Chapter 50), rheumatic heart disease, endocarditis (Chapter 76), myocardial infarction (Chapter 73), or the use of anorexigenic drugs.

Volume overload of the left ventricle displaces the apical impulse downward and to the left. S_1 may be reduced in intensity, whereas S_2 is usually physiologically split. In severe mitral regurgitation, S_2 is followed by S_3, which does not indicate heart failure but reflects rapid filling of the left ventricle by the large volume of blood stored in the left atrium during systole. The typical murmur of mitral regurgitation is a holosystolic apical murmur that often radiates toward the axilla (Chapter 50). There is a rough correlation between the intensity of the murmur and the severity of the disease, but this correlation is too weak to use in clinical decision making because the murmur may be soft when cardiac output is low. In contrast to aortic stenosis, murmur intensity does not usually vary with the RR interval. In acute mitral regurgitation, the presence of a large v wave may produce rapid equilibration of left atrial and LV pressure, thereby reducing the driving gradient and shortening the murmur. Pulmonary hypertension may develop and produce right-sided signs, including an RV lift, an increased P_2, and if RV dysfunction has developed, signs of right-sided heart failure.

DIAGNOSIS

The ECG usually shows LV hypertrophy and left atrial abnormality. The chest radiograph typically shows cardiomegaly; the absence of cardiomegaly indicates either that the mitral regurgitation is mild or that it has not been chronic enough to allow cardiac dilation to occur.

Echocardiography shows the extent of left atrial and LV enlargement (Chapter 55). Ultrasonic imaging of the mitral valve is excellent and offers clues to the mitral valve abnormalities responsible for the regurgitation. In some patients, three-dimensional echocardiography can add pathoanatomic information of potential use in aiding surgical repair of the valve. Color flow Doppler interrogation of the valve (Fig. 75-5) helps assess the severity of regurgitation, but because this technique images flow velocity rather than actual flow, it is subject to errors in interpretation. The Doppler technique is excellent for excluding the presence of mitral regurgitation and for distinguishing between mild and severe degrees. Although newer techniques may quantify regurgitation more precisely, they are not yet in widespread use, and standard color flow Doppler examination may not be sufficient for exact quantification of mitral regurgitation or to determine whether the severity of the lesion is sufficient to cause eventual LV dysfunction. When the severity of mitral regurgitation is in doubt or if mitral valve surgery is being contemplated, cardiac catheterization (Chapter 57) is helpful in resolving the severity of the lesion; coronary arteriography should be included in patients older than 40 years or with symptoms suggesting coronary disease (Chapter 71).

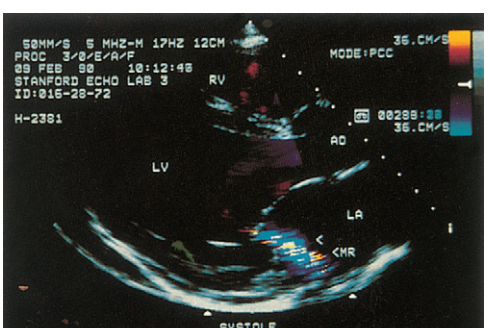

FIGURE 75-5. Two-dimensional echocardiogram of mitral regurgitation with Doppler flow mapping superimposed on a portion of the image. The color information is represented in the sector of the imaging plane extending from the apex of the triangular plane to the *two small arrows* at the *bottom* of the image plane. Mitral regurgitation (MR) is indicated (*open arrows*) and extends from the mitral valve leaflets toward the posterior aspect of the left atrium (LA) during systole. The mosaic of colors representing the mitral regurgitant signal is typical of high-velocity turbulent flow. The low-intensity *orange-brown* signal represents flow directed away from the transducer on the chest wall, and the *blue* shades represent blood in the left ventricular outflow tract moving toward the transducer. AO = aorta; LV = left ventricle; RV = right ventricle.

TREATMENT AND PROGNOSIS

Medical Therapy

Severe Acute Mitral Regurgitation

In severe acute mitral regurgitation, the patient is usually symptomatic with heart failure or even shock. The goal of medical therapy is to increase forward cardiac output while concomitantly reducing regurgitant volume (Chapter 59). Arterial vasodilators reduce systemic resistance to flow and preferentially increase aortic outflow and simultaneously decrease the amount of mitral regurgitation and left atrial hypertension. If hypotension already exists, vasodilators such as nitroprusside lower blood pressure further and cannot be used. In these cases, intra-aortic balloon counterpulsation (Chapter 107) is preferred if the aortic valve is competent. Counterpulsation increases forward cardiac output by lowering ventricular afterload while augmenting systemic diastolic pressure.

Chronic Symptomatic Mitral Regurgitation

In patients with *symptomatic* mitral regurgitation, angiotensin-converting enzyme inhibitors (such as lisinopril, 20 mg per day) reduce LV volume and improve symptoms. Mitral valve surgery rather than medical therapy is generally preferred, however, in most symptomatic patients with mitral regurgitation. When atrial fibrillation is present, long-term anticoagulation should achieve the same INR goal as for mitral stenosis.

Chronic Asymptomatic Mitral Regurgitation

Vasodilators have had little effect in reducing LV volume or improving normal exercise tolerance in patients with mitral regurgitation, perhaps because afterload is not usually increased in those with chronic asymptomatic mitral regurgitation. There is no definitive indication to begin afterload reduction before symptoms appear because no large randomized trials have been performed, and smaller trials have generally shown no benefit from these therapies.

Surgical Therapy

The timing of mitral valve surgery must weigh the risks of the operation and placement of a prosthesis, if one is inserted, against the risk for irreversible LV dysfunction if surgery is delayed unwisely. For most other types of valve diseases, surgical correction usually requires placement of a prosthetic valve, but in patients with mitral regurgitation, the native valve can often be repaired. Because conservation of the native valve obviates the risks associated with a prosthesis, the option of mitral valve repair should influence the patient and physician toward earlier surgery.

Types of Mitral Valve Surgery

Mitral Valve Repair

When feasible, mitral valve repair (Fig. 75-6) is the preferred operation. Repair restores valve competence, maintains the functional aspects of the apparatus, and avoids the insertion of a prosthesis. Repair is most applicable in cases of posterior chordal rupture; anterior involvement and rheumatic involvement make repair more difficult. Currently, the percentage of mitral valve surgeries that are valve repair varies from 0 to 95% at different hospital centers, averaging about 60% across the United States overall. Percutaneous mitral valve repair with implantation of a clip device is less effective than conventional mitral valve repair for reducing the amount of mitral regurgitation but is safer and provides equivalent clinical benefit.[3] In all cases, the feasibility of repair depends on the pathoanatomy that is causing the mitral regurgitation and the skill and experience of the operating surgeon.

Mitral Valve Replacement with Preservation of the Mitral Apparatus

In this procedure, a prosthetic valve is inserted, but continuity between the native leaflets and the papillary muscles is maintained. This procedure has the advantage of ensuring mitral valve competence while preserving the LV functional aspects of the mitral apparatus. Even if only the posterior leaflets and chordae are preserved, the patient benefits from improved postoperative ventricular function and better survival. In many cases, it is possible to preserve the anterior and posterior chordal attachments, although anterior continuity can be associated with LV outflow tract obstruction. Although the patient benefits from restored mitral valve competence and maintenance of LV function, insertion of a prosthesis still carries all prosthesis-associated risks.

Mitral Valve Replacement without Preservation of the Mitral Apparatus

When the native valve cannot be repaired or the chordae preserved, such as in severe rheumatic deformity, the mitral valve leaflets and its apparatus are removed, and a prosthetic valve is inserted. Although this operation almost guarantees mitral valve competence, the mitral valve apparatus is responsible for coordinating LV contraction and for helping maintain the efficient prolate ellipsoid shape of the left ventricle. Destruction of the apparatus leads to a sudden fall in LV function and a decline in postoperative ejection fraction that is often permanent.

Timing of Surgery

Symptomatic Patients

Most patients with symptoms of dyspnea, orthopnea, or fatigue should undergo surgery regardless of which operation is performed because they already have lifestyle limitations from their disease. The mere presence of symptoms may worsen the prognosis despite relatively well-preserved LV function. The onset or worsening of symptoms is a summary of the patient's pathophysiology and may give a broader view of cardiovascular integrity than possible with any single measurement of pressure or function.

Asymptomatic Patients with Normal Left Ventricular Function

Surgery has increasingly been considered in asymptomatic patients who have normal LV function but echocardiographic findings indicating that valve *repair* is likely to be successful. Although these patients are at low risk without surgery, the risk associated with valve repair is less than 1%, and this approach avoids the risks of later valve *replacement*, which may be required if the valvular disease progresses. Valve repair obviates the need for protracted, expensive follow-up and provides a durable correction of the lesion. This approach is sensible, however, only if it is certain that valve repair can be performed because insertion of a prosthesis carries unacceptable risk in this low-risk group.

Asymptomatic Patients with Left Ventricular Dysfunction

The onset of LV dysfunction in patients with mitral regurgitation may occur without causing symptoms. Early surgery is warranted to prevent the muscle dysfunction from becoming severe or irreversible. Regardless of whether valve repair or replacement is eventually performed, survival is prolonged to or toward normal if surgery is performed before the ejection fraction declines to less than 0.60 or before the left ventricle is unable to contract to an end-systolic dimension of 40 mm. Patients with severe mitral regurgitation should be monitored yearly with a history, physical examination, and echocardiographic evaluation of LV function. When the patient reports symptoms or echocardiography shows the onset of LV dysfunction, surgery should be undertaken.

Asymptomatic Elderly Patients

Patients older than 75 years may have poorer surgical results than younger patients, especially if coronary disease is present or if mitral valve replacement rather than repair must be performed. However, results of surgery in older patients with mitral regurgitation have steadily improved during the past decade, and elderly patients with symptoms refractory to medical therapy may benefit from surgery. Nevertheless, there is little compelling reason to commit elderly *asymptomatic* patients to a mitral valve operation.

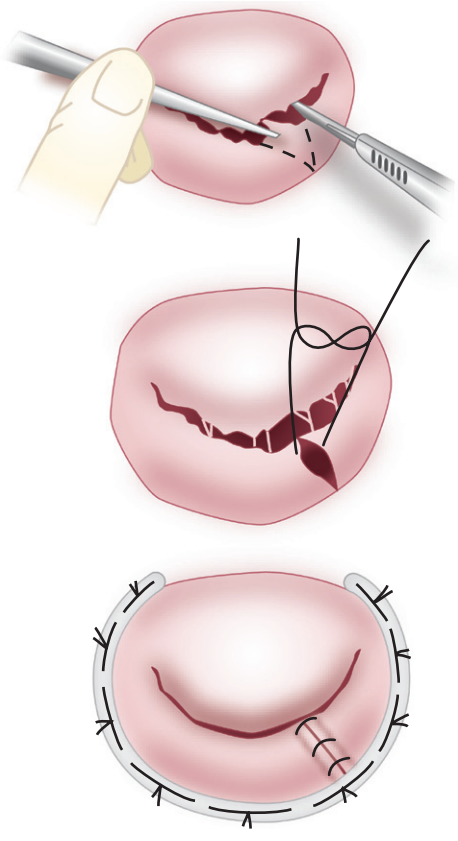

FIGURE 75-6. The stages of mitral valve repair. (Modified from http://my.clevelandclinic.org/heart/disorders/valve/mvrepair.aspx.)

MITRAL VALVE PROLAPSE

DEFINITION

Mitral valve prolapse occurs when one or both of the mitral valve leaflets prolapse into the left atrium superior to the mitral valve annular plane during systole. The importance of mitral valve prolapse varies from patient to patient. In some cases, prolapse is simply a consequence of normal LV physiology without significant medical impact, such as in situations that produce a small left ventricle (e.g., the Valsalva maneuver or an atrial septal defect), in which reduction of ventricular volume causes relative lengthening of the chordae tendineae and subsequent mitral valve prolapse. At the other end of the spectrum, severe redundancy and deformity of the valve, which occurs in myxomatous valve degeneration, increases the risk for stroke, arrhythmia, endocarditis, and progression to severe mitral regurgitation.

DIAGNOSIS

History

Most patients with mitral valve prolapse are asymptomatic. In some cases, however, mitral valve prolapse is associated with symptoms, including palpitations, syncope, and chest pain. In some cases, chest pain is associated with a positive thallium scintigram indicating the presence of true ischemia despite normal epicardial coronary arteries, perhaps because excessive tension on the papillary muscles increases oxygen consumption and causes ischemia. Palpitations, syncope, and presyncope, when present, are linked to autonomic dysfunction (Chapters 50, 62, and 427), which appears to be more prevalent in patients with mitral valve prolapse.

Physical Examination

On physical examination, the mitral valve prolapse syndrome produces the characteristic findings of a midsystolic click and a late systolic murmur. The click occurs when the chordae tendineae are stretched taut by the prolapsing mitral valve in mid-systole. As this occurs, the mitral leaflets move past their coaptation point, permit mitral regurgitation, and cause the late systolic murmur (see Table 50-7 in Chapter 50). Maneuvers that make the left ventricle smaller, such as the Valsalva maneuver, cause the click to appear earlier

and the murmur to be more holosystolic and often louder (see Table 50-8 in Chapter 50). In some cases of echocardiographically proven mitral valve prolapse, neither the click nor the murmur is present; in other cases, only one of these findings is present.

Noninvasive Evaluation

Echocardiography is useful to prove that prolapse is present, to image the amount of regurgitation and its physiologic effects, and to discern the pathoanatomy of the mitral valve. Although an echocardiogram is not necessary to diagnose prolapse in patients with the classic physical findings, the echocardiogram adds significant prognostic information because it can detect patients who have specifically abnormal valve morphology and in whom most of the complications of the disease occur.

In the 1990s, it became clear that the mitral annulus did not exist in a single plane but had a saddleback shape. Prolapse shown in the four-chamber echocardiographic view should be confirmed in the parasternal long-axis view. Echocardiographic diagnoses made before the understanding that the mitral valve plane was multidimensional (circa 1987) may have been made in error.

TREATMENT Rx

Because most cases of mitral valve prolapse are asymptomatic, therapy is unnecessary. Although prophylaxis against infective endocarditis was previously recommended in these patients, guidelines no longer recommend antibiotic prophylaxis based on available data (Chapter 76). In patients with palpitations and autonomic dysfunction, β-blockers are often effective in relieving symptoms. Low-dose aspirin therapy has been recommended for patients with redundant leaflets because these patients have a slightly increased risk for stroke. No data from large studies are available to support this contention, however. If severe mitral regurgitation develops, the therapy is the same as for other causes of mitral regurgitation.

PROGNOSIS

Most patients with mitral valve prolapse have a benign clinical course; even for complication-prone patients with redundant and misshapen mitral leaflets, complications are relatively rare. Approximately 10% of patients with thickened leaflets experience infective endocarditis, stroke, progression to severe mitral regurgitation, or sudden death. The progression to severe mitral regurgitation varies with gender and age, and men are approximately twice as likely to progress as women. By 50 years of age, only approximately 1 in 200 men requires surgery to correct mitral regurgitation. By the age of 70 years, the risk increases to approximately 3%.

AORTIC REGURGITATION

DEFINITION

Aortic regurgitation is caused either by abnormalities of the aortic leaflets or by abnormalities of the proximal aortic root. Leaflet abnormalities causing aortic regurgitation include a bicuspid aortic valve, infective endocarditis, and rheumatic heart disease; anorexigenic drugs have also been implicated. Common aortic root abnormalities that cause aortic regurgitation include Marfan syndrome (Chapter 268), hypertension-induced annuloaortic ectasia, aortic dissection (Chapter 78), syphilis (Chapter 327), ankylosing spondylitis (Chapter 273), and psoriatic arthritis (Chapter 273). Acute aortic regurgitation is usually caused by infective endocarditis (Chapter 76) or aortic dissection.

PATHOBIOLOGY

As with mitral regurgitation, aortic regurgitation imparts a volume overload on the left ventricle because the left ventricle must pump the forward flow entering from the left atrium and the regurgitant volume returning through the incompetent aortic valve. Also as with mitral regurgitation, the volume overload is compensated for by the development of eccentric cardiac hypertrophy, which increases chamber size and allows the ventricle to pump a greater total stroke volume and a greater forward stroke volume. Ventricular enlargement also allows the left ventricle to accommodate the volume overload at a lower filling pressure. In contrast to mitral regurgitation, the entire stroke volume is ejected into the aorta in aortic regurgitation. Because pulse pressure is proportional to stroke volume and elastance of the aorta, the increased stroke volume increases systolic pressure. Systolic hypertension leads to afterload excess, which does not generally occur in mitral regurgitation. Ventricular geometry also differs between mitral and aortic regurgitation because the afterload excess in aortic regurgitation causes a modest element of concentric hypertrophy, as well as severe eccentric hypertrophy.

In acute aortic insufficiency, such as might occur in infective endocarditis, severe volume overload of the previously unprepared left ventricle results in a sudden fall in forward output while precipitously increasing LV filling pressure. It is probably this combination of pathophysiologic factors that leads to rapid decompensation, presumably because the severely diminished gradient for coronary blood flow causes ischemia and progressive deterioration in LV function. In acute aortic insufficiency, reflex vasoconstriction increases peripheral vascular resistance. In compensated chronic aortic insufficiency, vasoconstriction is absent, and vascular resistance may be reduced and contribute to the hyperdynamic circulation observed in these patients.

CLINICAL MANIFESTATIONS

The most common symptoms from chronic aortic regurgitation are those of left-sided heart failure, that is, dyspnea on exertion, orthopnea, and fatigue. In acute aortic regurgitation, cardiac output and shock may develop rapidly. The onset of symptoms in patients with chronic aortic regurgitation usually heralds the onset of LV systolic dysfunction. Some patients with symptoms have apparently normal systolic function, however, and the symptoms may be attributed to diastolic dysfunction. Other patients may have ventricular dysfunction yet remain asymptomatic.

Angina may also occur in patients with aortic insufficiency but less commonly than in those with aortic stenosis. The cause of angina in aortic regurgitation is probably multifactorial. Coronary blood flow reserve is reduced in some patients because diastolic runoff into the left ventricle lowers aortic diastolic pressure while increasing LV diastolic pressure—these two influences lower the driving pressure gradient for flow across the coronary bed. When angina occurs in aortic regurgitation, it may be accompanied by flushing. Other symptoms include carotid artery pain and an unpleasant awareness of the heartbeat.

DIAGNOSIS

Physical Examination

Aortic regurgitation produces a myriad of signs because a hyperdynamic, enlarged left ventricle ejects a large stroke volume at high pressure into the systemic circulation. Palpation of the precordium finds a hyperactive apical impulse displaced downward and to the left. S_1 and S_2 are usually normal. S_2 is followed by a diastolic blowing murmur heard best along the left sternal border with the patient sitting upright. In mild disease, the murmur may be short and heard only in the beginning of diastole when the gradient between the aorta and the left ventricle is highest. As the disease worsens, the murmur may persist throughout diastole. A second murmur, a mitral valve rumble, is heard at the LV apex in patients with severe aortic insufficiency. Although the cause is still debated, this Austin Flint murmur is probably produced as the regurgitant jet impinges on the mitral valve and causes it to vibrate.

In chronic aortic regurgitation, the high stroke volume and reduced systemic arterial resistance result in a wide pulse pressure, which may generate a number of signs, including Corrigan's pulse (sharp upstroke and rapid decline of the carotid pulse), de Musset's sign (head bobbing), Duroziez's sign (combined systolic and diastolic bruits created by compression of the femoral artery with the stethoscope), and Quincke's pulse (systolic plethora and diastolic blanching in the nail bed when gentle traction is placed on the nail). Perhaps the most reliable of physical signs indicating severe aortic regurgitation is Hill's sign, an increase in femoral systolic pressure of 40 mm Hg or more compared with systolic pressure in the brachial artery.

In contrast to chronic aortic insufficiency with its myriad clinical signs, acute aortic insufficiency may have a subtle manifestation. The eccentric hypertrophy, which compensates for chronic aortic insufficiency, has not yet had time to develop, and the large total stroke volume responsible for most of the signs of chronic aortic insufficiency is absent. The only clues to the presence of acute aortic insufficiency may be a short diastolic blowing murmur and reduced intensity of S_1. This latter sign occurs because high diastolic LV pressure closes the mitral valve early in diastole (mitral valve preclosure) so that when ventricular systole occurs, only the tricuspid component of S_1 is heard.

Noninvasive Evaluation

The ECG in patients with aortic insufficiency is nonspecific but almost always demonstrates LV hypertrophy. The chest radiograph shows an enlarged heart, often with uncoiling and enlargement of the aortic root.

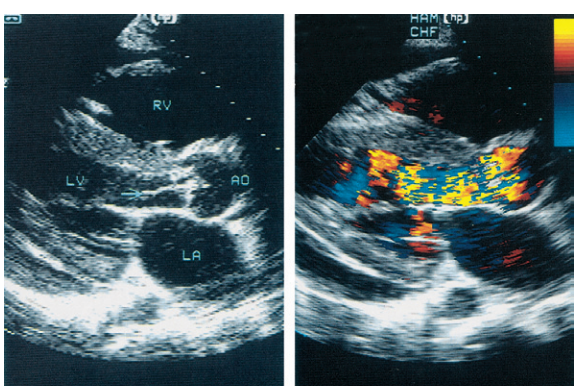

FIGURE 75-7. Echocardiogram of a patient with aortic regurgitation caused by infective endocarditis. The *left panel* shows a linear vegetation (*arrow*) prolapsing into the left ventricular outflow tract from the aortic valve leaflet in diastole. The *right panel* is a color flow Doppler image exhibiting turbulent blood flow filling the left ventricular tract during diastole. AO = aorta; LA = left atrium; LV = left ventricle; RV = right ventricle. (Courtesy of Dr. Anthony DeMaria.)

Echocardiography (Chapter 55) is the most important noninvasive tool for assessing the severity of aortic insufficiency and its impact on LV geometry and function (Fig. 75-7). During echocardiography, the LV end-diastolic dimension, end-systolic dimension, and fractional shortening are determined. Aortic valve anatomy and aortic root anatomy can be assessed and the cause of the aortic regurgitation can often be determined. Color flow Doppler examination of the aortic valve helps quantify the severity of aortic regurgitation by assessing the depth and width to which the diastolic jet penetrates the left ventricle. Another way to assess the severity of aortic regurgitation is the pressure half-time method: continuous-wave Doppler interrogation of the aortic valve displays the decay of the velocity of retrograde flow across the valve. In mild aortic insufficiency, the gradient across the valve is high throughout diastole, and its rate of decay is slow, with production of a long Doppler half-time (the time that it takes the velocity to decay from its peak to that value divided by the square root of 2). In severe aortic regurgitation, there is rapid equilibration between pressure in the aorta and pressure in the left ventricle, and the Doppler half-time is short. If mitral valve preclosure is detected in acute aortic insufficiency, urgent surgery is necessary. In cases in which the severity of aortic insufficiency is in doubt, catheterization to perform aortography is useful in resolving the issue.

TREATMENT AND PROGNOSIS

Medical Therapy

Asymptomatic Patients with Normal Left Ventricular Function

Because aortic regurgitation increases LV afterload, which decreases cardiac efficiency, afterload reduction with nifedipine and other vasodilators, including angiotensin-converting enzyme inhibitors and hydralazine, improves hemodynamics in the short term. Although initial data suggested that such therapy could delay or reduce the need for aortic valve surgery without any adverse effects when surgery is finally performed, more recent data suggest no benefit from such therapy. These discrepant results from relatively small trials preclude firm recommendations.

Symptomatic Patients or Patients with Left Ventricular Dysfunction

Patients who have symptoms or manifest LV dysfunction should not be treated medically, except for short-term stabilization, but should undergo aortic valve surgery as soon as feasible.

Surgical Therapy

Acute Aortic Regurgitation

When any of the symptoms or signs of heart failure develop, even if mild, medical mortality is high and approaches 75%. Therapy with vasodilators, such as nitroprusside, may temporarily improve the patient's condition before surgery but is never a substitute for surgery. In patients with acute aortic regurgitation caused by bacterial endocarditis (Chapter 76), surgery may be delayed to permit a full or partial course of antibiotics, but persistent, severe aortic regurgitation requires emergency valve replacement. Even when blood cultures have been positive recently and antibiotic therapy has been of brief duration, the valve reinfection rate is low, 0 to 10%, with valve replacement or valve repair. Emergency surgery should not be withheld simply because the duration of antibiotic therapy has been brief.

Chronic Aortic Regurgitation

Asymptomatic patients who manifest evidence of LV dysfunction benefit from surgery. Because loading conditions differ between aortic and mitral regurgitation, the objective markers for the presence of LV dysfunction also differ. In aortic regurgitation, when the ejection fraction is less than 0.55 or the end-systolic dimension is greater than 55 mm, postoperative outcome is impaired, presumably because these markers indicate that LV dysfunction has developed. Surgery should be performed before these benchmarks are reached. A calculated regurgitant orifice above 40 mm^2 portends a poorer prognosis and also may warrant surgery.

Patients with advanced symptoms are at increased risk for a suboptimal surgical outcome regardless of whether they have evidence of LV dysfunction. Patients should undergo aortic valve replacement before symptoms impair lifestyle.

Although some patients may be able to undergo successful aortic valve repair to restore aortic valve competence, most patients require insertion of an aortic valve prosthesis.

TRICUSPID REGURGITATION

DEFINITION

Tricuspid regurgitation is usually secondary to a hemodynamic load on the right ventricle rather than a structural valve deformity. Diseases that cause pulmonary hypertension, such as chronic obstructive airway disease or intracardiac shunts, lead to RV dilation and subsequent tricuspid regurgitation. Because most of the force that is needed to fill the left ventricle is provided by the right ventricle, LV dysfunction leading to elevated LV filling pressure also places the right ventricle under a hemodynamic load and can eventually lead to RV failure and tricuspid regurgitation. In some instances, tricuspid regurgitation may be caused by pathology of the valve itself. The most common cause of primary tricuspid regurgitation is infective endocarditis, usually stemming from drug abuse and unsterile injections. Other causes include carcinoid syndrome, rheumatic involvement of the tricuspid valve, myxomatous degeneration, RV infarction, and mishaps during endomyocardial biopsy.

DIAGNOSIS

The symptoms of tricuspid regurgitation are those of right-sided heart failure and include ascites, edema, and occasionally right upper quadrant pain. On physical examination, tricuspid regurgitation produces jugular venous distention accentuated by a large v wave as blood is regurgitated into the right atrium during systole. Regurgitation into the hepatic veins causes hepatic enlargement and liver pulsation. RV enlargement is detected as a parasternal lift. Ascites and edema are common.

The definitive diagnosis of tricuspid regurgitation is made during echocardiography. Doppler interrogation of the tricuspid valve shows systolic disturbance of the right atrial blood pool. Echocardiography (Chapter 55) can also be used to determine the severity of pulmonary hypertension, measure RV dilation, and assess whether the valve itself is intrinsically normal or abnormal.

TREATMENT AND PROGNOSIS

Therapy for secondary tricuspid regurgitation is generally aimed at the cause of the lesion. If LV failure has been responsible for RV failure and tricuspid regurgitation, the standard therapy for improving LV failure (Chapter 59) lowers LV filling pressure, reduces secondary pulmonary hypertension, relieves some of the hemodynamic burden of the right ventricle, and partially restores tricuspid valve competence. If pulmonary disease is the primary cause, therapy is directed toward improving lung function. Vasodilators, so useful in the treatment of left-sided heart failure, are often ineffective in treating pulmonary hypertension itself. Medical therapy directed at tricuspid regurgitation is usually limited to diuretic use.

Surgical intervention for the tricuspid valve is rarely entertained in isolation. However, if other cardiac surgery is planned in a patient with severe tricuspid regurgitation, concomitant ring annuloplasty or tricuspid valve repair is frequently attempted to ensure postoperative tricuspid competence. Since a second operation to address residual tricuspid regurgitation after successful left-sided valve surgery carries an unacceptably high mortality rate, concomitant tricuspid annuloplasty is now entertained for even mild to moderate tricuspid regurgitation during left-sided valve surgery. Tricuspid valve replacement is often not well tolerated and is rarely performed except when severe deformity, as is often seen in endocarditis or carcinoid disease, precludes valve repair.

PULMONIC STENOSIS

DEFINITION

Pulmonic stenosis is a congenital disease resulting from fusion of the pulmonic valve cusps (Chapter 69). It is usually detected and corrected during childhood, but occasionally cases are diagnosed for the first time in adulthood. Symptoms of pulmonic stenosis include angina and syncope. Occasionally, symptoms of right-sided heart failure develop. During physical examination, the uncalcified valve in pulmonic stenosis produces an early systolic ejection click on opening. During inspiration, the click diminishes or disappears because increased flow into the right side of the heart during inspiration partially opens the pulmonic valve in diastole so that systole causes less of an opening sound. The click is followed by a systolic ejection murmur that radiates to the base of the heart. If the transvalvular gradient is severe, RV hypertrophy develops and produces a parasternal lift.

The diagnosis of pulmonic stenosis is confirmed by echocardiography, which quantifies the transvalvular gradient and the degree of RV hypertrophy and dysfunction.

TREATMENT AND PROGNOSIS

Rx

In asymptomatic patients with a gradient less than 25 mm Hg, no therapy is required. If symptoms develop or the gradient exceeds 50 mm Hg, balloon commissurotomy is effective in reducing the gradient and relieving symptoms. Although long-term prognosis is not yet established, 90% of patients do not require reintervention 10 years after balloon therapy.

Postoperative Care of Patients with Substitute Heart Valves

After a prosthetic valve has been inserted, a baseline echocardiogram should be obtained to provide a reference point in the event that valve dysfunction is suspected at a later date. Echocardiography does not need to be repeated unless there is a change in clinical status or physical findings. The major causes of valve dysfunction are infective endocarditis, clot, and valve degeneration. Dysfunction is manifested most commonly by valvular regurgitation, but valvular stenosis can also occur with a clot, vegetations, or degeneration, especially degeneration of a bioprosthesis.

Whenever a patient with a prosthetic heart valve has a temperature higher than 100° F, endocarditis must be excluded by blood culture; for fever with signs of sepsis, broad-spectrum antibiotics must be begun while awaiting culture results. For patients with bioprosthetic valves, mechanical prostheses, and homografts, endocarditis prophylaxis should be instituted at the time of procedures that are associated with a high risk for bacteremia (Chapter 76). Whether prophylaxis is necessary for pulmonary autografts is currently unclear, but physicians usually prescribe prophylaxis for these patients.

All patients with a mechanical heart valve require anticoagulation. Recommended INR values range from 2.0 for a young normotensive patient in sinus rhythm with an aortic valve prosthesis to 3.5 for a patient with atrial fibrillation and a mitral valve prosthesis. Aspirin, 325 mg, is recommended in addition to warfarin to reduce the risk for valve thrombosis in patients who have mechanical prosthetic valves that are at higher risk for thromboembolic complications. When thrombosis occurs on a prosthetic valve, about 60% of patients can have restored valve function after intravenous infusion of a thrombolytic agent.

TABLE 75-2 ADVANTAGES AND DISADVANTAGES OF SUBSTITUTE CARDIAC VALVES

TYPE OF VALVE	ADVANTAGES	DISADVANTAGES
Bioprosthesis (Carpentier-Edwards, Hancock)	Avoids anticoagulation in patients with sinus rhythm	Durability limited to 10-15 yr Relatively stenotic
Mechanical valves (St. Jude, Medtronic-Hall, Starr-Edwards)	Good flow characteristics in small sizes Durable	Require anticoagulation
Homografts and autografts	Anticoagulation not required Durability increased over that of bioprostheses	Surgical implantation technically demanding

Choices among Prosthetic Valves

Different types of prosthetic valves (Fig. 75-8) have different advantages and disadvantages (Table 75-2). At long-term follow-up, primary valve failure with resulting need for reoperation is much more common with bioprosthetic valves,[1,2] and bleeding is generally more common with mechanical valves. For mitral valves, long-term survival is similar with bioprosthetic and mechanical valves.[3] Survival after aortic valve replacement is probably better with mechanical valves. Another alternative is to use the patient's own pulmonic valve to replace the diseased aortic valve and then to implant a prosthetic pulmonic valve (the Ross procedure). In a randomized trial, this procedure was superior to homograft valve and root replacement, with a 10-year survival of 97% compared with 83%.[4]

In general, a tissue valve is recommended in patients who have a life expectancy of less than 15 years or who are unable or unwilling to maintain warfarin anticoagulation. A mechanical valve is preferred in patients who already have another indication for anticoagulation or who have a longer life expectancy and want to minimize the risk of reoperation. Because many patients prefer the risk of reoperation to that of anticoagulation, the age at which bioprostheses are implanted has steadily declined, and many 60-year-old patients now request and receive a bioprosthetic valve.

76 INFECTIVE ENDOCARDITIS

VANCE G. FOWLER JR. AND ARNOLD S. BAYER

DEFINITION

Infective endocarditis is defined as an infection, usually bacterial, of the endocardial surface of the heart. Infective endocarditis affects primarily the cardiac valves, although in some cases the septa between the chambers or the mural endocardium may be involved. Traditionally, infective endocarditis has been categorized as acute or subacute, depending on the duration of symptoms before presentation; however, this distinction is somewhat arbitrary. A classification that considers the causative organism and the valve involved is more clinically relevant.

EPIDEMIOLOGY

The incidence of infective endocarditis is difficult to determine because of the different criteria for diagnosis and methods of reporting. An analysis based on strict case definitions reveals that only a relatively small proportion (about 20%) of clinically diagnosed cases are categorized as definite. Nevertheless, in 10 large surveys, infective endocarditis accounted for approximately 1 case per 1000 U.S. hospital admissions, with a range of 0.16 to 5.4 cases per 1000 admissions. This incidence has not changed appreciably over the past 30 years. Estimates from the American Heart Association place the annual incidence of infective endocarditis in the United States at 10,000 to 20,000 new cases.

Men are more commonly affected than women (mean male-female ratio of 1.7 : 1 in 18 large series). However, in patients younger than 35 years, more cases occur in women. More than 50% of patients with infective endocarditis in the United States are now older than 50 years owing to the low incidence of acute rheumatic fever (Chapter 298) and the low subsequent prevalence of rheumatic heart disease compared with prior eras and with developing countries, as well as a simultaneous rise in the prevalence of degenerative heart disease as the population lives longer.

Although some patients have no clearly definable risk factor for endocarditis, cardiac conditions that cause turbulent flow at the endocardial surface or across a valve (Chapter 75) predispose patients to infective endocarditis (Table 76-1). Historically, rheumatic heart disease with valvular dysfunction was the most common underlying condition, although its contribution has diminished in the antibiotic era, especially in developed countries.

TABLE 76-1 PREDISPOSING CONDITIONS ASSOCIATED WITH INCREASED RISK OF ENDOCARDITIS

MORE COMMON	LESS COMMON
Mitral valve prolapse	Rheumatic heart disease
Degenerative valvular disease	Idiopathic hypertrophic subaortic stenosis
Intravenous drug use*	Pulmonary-systemic shunts*
Prosthetic valve*	Coarctation of the aorta
Congenital abnormalities (valvular or septal defect)	Previous endocarditis*
	Complex cyanotic congenital heart disease*

*Indicates conditions with highest risk for endocarditis.

Degenerative valvular disease is also associated with infective endocarditis, particularly in elderly patients; the increasing relevance of senile calcification as a risk factor is reflected in the increasing proportion of aortic valve involvement in infective endocarditis. Most significant congenital heart defects (Chapter 69) confer an increased risk of infective endocarditis, particularly complex cyanotic disease such as single-ventricle states, transposition of the great vessels, and tetralogy of Fallot. Similarly, surgically constructed pulmonary-systemic shunts and ventricular septal defects place patients at high risk for infective endocarditis.

Mitral valve prolapse is currently the most common underlying cardiac condition in infective endocarditis, a statistic that reflects its prevalence in the general population (4%). Notably, mitral valve prolapse is a risk only in patients with thickened mitral leaflets and/or regurgitation, in which case the risk of endocarditis increases by about 10-fold over that of the general population. In addition, patients with hypertrophic cardiomyopathy are at increased risk of infective endocarditis, particularly in the presence of outflow obstruction. Finally, previous endocarditis is among the highest risk factors for infective endocarditis.

Prosthetic cardiac valves represent an important risk factor for infective endocarditis. More than 150,000 heart valves are implanted annually worldwide, and prosthetic valve infective endocarditis develops in 1 to 4% of prosthetic valve recipients in the first year after valve replacement and in approximately 0.8% of recipients annually thereafter. Mechanical prosthetic valves may initially be more susceptible to infective endocarditis, but bioprosthetic valves are more likely to develop infective endocarditis after 1 year; overall, the rate is similar with either type of valve.

The incidence of infective endocarditis in injection drug users (Chapter 33) may be 30 times higher than in the general population and 4 times higher than in adults with rheumatic heart disease. In some areas of the United States, injection drug use is the most common predisposing cause of infective endocarditis in patients younger than 40 years. *Staphylococcus aureus* is the predominant organism, and tricuspid valve involvement is noted in 78% of cases, mitral involvement in 24%, and aortic involvement in 8%. More than one valve is infected in approximately 20% of cases, and some of these infections are polymicrobial.

Health care–associated infective endocarditis arises primarily as a consequence of invasive therapies, including intravenous catheters, hyperalimentation lines, pacemakers, and dialysis shunts. In a recent prospective multinational cohort study of more than 1600 patients with native valve endocarditis and no injection drug use, more than one third of patients had health care–associated endocarditis, and many of these cases were community acquired (e.g., in patients on outpatient hemodialysis). The emerging importance of health care–associated infective endocarditis in industrialized nations has also influenced the microbiology of the disease, with an increasing prevalence of *S. aureus* and a decreasing prevalence of viridans streptococci in much of the industrialized world.

Systemic medical conditions predispose patients to the development of infective endocarditis. For example, HIV infection is an independent risk factor for the development of infective endocarditis in injection drug users, with the risk increasing as the CD4 count decreases. Catheter-related bacteremia is an important risk factor for nosocomial infective endocarditis. Patients with end-stage renal disease—particularly those receiving long-term hemodialysis—and patients with diabetes mellitus are also at increased risk, presumably because of the recurrent vascular access associated with the former and the low-level immunosuppression associated with both conditions.

The mitral valve has classically been the most commonly affected valve, followed by the aortic valve. Although mitral valve relapse remains the most common underlying condition, the decreasing frequency of rheumatic mitral disease and the increasing senescence of the population may account for the increase in aortic valve endocarditis reported in many studies. The next most commonly affected valves in descending order of prevalence are the mitral and aortic valves together, the tricuspid valve, mixed right- and left-sided infection, and the pulmonic valve.

Microbiology

About 90% of community-acquired, native valve infective endocarditis is due to staphylococci, streptococci, or enterococci, each of which is a normal inhabitant of the skin, oropharynx, and urogenital tract with frequent access to the blood stream. These organisms express specific receptors for attachment and adherence to damaged valve surfaces. Streptococcal species (Chapter 298) are the most common cause in community-dwelling patients

with no history of injection drug use or health care contact. In patients with either of these epidemiologic risk factors, *S. aureus* (Chapter 298) is the predominant cause of infective endocarditis. Because of the emergence of health care contact as the predominant risk factor for blood stream infections, *S. aureus* is now the most common cause of infective endocarditis in many regions of the world.

Viridans streptococci (Chapter 298) are the most common streptococci implicated in native valve infective endocarditis. This group of organisms, which normally inhabit the oropharynx, includes species such as *Streptococcus sanguis, Streptococcus mutans,* and *Streptococcus mitis*. Group B streptococci, β-hemolytic organisms that are also normal oropharyngeal and urogenital flora, most frequently cause infective endocarditis in patients with cirrhosis or diabetes mellitus and in injection drug users. By contrast, group A streptococci, although also β-hemolytic, rarely cause infective endocarditis. *Streptococcus bovis,* a group D streptococcus, is now a leading cause of infective endocarditis in some parts of the world; for example, its incidence in France has increased significantly in recent years. Its presence should prompt endoscopic evaluation for adenocarcinoma of the colon or other malignant lesions of the gastrointestinal tract.

Pneumococcal endocarditis is decreasing in incidence but is quite fulminant when present. It may occur as part of Austrian's (or Osler's) triad of endocarditis, meningitis, and pneumonia and is associated with high morbidity and mortality.

S. aureus (Chapter 296) is the pathogen of primary concern among injection drug users or patients with health care contact. The clinical course of *S. aureus* endocarditis is typically acute, with a rapid progression over the course of several days. Because approximately 12% of nonselected patients with *S. aureus* bacteremia have infective endocarditis, the possibility of cardiac involvement should always be considered in any patient with *S. aureus* bacteremia; those with persistent bacteremia or fever, community acquisition, or cutaneous findings are at particular risk for infective endocarditis and other complications. Coagulase-negative staphylococci are an unusual cause of native valve disease but are an important pathogen in prosthetic valve endocarditis; presentation is usually subacute.

Enterococcal bacteremia is far more common, particularly in hospitalized patients, than enterococcal endocarditis; however, enterococci are responsible for a significant number of cases of both community-acquired and nosocomial endocarditis. In most cases, the source of the bacteria is thought to be the genitourinary tract, and the presentation is usually subacute. Enterococcal endocarditis, as opposed to enterococcal bacteremia, is suggested by community acquisition of infection, the absence of a clear source of infection, preexistent valvular heart disease, and the absence of polymicrobial bacteremia. As in most enterococcal infections, the overwhelming majority of cases (>90%) are due to *Enterococcus faecalis*.

The HACEK group of gram-negative organisms (*Haemophilus* spp, *Actinobacillus actinomycetemcomitans, Cardiobacterium hominis, Eikenella corrodens,* and *Kingella* spp) accounts for about 5% of cases of endocarditis. Because these fastidious organisms usually grow in blood cultures within 7 days using current methods, prolonged incubation is no longer required to isolate HACEK strains. Many other gram-negative bacilli have been reported to cause infective endocarditis but are even more unusual. Traditionally, injection drug use has been regarded as the primary risk factor for enteric gram-negative bacterial endocarditis. However, recent experience from large multinational studies shows that health care contact, not injection drug use, is the most common risk factor for enteric gram-negative endocarditis.

Fungal endocarditis is difficult to diagnose and treat; it is most commonly found in patients with a history of injection drug use, recent cardiac surgery, or prolonged use of indwelling vascular catheters, especially those used for total parenteral nutrition. The most common fungi found in infective endocarditis are *Aspergillus* and *Candida* species. *Aspergillus* (Chapter 347) rarely grows in blood cultures and must usually be cultured from a pathologic specimen (either an embolic site or vegetation); by contrast, *Candida* (Chapter 346) frequently grows out of blood cultures. Mortality is very high, and valve replacement surgery is usually necessary.

Special Situations: Health Care–Associated Infective Endocarditis and Prosthetic Valves

Health care–associated infective endocarditis is defined as endocarditis occurring in the presence of extensive health care contact. Traditionally, this definition was synonymous with nosocomial in-hospital acquisition; however, the increased complexity of outpatient therapy and the increase in the number of patients in long-term care facilities have resulted in a growing number of nonhospitalized patients with health care–associated bacteremia and infective endocarditis. Such patients have many of the same risk factors (e.g., long-term intravascular catheters, extensive instrumentation) and are infected with the same array of pathogens (e.g., high rates of methicillin-resistant *S. aureus* [MRSA]) as patients with nosocomial infection. Health care–associated infective endocarditis now constitutes about one quarter of all cases and is most frequently associated with indwelling vascular catheters; as a result, the most common organisms implicated in nosocomial infective endocarditis are *S. aureus* and coagulase-negative staphylococci.

TABLE 76-2 CAUSES OF PROSTHETIC VALVE ENDOCARDITIS*

EARLY (<2 MO POSTOPERATIVELY)	LATE (>12 MO POSTOPERATIVELY)
Staphylococcus aureus	Coagulase-negative staphylococci
Coagulase-negative staphylococci	*Staphylococcus aureus*
Gram-negative bacilli	Coagulase-negative staphylococci
Enterococci	Enterococci
Fungi	
Diphtheroids	

*Listed in order of relative frequency.
Adapted from Wang A, Athan E, Pappas PA, et al. Contemporary clinical profile and outcome of prosthetic valve endocarditis. *JAMA*. 2007; 297:1354-1361.

Prosthetic valve endocarditis can be classified into one of three groups based on the time between valve surgery and disease onset: early (<2 months after surgery), intermediate (2 to 12 months), and late (>12 months) (Table 76-2). Staphylococci, particularly *S. aureus,* predominate during the early period, when most episodes of infective endocarditis are thought to be related to perioperative infection. The intermediate period has a fairly similar microbiologic spectrum, with unusual gram-negative organisms and diphtheroids decreasing and streptococci increasing. In the late period, 1 year or more after surgery, the spectrum of organisms becomes more akin to that of community-acquired native valve disease, in which *S. aureus* and streptococci predominate. Of note, approximately 50% of prosthetic valve recipients with *S. aureus* bacteremia develop infective endocarditis.

PATHOBIOLOGY

Experimental models of infective endocarditis have demonstrated that the disease follows a predictable sequence: endocardial damage, aggregation of platelets and fibrin to create a sterile vegetation, transient bacteremia resulting in seeding of the vegetation, microbial proliferation on and invasion of the endocardial surface, and metastatic infection to visceral organs and brain.

Most cases of infective endocarditis begin with a damaged endocardial surface. Damage to the endocardium may be caused by a number of factors, ranging from rheumatic disease to senile degeneration and calcification; indeed, any excessive turbulence or high-pressure gradient can cause injury to the nearby endocardium. Next, fibrin-platelet aggregates develop at the site of damage to form sterile vegetations, also termed *nonbacterial thrombotic endocarditis*. Nonbacterial thrombotic endocarditis may occur spontaneously in patients with systemic illnesses (e.g., the marantic endocarditis of malignancy [Chapter 60] or other wasting diseases, or Libman-Sacks endocarditis in systemic lupus erythematosus [Chapter 274]). When transient bacteremia occurs—for example, as a result of distant infection or gingival disease—the previously sterile vegetation may be seeded. Some bacterial species, such as staphylococci and streptococci, are more avidly adherent than others to vegetations and therefore more frequently cause endocarditis. The bacteria then proliferate within the vegetation and may ultimately achieve an organism load of 10^9 to 10^{11} colony-forming units per gram of tissue. The surfaces of cardiac valves and vegetations are avascular, making antibiotic therapy and healing difficult.

CLINICAL MANIFESTATIONS

History

The initial presentation of infective endocarditis varies enormously from patient to patient, so it is sometimes difficult to make the diagnosis. Some cases develop acutely, with symptoms progressing rapidly over several days. Other cases develop insidiously and present with nonspecific symptoms that

TABLE 76-3 PHYSICAL EXAMINATION AND LABORATORY FINDINGS IN INFECTIVE ENDOCARDITIS

FINDING	% OF CASES
Fever	96
Worsening of old murmur	20
New murmur	48
Vascular embolic event	17
Splenomegaly	11
Splinter hemorrhages	8
Osler's nodes	3

FIGURE 76-1. Petechiae in infective endocarditis.

FIGURE 76-2. Osler's node in infective endocarditis.

have been progressing for weeks or months. In patients suspected of having infective endocarditis, the initial history should include a complete review of systems, a travel history, and a thorough discussion of health-related behaviors such as illicit drug use and sexual activity. Most patients complain of fever and nonspecific constitutional symptoms such as fatigue, malaise, or weight loss. Nearly 50% of patients complain of musculoskeletal symptoms ranging from frank arthritis to diffuse myalgias; 5 to 10% of patients have low back pain as their chief complaint, even in the absence of osteomyelitis or epidural abscess. Many intravenous drug users with endocarditis complain of pleuritic chest pain, because tricuspid valve endocarditis mimics pneumonia. Health care–associated infective endocarditis is more likely to be clinically occult and requires a high index of suspicion.

Physical Examination

A thorough physical examination should be performed, including a search for the peripheral stigmata of infective endocarditis (Table 76-3). Fever is present in nearly 50% of patients in most studies; however, elderly patients and those with renal failure or heart failure may be less likely to mount a febrile response. A widened pulse pressure should alert the clinician to the possibility of acute aortic insufficiency (Chapter 75). The skin and nails should be carefully examined for embolic phenomena such as petechiae, Osler's nodes, Janeway's lesions, and splinter hemorrhages; these findings are uncommon in infective endocarditis in the current era but are extremely helpful diagnostic clues when present. Petechiae are most often found on the conjunctiva, palate, and extremities; like the other peripheral stigmata of infective endocarditis, they are a nonspecific but suggestive finding (Fig. 76-1). Osler's nodes are small, painful nodules found most often on the palmar surfaces of the fingers and toes; they frequently wax and wane (Fig. 76-2). Classically considered to be an immunologic phenomenon, Osler's nodes may have an immune complex–mediated component but are most likely initiated by microemboli. Janeway's lesions (Fig. 50-11 in Chapter 50) are hemorrhagic, nonpainful macules also found primarily on the palms and soles; they are embolic in origin and are less frequently noted than the other cutaneous stigmata. Splinter hemorrhages (see Fig. 50-11 in Chapter 50) are nonblanching, linear, brownish red lesions in the nail beds perpendicular to the direction of nail growth; they are nonspecific and may also be found in a significant percentage of hospitalized patients without infective endocarditis.

Funduscopic examination should be performed to look for Roth's spots (see Fig. 431-28 in Chapter 431), chorioretinitis, or endophthalmitis; the latter two are present in a substantial proportion of cases of fungal endocarditis. A careful cardiac examination should be performed to detect any systolic or diastolic murmurs or evidence of heart failure, which is an ominous sign. Of note, patients with health care–associated infective endocarditis are less likely than others to have a pathologic murmur on initial presentation.

The abdomen should be examined for evidence of splenomegaly (Chapter 171), a finding that is more common in patients with a subacute form of infective endocarditis. Finally, a thorough neurologic examination should be performed, both to assess for any focal neurologic deficits and to serve as a baseline during the patient's hospital stay. The neurologic examination may demonstrate evidence of major vessel embolism, cranial nerve palsies, visual field defects, or generalized toxic-metabolic encephalopathy with altered mental status.

Laboratory Findings

Initial laboratory tests should include a complete blood count with differential, serum electrolytes, measurement of renal function, urinalysis, chest radiograph, and electrocardiogram (ECG). All patients should receive at least three sets of blood cultures as well, and many require an echocardiogram (see later). Most patients with subacute infective endocarditis have anemia of chronic disease. The white blood cell count may or may not be elevated; it is more frequently elevated in cases of acute infective endocarditis, particularly if *S. aureus* or a fungus is the causative organism. Microscopic hematuria is noted in many cases, as is proteinuria. The chest radiograph is abnormal—demonstrating consolidation, atelectasis, pleural effusion, or clear septic emboli—in the overwhelming majority of patients with right-sided endocarditis; in others, it may provide evidence of heart failure. The ECG should be carefully examined for evidence of atrioventricular conduction blocks, especially a prolonged PR interval (see Figs. 64-7 through 64-11 in Chapter 64), suggestive of an aortic ring abscess or frank myocardial infarction (see Figs. 73-1 and 73-2 in Chapter 73). Other ancillary tests might include an erythrocyte sedimentation rate, which is elevated in nearly all cases of infective endocarditis, with a mean value of 57 mm/hour. Rheumatoid factor is positive in about half of cases, particularly in subacute endocarditis.

Complications

The complications of infective endocarditis can be divided into four groups for ease of classification: direct valvular damage and consequences of local

invasion, embolic complications, metastatic infections from bacteremia, and immunologic phenomena. Local damage to the endocardium or myocardium is a dreaded complication that can be difficult to diagnose and treat. Infection may directly erode through the involved cardiac valve or adjacent myocardial wall, resulting in hemodynamically significant valvular perforations or cardiac fistulas. Such local complications typically present clinically with the acute onset of heart failure and carry a poor prognosis, even with prompt cardiac surgery. Valve ring abscesses also require surgical intervention and are more frequent in patients with prosthetic valves. Although a conduction defect on ECG may suggest the diagnosis, transesophageal echocardiography (TEE) is the diagnostic technique of choice for paravalvular abscess, valve perforation, or intracardiac fistula. Frank myocardial abscess has been found in up to 20% of cases on autopsy; *Aspergillus* endocarditis invades the myocardium in more than 50% of cases. Pericarditis is rare and is associated with myocardial abscess in most cases. Myocardial infarction, thought to be due to embolism of vegetative material in the coronary arteries, has been found in 40 to 60% of cases on autopsy, although most cases are clinically silent and lack characteristic ECG changes. However, up to 16% of elderly patients may present with clinical evidence of acute myocardial infarction, with potentially disastrous complications if the myocardial infarction is thought to be the primary event and the patient is given thrombolytic therapy. Heart failure is the leading cause of death in infective endocarditis, usually related to direct valvular damage.

Embolic events are less common now than in the preantibiotic era; nevertheless, about 35% of patients have at least one clinically evident embolic event. In fungal endocarditis, the majority of patients have at least one embolic event, frequently with a large embolus. The presence of large (>10 mm), mobile vegetations on the echocardiogram, particularly when the anterior mitral valve leaflet is involved, predicts a high risk of embolic complications. Most of the classic peripheral stigmata of infective endocarditis are probably embolic in nature; in addition, patients may have frank infarction of cutaneous tissue from emboli. In addition to the skin, emboli most commonly lodge in the lungs (in right-sided endocarditis), kidneys, spleen, large blood vessels, or central nervous system (CNS). Vegetations of right-sided endocarditis usually embolize to the lungs, resulting in an abnormality on the chest radiograph.

Renal abscesses are rare in infective endocarditis, but renal infarction is seen in more than 50% of cases at autopsy. Similarly, splenic infarction occurs in up to 44% of autopsy-confirmed cases; although frequently silent, such emboli may cause left upper quadrant pain radiating to the left shoulder, sometimes as the presenting symptom of infective endocarditis. Splenic infarction progressing to abscess may be a cause of persistent fever in patients with infective endocarditis; patients with infective endocarditis and unexplained persistent fever should undergo abdominal computed tomography to exclude this complication. Vascular aneurysms, which frequently occur at bifurcation points, may be clinically silent until they rupture (which may be months to years after apparently successful antibiotic treatment of infective endocarditis) and have been found in 10 to 15% of cases at autopsy. The presence of large emboli occluding major vessels can suggest the presence of fungal infective endocarditis. Peripheral mycotic aneurysms require surgical resection; intracerebral aneurysms should be resected if they bleed or if they are causing a mass effect.

Finally, many patients have evidence of cerebrovascular emboli, which have a predilection for the middle cerebral artery distribution and may be devastating. Most emboli to the CNS occur early in the course of the disease and are evident at the time of presentation or shortly thereafter. Cerebrovascular accidents related to these emboli are prone to catastrophic hemorrhagic transformation. The possibility of right-sided infective endocarditis leading to a paradoxical CNS embolism through a patent foramen ovale (Chapter 69) should not be neglected. Of note, the majority of patients with fungal endocarditis have a CNS embolic event.

Some complications of infective endocarditis are a result of bacteremic seeding causing metastatic infection at a distant site. Patients may present with osteomyelitis, septic arthritis, or epidural abscess. Purulent meningitis (Chapter 420) is a rare complication except in pneumococcal endocarditis, although many patients with *S. aureus* infective endocarditis who undergo lumbar puncture have a pleocytosis. Importantly, the finding of one metastatic complication of infective endocarditis does not exclude the possibility of additional sites of hematogenous infection, particularly in *S. aureus* endocarditis. Thus, the need for additional diagnostic evaluations should be guided by the patient's clinical course. Intracranial abscesses are uncommon in bacterial endocarditis but frequent in *Aspergillus* endocarditis; such a finding in the setting of culture-negative endocarditis should prompt the consideration of *Aspergillus* as an etiologic agent.

Multiple immunologic phenomena may occur, many of which are directly related to the circulating immune complexes characteristic of the disease. Renal biopsies performed in the setting of active infective endocarditis show some abnormality in nearly all cases. Infective endocarditis classically causes a hypocomplementemic glomerulonephritis. Histopathologically, the glomerular changes may be focal, diffuse, or membranoproliferative, or they may be akin to the immune complex disease found in systemic lupus erythematosus. In addition, many of the musculoskeletal conditions associated with infective endocarditis, including monoarticular and oligoarticular arthritides, are probably immune mediated.

DIAGNOSIS

The "gold standard" for the diagnosis of infective endocarditis is culture of a pathologic organism from a valve or other endocardial surface. However, unless the patient undergoes valve replacement or postmortem examination, the diagnosis is made clinically. As a result, various clinical criteria have been proposed over the years, the most widely accepted of which are the modified Duke criteria (Table 76-4), which have an estimated 76 to 100% sensitivity and 88 to 100% specificity, with a negative predictive value of at least 92%.

TABLE 76-4 MODIFIED DUKE CRITERIA FOR THE DIAGNOSIS OF INFECTIVE ENDOCARDITIS

MAJOR CRITERIA

1. Blood culture positive
   a. Typical organism (α-hemolytic streptococcus, *Streptococcus bovis*, HACEK organisms, or community-acquired *Staphylococcus aureus* or enterococcus without a primary focus) from 2 separate blood cultures
   or
   b. Persistent bacteremia with any organism (2 positive cultures >12 hr apart or 3 positive cultures or a majority of ≥4 cultures positive >1 hr apart)
   or
   c. Bacteremia with *S. aureus*, regardless of whether the bacteremia was nosocomially acquired or whether a removable focus of infection is found
2. Evidence of endocardial involvement
   a. Echocardiographic findings: mobile mass attached to valve or valve apparatus, abscess, or new partial dehiscence of prosthetic valve
   b. New valvular regurgitation
3. Serology: single positive blood culture for *Coxiella burnetii* or antiphase 1 IgG antibody titer >1 : 800

MINOR CRITERIA

1. Predisposing condition: intravenous drug use or predisposing cardiac condition
2. Fever ≥38° C
3. Vascular phenomena: arterial embolism, septic pulmonary emboli, mycotic aneurysm, intracranial hemorrhage, conjunctival hemorrhages, Janeway's lesions
4. Immunologic phenomena: glomerulonephritis, Osler's nodes, Roth's spots, rheumatoid factor
5. Echocardiogram findings consistent with endocarditis but not meeting major criteria
6. Microbiologic evidence: positive blood cultures not meeting major criteria or serologic evidence of active infection consistent with endocarditis

DEFINITIVE INFECTIVE ENDOCARDITIS

1. Pathologically proven infective endocarditis
or
2. Clinical criteria meeting
   a. Two major criteria *or*
   b. One major and one minor criteria *or*
   c. Three minor criteria

POSSIBLE INFECTIVE ENDOCARDITIS

Findings that fall short of definitive infective endocarditis but do not reject it

REJECTED INFECTIVE ENDOCARDITIS

1. Firm alternative diagnosis *or*
2. Resolution of infective endocarditis syndrome with antibiotic therapy for ≤4 days *or*
3. No pathologic evidence of infective endocarditis at surgery or autopsy with antibiotic therapy for ≤4 days

HACEK = *Haemophilus* spp, *Actinobacillus actinomycetemcomitans, Cardiobacterium hominis, Eikenella corrodens,* and *Kingella* spp; IgG = immunoglobulin G.

Adapted from Li JS, Sexton DJ, Mick N, et al. Proposed modifications to the Duke criteria for the diagnosis of infective endocarditis. *Clin Infect Dis.* 2000;30:633-638.

TABLE 76-5 ORGANISMS CAUSING "CULTURE-NEGATIVE" ENDOCARDITIS*

ORGANISM	EPIDEMIOLOGY	DIAGNOSTIC TESTS
HACEK spp	Mostly oral flora, so often preceded by dental work or history of periodontal disease	Prolonged incubation of standard blood cultures; may need to be subcultured onto blood or chocolate agar
Nutritionally variant streptococci	Slow and indolent course	Supplemented culture media or growth as satellite colonies around *Staphylococcus aureus* streak
Coxiella burnetii (Q fever)	Worldwide; exposure to raw milk, farm environment, or rural areas	Serologic tests (high titers of antibody to both phase 1 and phase 2 antigens); also PCR on blood or valve tissue
Brucella spp	Ingestion of contaminated milk or milk products; close contact with infected livestock	Bulky vegetations usually seen on echocardiography; blood cultures positive in 80% of cases with incubation time of 4-6 wk; lysis-centrifugation technique may expedite growth; serologic tests are available
Bartonella spp	*B. henselae:* transmitted by cat scratch or bite or by cat fleas *B. quintana:* transmitted by human body louse; predisposing factors include homelessness and alcohol abuse	Bulky vegetations usually seen on echocardiography; serologic testing (may cross-react with *Chlamydia* spp); PCR of valve or emboli is best test; lysis-centrifugation technique may be useful
Chlamydia psittaci	Exposure to birds; lawn mowing	Serologic tests available, but must exclude *Bartonella* because of cross-reactivity; monoclonal antibody direct stains on tissue may be useful; PCR now available
Tropheryma whippelii (Whipple's disease)	Systemic symptoms include arthralgias, diarrhea, abdominal pain, lymphadenopathy, weight loss, CNS involvement; however, endocarditis may be present without systemic symptoms	Histologic examination of valve with PAS stain; valve cultures may be done using fibroblast cell lines; PCR on vegetation material
Legionella spp	Contaminated water distribution systems; often nosocomial outbreaks; usually prosthetic valves	Lysis-centrifugation technique; also periodic subcultures onto buffered charcoal yeast extract medium; serologic tests and PCR available
Aspergillus and other noncandidal fungi	Prosthetic valve	Lysis-centrifugation technique; also culture and direct examination of any emboli

*Listed in approximate order of relative frequency.
CNS = central nervous system; HACEK = *Haemophilus* spp, *Actinobacillus actinomycetemcomitans, Cardiobacterium hominis, Eikenella corrodens,* and *Kingella* spp; PAS = periodic acid–Schiff; PCR = polymerase chain reaction.

The Duke criteria rely heavily on the appropriate use of blood cultures and echocardiographic data. At least three sets of blood cultures, with each set consisting of one aerobic and one anaerobic bottle, should be obtained from separate sites, with careful attention to aseptic technique. Ideally, these sets should be collected at least 1 hour apart to document continuous bacteremia; however, when patients are critically ill, this approach may not be feasible.

In most cases of endocarditis, in the absence of prior antibiotic therapy, every blood culture is positive because the bacteremia of endocarditis is continuous. Blood cultures are truly negative in less than 5% of cases of endocarditis; however, prior antibiotic administration may decrease the yield of blood cultures by up to 35%. Accordingly, most "culture-negative" cases of endocarditis occur in patients who have recently received antimicrobial agents. These cases are probably caused by the same organisms responsible for most native valve endocarditis; viridans streptococci and the HACEK organisms are the most likely suspects because they are much more fastidious than staphylococci and enterococci and are therefore more likely to be affected by previous antibiotic administration. Ultimately, however, when blood cultures are negative and endocarditis is suspected, especially when a history of recent antimicrobials is lacking, consideration should be given to fastidious organisms, fungi, and noncultivatable organisms (Table 76-5). This possibility should receive particular attention when the patient's history suggests exposure to farm animals or unpasteurized milk *(Coxiella burnetii, Brucella)*, cats *(Bartonella henselae)*, or body lice *(Bartonella quintana)* or contact with birds or frequent lawn mowing *(Chlamydia psittaci)*. It is important to notify the microbiology laboratory that endocarditis is suspected because special culture techniques can increase the yield for the HACEK species, nutritionally variant streptococci (*Abiotrophia* and *Granulicatella* spp), *Brucella, Legionella,* and some fungi. The traditional practice of "holding" blood cultures for 2 to 4 weeks to investigate culture-negative endocarditis is no longer required routinely. Specific serologic tests can be used to diagnose endocarditis related to *C. burnetii* (the agent of Q fever), *Brucella* species, *Bartonella*, and *C. psittaci*. *Tropheryma whippelii*, the etiologic agent in Whipple's disease, and multiple other organisms may be diagnosed by polymerase chain reaction. If the search for a causative organism is fruitless, noninfectious causes such as marantic or Libman-Sacks endocarditis and atrial myxoma (Chapter 60) should be considered.

Both transthoracic echocardiography (TTE) and TEE (Chapter 55) are highly specific tests (≈98%) when used as part of the diagnostic evaluation of suspected endocarditis. By contrast, TEE has a sensitivity of 90 to 95% in this setting, which is significantly better than TTE's usual sensitivity of 48 to 63%. Significant controversy still exists over whether the diagnostic evaluation of suspected infective endocarditis should begin with TTE or TEE. In most cases in which endocarditis is a serious diagnostic consideration, the evaluation should begin with TEE because negative TTE is not sensitive enough to exclude endocarditis (Fig. 76-3). If TEE is unavailable, technically impossible, or considered too invasive by the patient, it is reasonable to begin with TTE.

Some special situations may also dictate whether to begin with TTE or TEE. TEE is the only relatively noninvasive means of detecting perivalvular extension of infection; the esophageal probe's proximity to the aortic root and basal septal wall of the myocardium allows better visualization of these structures, which are most frequently involved in local spread of infection. For this reason, any patient with a new conduction system abnormality or persistent fever—clinical predictors of perivalvular extension—should be evaluated with TEE. Likewise, TEE's heightened sensitivity is especially important in the evaluation of suspected prosthetic valve endocarditis; TEE provides superior definition of prosthetic valve vegetations and valve ring abscesses. Finally, the high sensitivity of TEE in detecting valvular vegetations on native valves may be used in combination with clinical parameters (e.g., prompt resolution of bacteremia and defervescence) to support the clinical decision to abbreviate therapy in patients with vascular catheter–associated *S. aureus* bacteremia.

The combination of negative TTE and negative TEE has a negative predictive value of 95%. Nevertheless, when clinical suspicion of endocarditis is high and the initial TEE is negative, repeat TEE in 7 to 10 days may reveal the diagnosis.

TREATMENT Rx

Definitive antibiotic treatment of infective endocarditis (Table 76-6) is guided by antimicrobial susceptibility testing of the responsible pathogen isolated from clinical cultures. Although it is often advisable to begin empirical treatment before definitive culture results are available, not all patients admitted to rule out endocarditis need to be treated empirically. Patients who are clinically stable, with a subacute presentation of disease and without evidence of heart failure or other end-organ complications, can be closely observed without antibiotics so that serial blood cultures can be obtained. Likewise, stable patients who were started on empirical antibiotics before

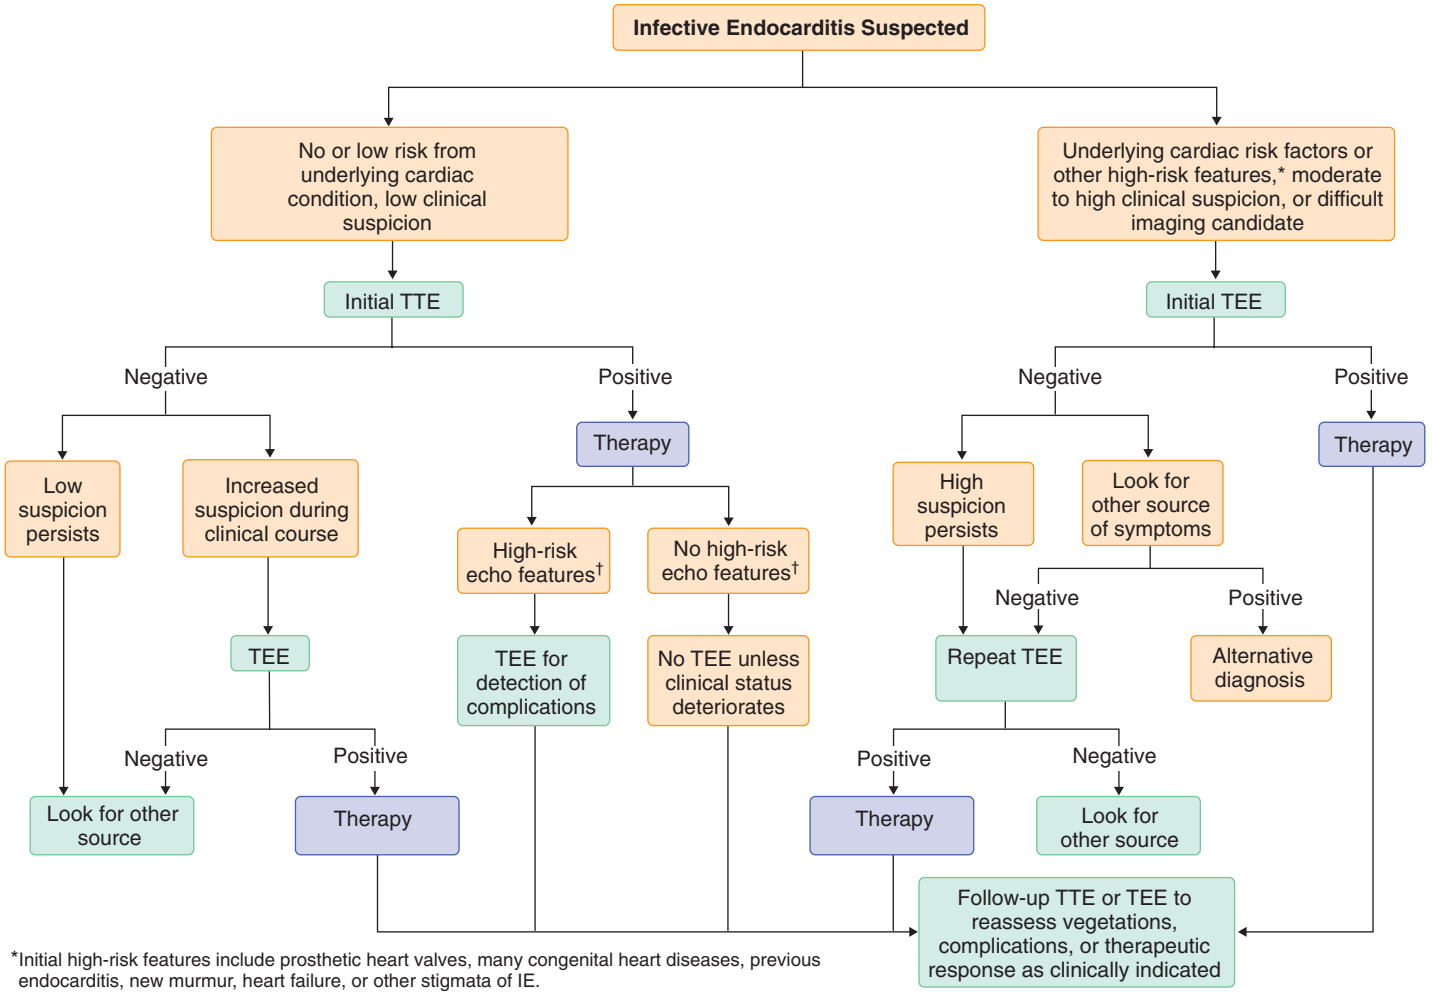

FIGURE 76-3. Algorithm for the diagnostic use of echocardiography in suspected cases of infective endocarditis (IE). TEE = transesophageal echocardiography; TTE = transthoracic echocardiography. (Adapted from Bayer AS, Bolger AF, Taubert KA, et al. Diagnosis and management of infective endocarditis and its complications. *Circulation.* 1998;98:2936-2948.)

hospitalization and before blood was drawn for cultures can discontinue the antibiotics so that blood cultures can be obtained, preferably as long as possible after stopping the antibiotics. By contrast, acutely ill patients, those with evidence of complications of endocarditis, and patients who are at high risk for endocarditis should be treated empirically with antibiotics pending culture results. In most cases of infective endocarditis, it is advisable to seek consultation from an infectious diseases specialist to assist in designing an appropriate antibiotic regimen.

Either of two regimens provides appropriate empirical coverage for patients with suspected native valve endocarditis: nafcillin (or oxacillin)-penicillin-gentamicin or vancomycin-gentamicin (Table 76-7). Nafcillin-penicillin-gentamicin is suitable in most cases of suspected native valve endocarditis, providing optimal coverage for streptococci, staphylococci, enterococci, and HACEK organisms. If MRSA is an important consideration, as it is for injection drug users and those with health care contact, empirical therapy should consist of vancomycin and gentamicin. This regimen is also acceptable for patients with a severe penicillin allergy. Patients with prosthetic valves should be empirically treated with vancomycin, gentamicin, and rifampin for adequate coverage of *S. aureus* (including MRSA), coagulase-negative staphylococci, and gram-negative organisms.

Treatment of Specific Organisms

When the organism is definitively identified, antibiotic treatment must be narrowed accordingly. Standardized regimens have been developed and validated for the most common organisms, and these protocols should be followed assiduously (see Table 76-6). More controversy exists over the treatment of unusual organisms, and consultation with infectious disease specialists is advisable in such circumstances. Of note, these regimens recommend low-dose gentamicin, which reduces the risk of toxicity while providing adequate levels for synergism. In cases in which the risk of aminoglycoside toxicity is significantly increased (e.g., elderly people, patients with preexisting renal disease or hearing impairment, diabetics), exposure to gentamicin should be minimized or avoided entirely. In fact, for the organisms listed in Table 76-6, gentamicin is critical for cure only in cases of enterococcal endocarditis. As a result, current American Heart Association guidelines classify even low-dose, short-course gentamicin therapy as "optional" for the treatment of native valve *S. aureus* endocarditis. Since the publication of these guidelines, a post hoc analysis of the data from a large randomized trial showed that a decrease in creatinine clearance occurred in 22% of patients receiving initial low-dose gentamicin, compared with 8% of patients not receiving it. Based on these results and on the minimal data supporting its benefit, initial low-dose gentamicin probably should not be used for *S. aureus* bacteremia in patients without prosthetic valves and should not be used for native valve endocarditis except when enterococcal or gram-negative infection is suspected.

In uncomplicated viridans streptococcal endocarditis, outpatient therapy with once-daily ceftriaxone is as effective as more complex regimens, provided the patient has been observed in the hospital for the development of complications. The decision to administer antimicrobial therapy in the outpatient setting must, of course, take into account the patient's social situation, likelihood of compliance, and other risks involved with either an indwelling intravenous line or recurrent peripheral intravenous placement.

Standard therapy for infective endocarditis caused by fully susceptible enterococci includes penicillin or ampicillin plus either streptomycin or gentamicin. Although gentamicin is preferred over streptomycin, the choice of a specific aminoglycoside should be based on in vitro susceptibility testing, and the duration of aminoglycoside therapy can be as short as 2 to 3 weeks in some clinical settings. Although the optimal therapy for infective endocarditis due to ampicillin-sensitive aminoglycoside-resistant enterococci is undefined, in vitro and experimental data suggest the potential efficacy of a combination of ceftriaxone plus ampicillin for such infections.

Optimal therapy for enterococci that are "resistant" (e.g., to aminoglycosides and/or vancomycin) is not well defined. Endocarditis caused by vancomycin-resistant strains of enterococci may be treatable with daptomycin, quinupristin-dalfopristin (7.5 mg/kg intravenously every 8 hours), or linezolid (600 mg

TABLE 76-6 DEFINITIVE THERAPY OF BACTERIAL ENDOCARDITIS

ORGANISM/REGIMEN*	COMMENTS
PCN-SUSCEPTIBLE VIRIDANS STREPTOCOCCI (MIC ≤0.1 μg/mL) AND *STREPTOCOCCUS BOVIS*	
1. PCN 2-3 million units IV q4h × 4 wk	1. Also effective for other PCN-susceptible nonviridans streptococci
2. Ceftriaxone 2 g IV qd × 4 wk	2. Uncomplicated infection with viridans streptococci in a candidate for outpatient therapy; also for those with PCN allergy
3. PCN 2-3 million units IV q4h × 2 wk plus gentamicin 1 mg/kg IV q8h × 2 wk	3. Uncomplicated infection with none of the following features: renal insufficiency, eighth cranial nerve deficit, prosthetic valve infection, CNS complications, severe heart failure, age >65 yr; also not acceptable for nutritionally variant streptococci
4. PCN 2-4 million units IV q4h × 4 wk plus gentamicin 1 mg/kg IV q8h × 2 wk	4. Nutritionally variant strain; for prosthetic valve, give 6 wk of PCN
5. Vancomycin 15-20 mg/kg IV q8-12h × 4 wk	5. For PCN allergy; goal trough level of 15-20 mg/L
RELATIVELY PCN-RESISTANT VIRIDANS STREPTOCOCCI (MIC 0.12-<0.5 μg/mL)	
1. PCN 4 million units IV q4h × 4 wk plus gentamicin 1 mg/kg IV q8h × 2 wk	—
2. Vancomycin 15-20 mg/kg IV q8-12h × 4 wk	2. For PCN allergy or to avoid gentamicin; goal trough level of 15-20 mg/L
ENTEROCOCCI† AND PCN-RESISTANT VIRIDANS STREPTOCOCCI (PENICILLIN MIC >0.5 μg/mL)	
1. PCN‡ 18-30 million units IV per day in divided doses × 4-6 wk or ampicillin 12 g/24 hr IV in 6 equally divided doses plus gentamicin 1 mg/kg IV q8h × 4-6 wk	1. Increase duration of both drugs to 6 wk for prosthetic valve infection or symptoms >3 mo in enterococcal infection
2. Vancomycin 15-20 mg/kg IV q8-12h × 6 wk plus gentamicin 1 mg/kg q8h × 6 wk§	2. For PCN allergy; PCN desensitization is also an option; high risk of nephrotoxicity with this regimen
STAPHYLOCOCCUS AUREUS	
1. Nafcillin 2 g IV q4h × 4-6 wk with optional addition of gentamicin 1 mg/kg IV q8h × 3-5 days	1. Methicillin-susceptible strain; omit gentamicin if significant renal insufficiency
2. Vancomycin 15-20 mg/kg IV q8-12h × 6 wk	2. PCN allergy (immediate hypersensitivity or anaphylaxis) or MRSA
3. Nafcillin 2 g IV q4h × 2 wk plus gentamicin 1 mg/kg IV q8h × 2 wk	3. Methicillin-susceptible strain; 2-wk regimen only for use in IV drug abusers with only tricuspid valve infection, no renal insufficiency, and no extrapulmonary infection
4. Nafcillin 2 g IV q4h × >6 wk plus gentamicin 1 mg/kg IV q8h × 2 wk plus rifampin 300 mg PO/IV q8h × ≥6 wk	4. Prosthetic valve infection with methicillin-susceptible strain; use vancomycin instead of nafcillin for MRSA
5. Cefazolin 2 g IV q8h × 4-6 wk with optional addition of gentamicin 1 mg/kg IV q8h × 3-5 days	5. PCN allergy other than immediate hypersensitivity
6. Daptomycin 6 mg/kg IV qd × 14-42 days	Daptomycin is FDA-approved for treatment of right-sided *S. aureus* infective endocarditis; for adults, some experts recommend 8-10 mg/kg IV
COAGULASE-NEGATIVE STAPHYLOCOCCI, PROSTHETIC VALVE INFECTION	
Vancomycin 15-20 mg/kg IV q8-12h × >6 wk plus gentamicin 1 mg/kg IV q8h × 2 wk plus rifampin 300 mg PO/IV q8h × >6 wk	Can substitute nafcillin in above doses for vancomycin if isolate is methicillin sensitive
HACEK STRAINS	
1. Ceftriaxone 2 g IV qd × 4 wk; 6 wk for prosthetic valves	—
2. Ampicillin-sulbactam 3 g IV q6h × 4 wk; 6 wk for prosthetic valves	2. HACEK strains increasingly may produce β-lactamase
NON-HACEK GRAM-NEGATIVE BACILLI	
Enterobacteriaceae	
Extended-spectrum PCN or cephalosporin plus aminoglycosides for susceptible strains	Treat for a minimum of 6-8 wk; some species exhibit inducible resistance to third-generation cephalosporins; valve surgery is required for most patients with left-sided endocarditis caused by gram-negative bacilli; consultation with a specialist in infectious diseases is recommended
Pseudomonas aeruginosa	
High-dose tobramycin (8 mg/kg/day IV or IM in once-daily doses) with maintenance of peak and trough concentrations of 15 to 20 μg/mL and ≤2 μg/mL, respectively, in combination with an extended-spectrum penicillin (e.g., ticarcillin, piperacillin, azlocillin); ceftazidime, cefepime, or imipenem in full doses; or imipenem	Treat for a minimum of 6-8 wk; early valve surgery usually required for left-sided *Pseudomonas* endocarditis; consultation with a specialist in infectious diseases is recommended
Fungi	
Treatment with a parenteral antifungal agent (usually an amphotericin B–containing product) and valve replacement	Long-term/lifelong suppressive therapy with oral antifungal agents often required; consultation with a specialist in infectious diseases is recommended

*Dosages are for patients with normal renal function; for those with renal insufficiency, adjustments must be made for all drugs except nafcillin, rifampin, and ceftriaxone. Gentamicin doses should be adjusted to achieve a peak serum concentration of approximately 3 μg/mL 30 min after dosing and a trough gentamicin level of <1 μg/mL.
†Enterococci must be tested for antimicrobial susceptibility. These recommendations are for enterococci sensitive to PCN, gentamicin, and vancomycin.
‡Ampicillin 12 g/day can be used instead of PCN.
§The need to add an aminoglycoside has not been demonstrated for PCN-resistant streptococci.
HACEK = *Haemophilus* spp, *Actinobacillus actinomycetemcomitans, Cardiobacterium hominis, Eikenella corrodens*, and *Kingella* spp; MIC = minimum inhibitory concentration; MRSA = methicillin-resistant *Staphylococcus aureus*; PCN = penicillin.

TABLE 76-7 EMPIRICAL TREATMENT OF ENDOCARDITIS

CHARACTERISTICS OF PATIENTS	TREATMENT REGIMEN*
Native valve, community-acquired infection, MRSA unlikely	Nafcillin 2 g IV q4h plus penicillin 4 million units IV q4h plus gentamicin 1 mg/kg IV q8h
Any of the following: health care–associated infection or other reason to suspect MRSA; severe penicillin allergy	Vancomycin 15-20 mg/kg IV q8-12h† plus gentamicin 1 mg/kg IV q8h
Prosthetic valve	Vancomycin 15-20 mg/kg IV q8-12h† plus gentamicin 1 mg/kg IV q8h plus rifampin 300 mg PO/IV q8h

*Dosages are for patients with normal renal function; for those with renal insufficiency, adjustments must be made for all drugs except nafcillin.
†Goal is trough level of 15-20 mg/L.
MRSA = methicillin-resistant *Staphylococcus aureus*.

orally or intravenously twice daily); however, clinical experience with these agents is limited. In this situation, relapse or failure rates are likely to be high, and many cases require surgical intervention (discussed later).

Data suggest that patients with MRSA endocarditis treated with vancomycin have higher rates of bacteriologic failure than those treated with nafcillin. Therefore, every attempt should be made to treat MRSA endocarditis with an antistaphylococcal β-lactam. In a recent randomized trial, daptomycin 6 mg/kg/day for 10 to 42 days, depending on the severity of infection, was as effective as either semisynthetic antistaphylococcal penicillin or vancomycin for the treatment of *S. aureus* bacteremia and right-sided infective endocarditis,[2] and it is approved by the Food and Drug Administration for these indications.

Fungal endocarditis is usually a consequence of extensive health care contact. Traditionally, fungal endocarditis was regarded as an indication for valvular surgery, and amphotericin B (Chapter 339) was considered the treatment of choice. However, the high mortality associated with fungal endocarditis and the availability of new classes of antifungals suggest that these principles should be re-evaluated. The management of fungal endocarditis should always involve the collaboration of an experienced infectious diseases specialist.

Zoonotic endocarditis is usually culture-negative and most commonly caused by *Bartonella* species (Chapter 323), *C. burnetii* (Chapter 335), or *Brucella* species (Chapter 318). The treatments of choice for these fastidious pathogens are based on limited data, but documented *Bartonella* endocarditis is treated with doxycycline for 6 weeks and gentamicin for 2 weeks.

In cases of presumed culture-negative endocarditis in which unusual organisms (see Table 76-5) and other infections have been reasonably excluded, an empirical course of treatment may be undertaken. In this situation, most authorities recommend a 4- to 6-week regimen of ceftriaxone alone, vancomycin-ceftriaxone, or vancomycin-gentamicin (if the clinical setting suggests enterococci).

Continuing Care of the Patient with Endocarditis

In addition to antibiotics, appropriate inpatient care includes careful surveillance for the development of complications. Repeat echocardiography, as clinically indicated in the acute setting and at the end of antibiotic therapy, and serial ECGs should be obtained to look for the development of conduction system disease that might herald perivalvular extension, especially in patients with prosthetic valves and persistent fever. Widening pulse pressure should alert the clinician to the possible development of acute aortic insufficiency (Chapter 75). Similarly, a careful cardiac examination should be performed on a daily basis to assess for new regurgitant murmurs. Any new neurologic findings should prompt a search for evidence of CNS complications such as embolic events, cerebral hemorrhage, mycotic aneurysm, and brain abscess. Renal function should be closely monitored so that antibiotic doses can be adjusted, if necessary. If gentamicin is used for more than a few days, the patient should be alerted to watch for the signs and symptoms of vestibular or otic toxicity. Audiometric testing at baseline and periodically thereafter should be considered in patients at high risk for aminoglycoside-induced ototoxicity, including the elderly, patients with preexisting renal dysfunction or hearing damage, and patients receiving prolonged courses of gentamicin. Serum gentamicin trough concentrations should also be assayed at regular intervals (e.g., twice weekly, and more often if renal function is changing) and should be less than 1 μg/mL; higher concentrations should lead to lower or less frequent dosing or both. Follow-up blood cultures may be indicated toward the end of the first week of therapy in patients whose infective endocarditis is caused by organisms that commonly fail first-line treatment, such as *S. aureus* and enterococci. Positive cultures in this setting might suggest the need to change therapy or intervene surgically, whereas negative cultures are reassuring.

Patients with infective endocarditis may continue to be febrile for some time after the institution of appropriate antibiotic treatment. About 50% of patients defervesce within 3 days of starting antibiotics, 75% by 1 week, and 90% by 2 weeks. Patients whose endocarditis is caused by *S. aureus*, gram-negative organisms, or fungi tend to defervesce more slowly than patients infected with other organisms. Prolonged fever (>1 week after the institution of appropriate antibiotics) should prompt repeat blood cultures. If such cultures are negative, several possibilities should be considered: myocardial abscess, extracardiac infection (e.g., mycotic aneurysm, psoas or splenic abscess, vertebral osteomyelitis, septic arthritis), immune complex–mediated tissue damage, or a complication of hospitalization and therapy (e.g., drug fever, nosocomial superinfection, pulmonary embolism). Appropriate studies might include TEE, computed tomography of the abdomen, bone scan, and urinalysis with microscopy (to elicit evidence of interstitial nephritis). Intravenous line sites should be carefully examined for evidence of infection, and indwelling central lines should be changed.

Anticoagulation in individuals with infective endocarditis is controversial. Although new anticoagulation in the setting of native valve endocarditis does not appear to provide a benefit, continuing ongoing anticoagulation may be advisable. Some authorities recommend continuing anticoagulation in patients with mechanical prosthetic valve endocarditis. However, discontinuation of all anticoagulation for at least the first 2 weeks of antibiotic therapy is generally advised in patients with *S. aureus* prosthetic valve endocarditis who have experienced a recent CNS embolic event; this allows the thrombus to organize and potentially prevents the acute hemorrhagic transformation of embolic lesions. Reintroduction of anticoagulation in these patients must be cautious, and the international normalized ratio must be monitored carefully. The best option for patients with other indications for anticoagulation, such as deep venous thrombosis, major vessel embolization, or atrial fibrillation, is less clear and should be decided in a multidisciplinary fashion that balances the risks and benefits for each individual patient. Aspirin does not prevent embolic events and tends to increase the incidence of bleeding.[3]

Surgery

Some patients require surgical treatment, either to cure infective endocarditis or to prevent death from it (Table 76-8). Most patients with evidence of direct extension of infection to myocardial structures, prosthetic valve dysfunction, or heart failure from endocarditis-induced valvular damage should undergo surgery. In addition, many cases of endocarditis caused by fungi or by gram-negative or resistant organisms (e.g., vancomycin- or gentamicin-resistant enterococci) require surgical management. Progression of disease or persistence of fever and bacteremia for more than 7 to 10 days in the presence of appropriate antibiotic therapy may indicate the need for surgery; however, a thorough search must first be conducted to exclude other foci of infection. Surgical management should also be considered for patients with recurrent (two or more) embolic events or those with large vegetations (>10 mm) on echocardiography and one embolic event, although the data in these situations are less convincing. The presence of *S. aureus* endocarditis involving the anterior mitral valve leaflet and large vegetations (>10 mm) may be a special circumstance calling for early surgical intervention to reduce the high risk of CNS emboli, especially when mitral valve repair, rather than valve replacement, can be accomplished.

Delaying surgery in patients with deteriorating cardiac function in an attempt to "sterilize" the affected valve is ill advised because the risk of progressive heart failure or further complications usually outweighs the relatively small risk of recurrent infective endocarditis after prosthetic valve implantation. Relative contraindications to valve replacement include recent CNS emboli or bleed (because of the risk of bleeding in the perioperative period, when anticoagulation is required), multiple prior valve replacements (because of the difficulty of sewing a new valve into tissue already weakened from previous surgeries), and ongoing injection drug use. On occasion, patients have both a compelling indication for valve replacement (e.g., acute heart failure) and a recent CNS embolic event. The risk of hemorrhagic transformation of such lesions during cardiac bypass–associated anticoagulation is controversial. However, it appears that the greatest risk of such transformation events is in larger (>2 cm) emboli, especially those that have exhibited a hemorrhagic component. In these latter scenarios, it is prudent to try to delay surgery for at least 2 to 4 weeks to allow organization and resolution of such emboli. It appears that valve replacement can be performed safely without such delays in patients with smaller, nonhemorrhagic CNS emboli.

After definitive surgical treatment, most patients should receive further antibiotic therapy unless a full course of antibiotics was administered before surgery and there is no evidence of ongoing infection. If the patient received antibiotics for less than 1 week before surgery or the culture from the operative site is positive, the patient should receive the equivalent of a full initial course of antibiotics appropriate for the organism. If the patient received antibiotics for 2 weeks or more and the culture from the operative site is negative, the patient should receive whatever remains of the originally planned course of appropriate antibiotic therapy.

TABLE 76-8 INDICATIONS FOR SURGERY IN ENDOCARDITIS

INDICATION	CLASS*
NATIVE VALVE ENDOCARDITIS	
Acute aortic insufficiency or mitral regurgitation with heart failure	I
Acute aortic insufficiency with tachycardia and early closure of the mitral valve on echocardiogram	I
Fungal endocarditis	I
Evidence of annular or aortic abscess, sinus or aortic true or false aneurysm, valvular dehiscence, rupture, perforation, or fistula	I
Evidence of valve dysfunction and persistent infection after a prolonged period (7-10 days) of appropriate therapy, provided there are no noncardiac causes for infection	I
Recurrent emboli after appropriate antibiotic therapy	I
Infection with gram-negative organisms or organisms with a poor response to antibiotics in patients with evidence of valve dysfunction	I
Anterior mitral leaflet vegetation (especially with size >10 mm) or persistent vegetation after systemic embolization	IIa
Increase in vegetation size despite appropriate antimicrobial therapy	IIb
Early infections of the mitral valve that can probably be repaired	III
Persistent fever and leukocytosis with negative blood cultures	III
PROSTHETIC VALVE ENDOCARDITIS	
Early prosthetic valve endocarditis (<2 mo after surgery)	I
Heart failure with prosthetic valve dysfunction	I
Nonstreptococcal endocarditis	I
Evidence of perivalvular leak, annular or aortic abscess, sinus or aortic true or false aneurysm, fistula formation, or new-onset conduction disturbances	I
Persistent bacteremia after 7-10 days of appropriate antibiotic therapy, with no noncardiac causes for bacteremia	IIa
Recurrent peripheral embolus despite therapy	IIa

Prevention of infective endocarditis guidelines from the American Heart Association: a guideline from the American Heart Association Rheumatic Fever, Endocarditis, and Kawasaki Disease Committee, Council on Cardiovascular Disease in the Young, and the Council on Clinical Cardiology, Council on Cardiovascular Surgery and Anesthesia, and the Quality of Care and Outcomes Research Interdisciplinary Working Group. *Circulation.* 2007;116:1736-1754.

TABLE 76-10 RECOMMENDATIONS FOR ENDOCARDITIS PROPHYLAXIS

PROPHYLAXIS IS REASONABLE*

Dental: All dental procedures involving manipulation of gingival tissue or the periapical region of teeth or perforation of the oral mucosa
Respiratory: Procedures involving incision or biopsy of the respiratory mucosa, such as tonsillectomy and adenoidectomy
Other: Infected skin, skin structures, or musculoskeletal tissue

PROPHYLAXIS IS NOT RECOMMENDED

Dental: Routine anesthetic injections through noninfected tissue, dental radiographs, placement of removable prosthodontic or orthodontic appliances, adjustment of orthodontic appliances, placement of orthodontic brackets, shedding of deciduous teeth, bleeding from trauma to the lips or oral mucosa
Respiratory: Procedures not involving incision or biopsy of the respiratory mucosa, including bronchoscopy (unless the procedure involves incision of the respiratory tract mucosa)
Genitourinary: Antibiotic prophylaxis solely to prevent infective endocarditis is not recommended
Gastrointestinal: Antibiotic prophylaxis solely to prevent infective endocarditis is not recommended

*Only in patients with underlying cardiac conditions associated with the highest risk for adverse outcome from endocarditis (listed in Table 76-9).
Adapted from Wilson W, Taubert KA, Gewitz M, et al. Prevention of infective endocarditis guidelines from the American Heart Association: a guideline from the American Heart Association Rheumatic Fever, Endocarditis, and Kawasaki Disease Committee, Council on Cardiovascular Disease in the Young, and the Council on Clinical Cardiology, Council on Cardiovascular Surgery and Anesthesia, and the Quality of Care and Outcomes Research Interdisciplinary Working Group. *Circulation.* 2007;116:1736-1754.

PREVENTION

Although the administration of prophylactic antibiotics to patients with known risk factors for infective endocarditis before undergoing procedures known to cause bacteremia is widespread, the efficacy of this practice has not been established. In 2007 the American Heart Association substantially reduced the situations in which prophylactic antibiotics were recommended. These revised recommendations were based on the following points: (1) endocarditis is much more likely to result from frequent exposure to random bacteremias associated with daily activities than from bacteremia caused by a dental, gastrointestinal tract, or genitourinary tract procedure; (2) prophylaxis may prevent an exceedingly small number of infective endocarditis cases, if any, in individuals who undergo dental, gastrointestinal tract, or genitourinary tract procedures; (3) the risk of antibiotic-associated adverse events often exceeds the benefit, if any, from prophylactic antibiotic therapy; and (4) maintenance of optimal oral health may reduce the incidence of bacteremia from daily activities and is more important than prophylactic antibiotics for a dental procedure to reduce the risk of infective endocarditis.

Prophylaxis is now judged to be reasonable for patients with the highest risk of adverse outcomes from endocarditis (Table 76-9) who must undergo dental procedures that involve manipulation of gingival tissue or the periapical region of teeth or perforation of the oral mucosa; an invasive procedure of the respiratory tract that involves incision or biopsy of the respiratory mucosa, such as tonsillectomy and adenoidectomy; or invasive procedures involving infected skin, skin structures, or musculoskeletal tissue (Table 76-10). The new recommendations focus on single-dose oral regimens in most clinical scenarios.

The antibiotics chosen for pre-procedure prophylaxis should be active against the organisms most likely to be released into the blood stream by the procedure (Table 76-11). Antibiotics that cover primarily oral flora are recommended. For patients with the conditions listed in Table 76-9 who undergo a procedure for infected skin, skin structure, or musculoskeletal tissue, it may be reasonable that the therapeutic regimen administered to treat the infection contain an agent active against staphylococci and β-hemolytic streptococci.

PROGNOSIS

Untreated, infective endocarditis is uniformly fatal. Aggressive medical and surgical management, however, has dramatically improved the outcome. Mortality overall from both native and prosthetic valve endocarditis remains fairly high, ranging from 17 to 36%. Certain subgroups carry a lower risk of death (endocarditis related to viridans streptococci), whereas *S. aureus*, fungal, and zoonotic endocarditis have higher mortalities. Heart failure and CNS events are the most frequent causes of death.

Endocarditis recurs in 12 to 16% of patients and is more common in injection drug users, elderly people, and patients with prosthetic valves. The rate

TABLE 76-11 SUGGESTED ANTIBIOTICS FOR ENDOCARDITIS PROPHYLAXIS FOR DENTAL OR RESPIRATORY TRACT PROCEDURES* IN PATIENTS WITH HIGH-RISK CARDIAC CONDITIONS†

PATIENT CHARACTERISTICS	REGIMEN‡
Able to take oral medications	Amoxicillin 2 g PO
Unable to take oral medications	Ampicillin 2 g IV or IM; or cefazolin or ceftriaxone 1 g IM or IV
Allergic to penicillin or ampicillin and able to take oral medications	Cephalexin 2 g PO (or other first- or second-generation oral cephalosporin in equivalent adult doses); clindamycin 600 mg PO; azithromycin 500 mg PO; or clarithromycin 500 mg PO Cephalosporins should not be used in an individual with a history of anaphylaxis, angioedema, or urticaria with penicillin or ampicillin
Allergic to penicillin or ampicillin and unable to take oral medications	Cefazolin or ceftriaxone 1 g IM or IV; or clindamycin 600 mg IM or IV

*For the applicable procedures, see Table 76-10.
†For the applicable conditions, see Table 76-9.
‡All regimens consist of a single dose 30-60 min before the procedure.
Adapted from Wilson W, Taubert KA, Gewitz M, et al. Prevention of infective endocarditis guidelines from the American Heart Association: a guideline from the American Heart Association Rheumatic Fever, Endocarditis, and Kawasaki Disease Committee, Council on Cardiovascular Disease in the Young, and the Council on Clinical Cardiology, Council on Cardiovascular Surgery and Anesthesia, and the Quality of Care and Outcomes Research Interdisciplinary Working Group. *Circulation.* 2007;116:1736-1754.

of relapse also varies depending on the causative organism. Easily treated infections, such as those with α-hemolytic streptococci, have a low rate of relapse (5%), whereas more difficult to eradicate organisms may have significantly higher rates.

FUTURE DIRECTIONS

As cardiac imaging technology continues to improve, the duration of treatment of endocarditis may be dictated in part by the characteristics of visualized vegetations. In addition, now that large vegetations have been demonstrated to cause more embolic events, interventions to remove vegetations (e.g., valve repair, vegectomy) or to introduce agents that prevent the formation or promote the dissolution of vegetations may be feasible. Finally, novel therapeutic approaches (e.g., antibacterial antibodies and cell wall–specific enzymes) that act as adjuncts to antibiotics in facilitating bacteriologic clearance are currently in development.

PERICARDIAL DISEASES

WILLIAM C. LITTLE AND JAE K. OH

The pericardium, which is a relatively avascular fibrous sac that surrounds the heart, has two layers: the visceral and parietal pericardium. The potential space between the two layers normally contains only 10 to 50 mL of fluid, which is an ultrafiltrate of plasma. The pericardium is well innervated, so pericardial inflammation may produce severe pain and trigger vagally mediated reflexes.

As a result of its relatively inelastic physical properties, the pericardium limits acute cardiac dilation and enhances mechanical interactions of the cardiac chambers. In response to long-standing stress, the pericardium dilates to allow a slowly accumulating pericardial effusion to become quite large without compressing the cardiac chambers and to allow left ventricular remodeling to occur without pericardial constriction. Conversely, a scarred or thickened pericardium can limit the filling of the heart, resulting in pericardial constriction. Despite the important functions of the normal pericardium, congenital absence or surgical resection of the pericardium does not appear to have any major untoward effects.

ACUTE PERICARDITIS

EPIDEMIOLOGY AND PATHOBIOLOGY

Acute inflammation of the pericardium, with or without an associated pericardial effusion, can occur as an isolated clinical problem or as a manifestation of systemic disease. Although about 85% of isolated cases of acute pericarditis are idiopathic or viral, the list of other potential causes is quite extensive (Table 77-1). Patients with fever greater than 38° C or a subacute course or who fail to respond promptly to therapy are most likely to have pericarditis caused by a systemic autoimmune disease, malignancy, or viral or bacterial infection.

Pericarditis can occur after an acute myocardial infarction (MI). It occurs 1 to 3 days after a transmural MI, presumably owing to the interaction between the healing necrotic epicardium and the overlying pericardium. Dressler's syndrome, which is another form of pericarditis associated with MI, typically occurs weeks to months after MI. It is similar to the pericarditis that can occur days to months following traumatic pericardial injury, surgical manipulation of the pericardium, or pulmonary infarction. This syndrome is presumed to be mediated by an autoimmune mechanism and is associated with signs of systemic inflammation, including fever and polyserositis.

CLINICAL MANIFESTATIONS

Most patients with acute pericarditis experience sharp retrosternal chest pain (see Table 50-2 in Chapter 50), which can be quite severe and debilitating. In some cases, however, pericarditis is asymptomatic, such as when it accompanies rheumatoid arthritis. Pericardial pain is usually worse with inspiration and when supine, and it is generally relieved by sitting and leaning forward. Typically, pericardial pain is referred to the scapular ridge, presumably owing to irritation of the phrenic nerves, which pass adjacent to the pericardium. The chest pain of acute pericarditis must be differentiated from pulmonary embolism and myocardial ischemia or infarction (Table 77-2).

The pericardial friction rub is the classic finding in patients with acute pericarditis. A friction rub is a high-pitched, scratchy sound that can have one, two, or three components occurring when the cardiac volumes are most rapidly changing: during ventricular ejection, during rapid ventricular filling in early diastole, and during atrial systole. A pericardial rub, which is differentiated from a murmur by its scratchy quality, is sometimes localized to a small area on the chest wall and may come and go spontaneously or with changes in position. To hear a rub, it may be necessary to auscultate the heart with the patient in multiple positions, especially using the diaphragm with the patient learning forward and not breathing. The pericardial friction rub must be differentiated from a pleural rub, which is absent during suspended respiration, whereas the pericardial rub is unaffected.

DIAGNOSIS

Early in the course of acute pericarditis, the electrocardiogram (ECG) typically displays diffuse ST elevation in association with PR depression (Fig. 77-1). The ST elevation is usually present in all leads except for aVR, but the

TABLE 77-1 CAUSES OF PERICARDITIS: INFECTIOUS AND NONINFECTIOUS

INFECTIOUS PERICARDITIS (⅔ OF CASES)

Viral (most common): echovirus and coxsackievirus (usual), influenza, EBV, CMV, adenovirus, varicella, rubella, mumps, HBV, HCV, HIV, parvovirus B19, human herpesvirus 6 (increasing reports)
Bacterial: tuberculosis (4-5%)* and *Coxiella burnetii* (most common); other bacterial causes (rare) include pneumococcosis, meningococcosis, gonococcosis, *Haemophilus*, staphylococci, chlamydia, *Mycoplasma, Legionella, Leptospira, Listeria*
Fungal (rare): histoplasmosis more likely in immunocompetent patients; aspergillosis, blastomycosis, candidiasis more likely in immunosuppressed patients
Parasitic (very rare): *Echinococcus, Toxoplasma*

NONINFECTIOUS PERICARDITIS (⅓ OF CASES)

Autoimmune pericarditis (<10%)*
- Pericardial injury syndromes: post–myocardial infarction syndrome, post-pericardiotomy syndrome, post-traumatic pericarditis, including iatrogenic pericarditis (e.g., after percutaneous coronary interventions, pacemaker insertion, ablation)
- Pericarditis in systemic autoimmune and autoinflammatory diseases: more common in systemic lupus erythematosus, Sjögren's syndrome, rheumatoid arthritis, systemic sclerosis, systemic vasculitides, Behçet's syndrome, sarcoidosis, familial Mediterranean fever
- Autoreactive pericarditis*

Neoplastic pericarditis (5-7%)*
- Primary tumors (rare): pericardial mesothelioma
- Secondary metastatic tumors (common): lung and breast cancer, lymphoma

Metabolic pericarditis: uremia, myxedema (common); others rare
Traumatic pericarditis (rare)
- Direct injury: penetrating thoracic injury, esophageal perforation, iatrogenic
- Indirect injury: nonpenetrating thoracic injury, radiation injury

Drug-related pericarditis (rare): procainamide, hydralazine, isoniazid, and phenytoin (lupus-like syndrome), penicillins (hypersensitivity pericarditis with eosinophilia), doxorubicin, and daunorubicin (often associated with cardiomyopathy; may cause pericardiopathy)

*Percentages refer to unselected cases.
The diagnosis of autoreactive pericarditis is established using the following criteria: (1) increased number of lymphocytes and mononuclear cells >5000/mm^3 (autoreactive lymphocytic) or the presence of antibodies against heart muscle tissue (antisarcolemmal) in the pericardial fluid (autoreactive antibody mediated); (2) signs of myocarditis on epicardial or endomyocardial biopsies by ≥14 cells/mm^2; and (3) exclusion of infections, neoplasia, and systemic and metabolic disorders.
CMV = cytomegalovirus; EBV = Epstein-Barr virus; HBV = hepatitis B virus; HCV = hepatitis C virus; HIV = human immunodeficiency virus.

TABLE 77-2 DIFFERENTIATION OF PERICARDITIS FROM MYOCARDIAL ISCHEMIA OR INFARCTION AND PULMONARY EMBOLISM

FINDINGS	MYOCARDIAL ISCHEMIA OR INFARCTION	PERICARDITIS	PULMONARY EMBOLISM
CHEST PAIN			
Character	Pressure-like heavy, squeezing	Sharp, stabbing, occasionally dull	Sharp, stabbing
Change with respiration	No	Worsened with inspiration	In phase with respiration (absent when the patient is apneic)
Change with position	No	Worse when supine; improved when sitting up or leaning forward	No
Duration	Minutes (ischemia); hours (infarction)	Hours to days	Hours to days
Response to nitroglycerin	Improved	No change	No change
PHYSICAL EXAMINATION			
Friction rub	Absent (unless pericarditis is present)	Present in most patients	Pleural friction rub may occur
ELECTROCARDIOGRAM			
ST segment elevation	Localized convex	Widespread concave	Limited to leads III, aVF, and V_1
PR segment depression	Rare	Frequent	None

Modified from Little WC, Freeman GL. Pericardial disease. *Circulation.* 2006;113:1622-1632.

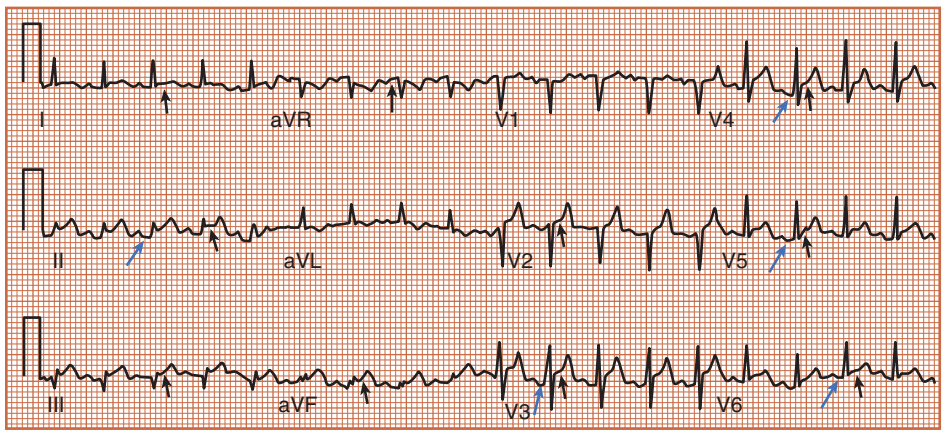

FIGURE 77-1. Electrocardiogram demonstrating typical features of acute pericarditis on presentation. There is diffuse ST elevation and PR depression except in aVR, where there is ST depression and PR elevation.

changes may be more localized in post-MI pericarditis. Classically, the ECG changes of acute pericarditis evolve over several days; resolution of the ST elevation is followed by widespread T wave inversion that subsequently normalizes. Uremic pericarditis frequently occurs without the typical electrocardiographic abnormalities.

Patients with acute pericarditis usually have evidence of systemic inflammation, including leukocytosis, an elevated erythrocyte sedimentation rate, and increased C-reactive protein level. A low-grade fever is common, but a temperature greater than 38° C is unusual and suggests the possibility of bacterial pericarditis.

About 85% of cases of acute pericarditis are idiopathic or viral. Viral causes include echoviruses and group B coxsackieviruses, but obtaining specific viral titers does not alter patient management. About 6% of cases are neoplastic in origin, about 4% are caused by tuberculosis, about 3% are caused by other bacterial or fungal infections, and about 2% are caused by collagen vascular disease. A targeted evaluation (Table 77-3) can help identify the various causes (Table 77-4).

Troponin levels typically are minimally elevated in acute pericarditis owing to some involvement of the epicardium by the inflammatory process. An elevated troponin level in acute pericarditis usually returns to normal within 1 to 2 weeks and is not associated with a worse prognosis. Although the elevated troponin level may lead to the misdiagnosis of an ST elevation MI (Chapter 73), most patients with elevated troponin levels and acute pericarditis have normal coronary angiograms. An echocardiogram (Chapter 55) can help avoid a misdiagnosis of MI.

Echocardiography may demonstrate a small pericardial effusion in the presence of acute pericarditis, but a normal echocardiogram does not exclude the diagnosis of acute pericarditis. An echocardiogram is critical, however, in excluding the diagnosis of cardiac tamponade (see later). When the diagnosis of acute pericarditis is unclear, cardiac magnetic resonance imaging (MRI) can demonstrate pericardial inflammation as delayed enhancement of the pericardium (Fig. 77-2). Diagnostic pericardiocentesis is indicated in suspected purulent tuberculosis or malignant pericarditis or if the patient has cardiac tamponade.

TABLE 77-3 SELECTED DIAGNOSTIC TESTS IN ACUTE PERICARDITIS

IN ALL PATIENTS
Tuberculin skin test (plus control skin test to exclude anergy)
BUN and creatinine to exclude uremia
Erythrocyte sedimentation rate
Electrocardiogram
Chest radiograph
Echocardiogram
IN SELECTED PATIENTS
Cardiac magnetic resonance imaging
ANA and rheumatoid factor to exclude systemic lupus erythematosus or rheumatoid arthritis in patients with acute arthritis or pleural effusion
TSH and T_4 to exclude hypothyroidism in patients with clinical findings suggestive of hypothyroidism and in asymptomatic patients with unexplained pericardial effusion
HIV test to exclude AIDS in patients with risk factors for HIV disease or a compatible clinical syndrome
Blood cultures in febrile patients to exclude infective endocarditis and bacteremia
Fungal serologic tests in patients from endemic areas or in immunocompromised patients
ASO titer in children or teenagers with suspected rheumatic fever
Heterophil antibody test to exclude mononucleosis in young or middle-aged patients with a compatible clinical syndrome or acute fever, weakness, and lymphadenopathy

AIDS = acquired immunodeficiency virus; ANA = antinuclear antibody; ASO = antistreptolysin O; BUN = blood urea nitrogen; HIV = human immunodeficiency virus; T_4 = thyroxine; TSH = thyroid-stimulating hormone.
Modified from Nishimura RA, Kidd KR. Recognition and management of patients with pericardial disease. In: Braunwald E, Goldman L, eds. *Primary Cardiology*, 2nd ed. Philadelphia: WB Saunders; 2003:625.

TABLE 77-4 PRESENTATION AND TREATMENT OF THE MOST COMMON CAUSES OF PERICARDITIS

TYPE	PATHOGENESIS OR ETIOLOGY	DIAGNOSIS	TREATMENT	COMPLICATIONS	COMMENTS
Viral	Coxsackievirus B Echovirus type 8 Epstein-Barr virus	Leukocytosis Elevated erythrocyte sedimentation rate Mild cardiac biomarker elevation	Symptomatic relief, NSAIDs	Tamponade Relapsing pericarditis	Peaks in spring and fall
Tuberculous	*Mycobacterium tuberculosis*	Isolation of organism from biopsy fluid Granulomas not specific	Triple-drug antituberculosis regimen Pericardial drainage followed by early (4-6 wk) pericardiectomy if signs of tamponade or constriction develop	Tamponade Constrictive pericarditis	1-8% of patients with tuberculosis pneumonia; rule out HIV infection
Bacterial	Group A streptococcus *Staphylococcus aureus* *Streptococcus pneumoniae*	Leukocytosis with marked left shift Purulent pericardial fluid	Pericardial drainage by catheter or surgery Systemic antibiotics Pericardiectomy if constrictive physiology develops	Tamponade in one third of patients	Very high mortality rate if not recognized early
Post–myocardial infarction	12 hr–10 days after infarction	Fever Pericardial friction rub Echo: effusion	Aspirin Prednisone	Tamponade rare	More frequent in large Q wave infarctions Anterior > inferior
Uremic	Untreated renal failure: 50% Chronic dialysis: 20%	Pericardial rub: 90%	Intensive dialysis Indomethacin: probably ineffective Catheter drainage Surgical drainage	Tamponade Hemodynamic instability on dialysis	Avoid NSAIDs About 50% respond to intensive dialysis
Neoplastic	In order of frequency: lung cancer, breast cancer, leukemia and lymphoma, others	Chest pain, dyspnea Echo: effusion CT, MRI: tumor metastases to pericardium Cytologic examination of fluid positive in 85%	Catheter drainage Subxiphoid pericardiectomy Chemotherapy directed at underlying malignant neoplasm	Tamponade Constriction	

CT = computed tomography; HIV = human immunodeficiency virus; MRI = magnetic resonance imaging; NSAIDs = nonsteroidal anti-inflammatory drugs.

FIGURE 77-2. Cardiac magnetic resonance image of a patient with acute pericarditis shows late gadolinium hyperenhancement of the pericardium and epicardium.

TREATMENT

Rx

Acutely ill patients with fever should be hospitalized, as should patients with suspected acute MI (Chapter 73), large effusions, evidence of impending hemodynamic compromise, or a cause other than viral or idiopathic pericarditis, because of the risk of a rapidly accumulating effusion with potential tamponade. Patients without effusions can usually be followed as outpatients (Fig. 77-3).

If acute pericarditis is a manifestation of an underlying disease, it often responds to treatment of the primary condition. Most cases of acute idiopathic or viral pericarditis are self-limited and respond to treatment with aspirin (650 mg every 6 hours) or another nonsteroidal anti-inflammatory drug (NSAID) such as ibuprofen (300 to 800 mg every 6 to 8 hours). The dose of NSAID should be tapered once symptoms or the pericardial effusion have resolved, but the medication should be taken for at least 3 to 4 weeks to minimize the risk of recurrent pericarditis.

If the pericardial pain and inflammation do not respond to NSAIDs or if the acute pericarditis recurs, colchicine (0.6 mg once or twice daily) for 3 months is effective in relieving pain and preventing recurrent pericarditis.■ Alternatively, colchicine can be started in all patients to increase the likelihood of a favorable response to treatment. A major side effect is diarrhea. Colchicine should be avoided in patients with abnormal renal or hepatic function and in those being treated with macrolide antibiotics, which alter its metabolism.

Although acute pericarditis usually responds dramatically to systemic corticosteroids, observational studies strongly suggest that the use of steroids increases the probability of relapse in patients treated with colchicine. Accordingly, systemic steroids should be considered only in patients with recurrent pericarditis unresponsive to NSAIDs and colchicine or when needed to treat an underlying inflammatory disease. If steroids are used, low-dose prednisone (0.2 to 0.5 mg/kg) appears to be as effective as higher doses and is less likely to be associated with recurrence. Steroids should be continued for at least 1 month prior to slow tapering.

A proton pump inhibitor, such as omeprazole (20 mg/day), should be considered to improve the gastric tolerability of NSAIDs. Warfarin and heparin should be avoided to minimize the risk of hemopericardium, but anticoagulation may be required if the patient is in atrial fibrillation or has a prosthetic heart valve. It is prudent to avoid exercise until after the chest pain completely resolves. If pericarditis reoccurs, the patient can be reloaded with colchicine and intravenous ketorolac (20 mg) and then continued on an oral NSAID and colchicine for at least 3 months. Every effort should be made to avoid the use of steroids, reserving low-dose steroids for patients who cannot tolerate aspirin and other NSAIDs or whose recurrence is not responsive to colchicine and intravenous NSAIDs. Pericardiocentesis is not recommended unless purulent or tuberculous pericarditis is clinically suspected or the patient fails to respond to 2 to 3 weeks of NSAID therapy.

PROGNOSIS

The course of viral and idiopathic pericarditis is usually self-limited, and most patients recover completely. About 25% of patients, however, have recurrent pericarditis weeks to months later, probably due to an immune response, and some patients may have multiple debilitating episodes. Recurrent pericarditis is more common in patients treated with steroids for the acute episode, especially during a rapid steroid taper. In these patients, prolonged high-dose NSAID treatment (e.g., ibuprofen 300 to 600 mg three times a day) plus colchicine (0.6 mg twice daily, declining to once daily after 3 to 6 months) is recommended.■ In patients who cannot tolerate colchicine or who have recurrent episodes despite high-dose NSAID treatment (e.g., indomethacin 50 mg three times a day or ibuprofen 800 mg four times a day), oral steroids (e.g., prednisone 0.2 to 0.5 mg/kg/day for 2 to 4 weeks, then slowly tapered over several months) are generally recommended, with pericardiectomy reserved for refractory cases. Patients who have recurrent pericarditis are at increased risk for progression to constrictive pericarditis (see later).

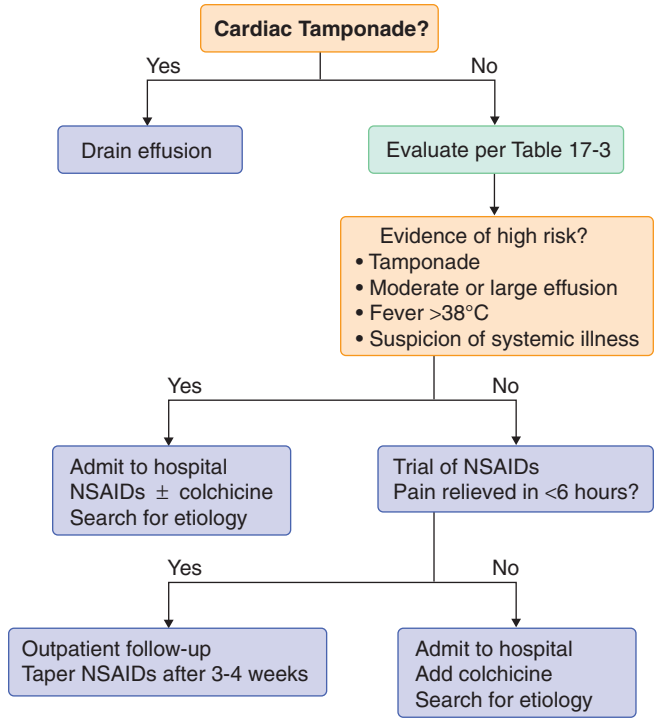

FIGURE 77-3. Initial management of patients with pericarditis. NSAIDs = nonsteroidal anti-inflammatory drugs.

CARDIAC EFFUSION AND TAMPONADE

EPIDEMIOLOGY

A pericardial effusion can be caused by any disease that causes acute pericarditis (see Table 77-1), but a majority of cases are caused by conditions other than viral or idiopathic pericarditis (Table 77-5). For example, tamponade occurs in about 10 to 15% of patients with idiopathic pericarditis, but it develops in more than 50% of patients with malignant, tuberculous, or purulent pericarditis. Tuberculosis and neoplastic disease are typically associated

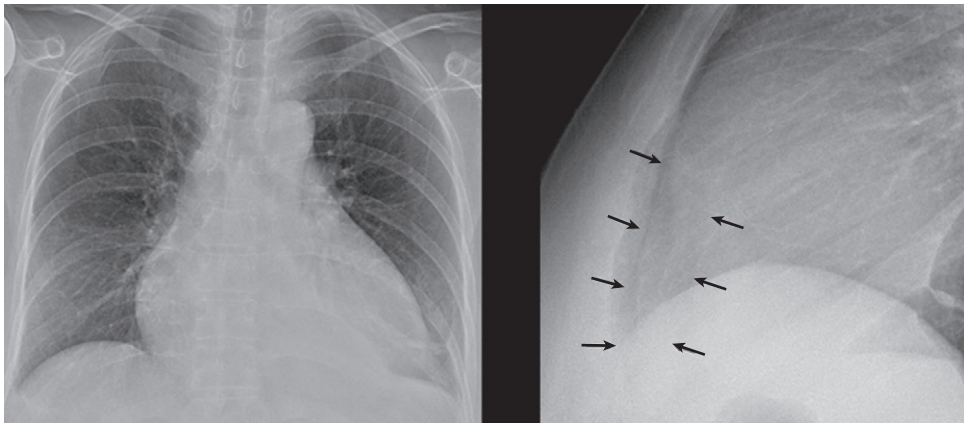

FIGURE 77-4. Chest radiographs in a patient with a large pericardial effusion. The cardiac silhouette on the posteroanterior view *(left)* is enlarged with a "water bag" configuration. The lateral view *(right)* shows a separation between the pericardial and epicardial fat stripes *(arrows)*.

with serosanguineous effusions, but such effusions can also be seen with typical viral or idiopathic pericarditis, with uremia, and after mediastinal irradiation. Hemopericardium is seen most commonly with trauma, myocardial rupture after MI, catheter-induced myocardial or epicardial coronary artery rupture, aortic dissection with rupture into the pericardial space, or primary hemorrhage in patients receiving anticoagulant therapy, often after cardiac valve surgery. Chylopericardium is rare and results from leakage or injury to the thoracic duct.

PATHOBIOLOGY

Under normal conditions, the space between the parietal and visceral pericardium can accommodate only a small amount of fluid before the development of tamponade physiology. The clinical consequences of a pericardial effusion depend on the rate of increase. A rapidly accumulating effusion, as in hemopericardium caused by trauma or aortic dissection, may result in tamponade physiology with just 100 to 200 mL of fluid. It is not surprising, therefore, that cardiac perforation quickly results in tamponade. By comparison, a more slowly developing effusion, as is typical with uremia and hypothyroidism, may allow the gradual stretching of the pericardium, with asymptomatic or minimally symptomatic effusions of 1500 mL or more.

Tamponade physiology occurs when fluid accumulation in the intrapericardial space is sufficient to compress the heart, resulting in impaired cardiac filling. The increased pericardial pressure in cardiac tamponade accentuates the interdependence among the cardiac chambers as the total cardiac volume is limited by the pericardial effusion. With normal inspiration, right ventricular filling is enhanced, the intraventricular septum is displaced toward the left ventricle, and left ventricular filling and the resulting stroke volume are reduced. Because of its lower pressures, the right ventricle is most vulnerable to compression by a pericardial effusion, and abnormal right heart filling is the earliest sign of a hemodynamically significant pericardial effusion. In tamponade, left heart filling occurs preferentially during expiration, when there is less filling of the right heart. The small normal respiratory increase in right ventricular volume, with a concomitant decrease in left ventricular stroke volume and systolic arterial pressure, is markedly accentuated in cardiac tamponade and results in the clinical finding of "paradoxical pulse." A small (<10 mm Hg) pulsus paradoxus, which is a decline in systemic blood pressure during inspiration, is normal and is related to the ventricles being confined within the pericardium and sharing a common septum. In cardiac tamponade, this phenomenon is exaggerated, and systemic blood pressure falls by more than 10 mm Hg during inspiration. A pulsus paradoxus also may be present with hypovolemic shock, chronic obstructive pulmonary disease, and bronchospasm.

CLINICAL MANIFESTATIONS

A slowly accumulating, isolated pericardial effusion is often completely asymptomatic. The physical examination may be normal, but the heart sounds may be muffled. The diagnosis is usually suggested by a chest radiograph that shows cardiomegaly with a globular heart (Fig. 77-4; see also Fig. 53-12 in Chapter 53) or by an echocardiogram, computed tomography (CT) scan, or MRI performed for another indication. Patients with hypothyroidism, uremia, or collagen vascular disease may have asymptomatic effusions discovered during comprehensive evaluations.

Patients with impending or early tamponade are usually anxious and tachycardic, and they may complain of dyspnea, orthopnea, and chest pain. The

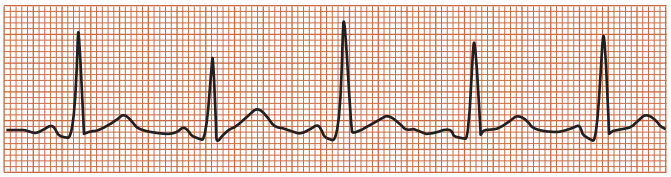

FIGURE 77-5. Electrical alternans. Lead V_5 rhythm strip from a patient with a large pericardial effusion and tamponade physiology. Note the relatively low voltage and electrical alternans.

increased venous pressure is usually apparent as jugular venous distention. The x descent (during ventricular systole) is typically the dominant jugular venous wave, with little or no y descent (during early diastole) (Chapter 50). The heart sounds are classically soft or muffled, especially if there is a large pericardial effusion. In rapidly developing cardiac tamponade, especially hemorrhagic cardiac tamponade, the jugular veins may not be distended because the time course has been insufficient for a compensatory increase in venous pressure. Such "low-pressure" tamponade may also occur with uremic pericarditis in volume-depleted patients. The patient may have signs of right heart failure, with peripheral edema, right upper quadrant pain caused by hepatic congestion, or abnormal liver enzymes and serum bilirubin level.

The hallmark of cardiac tamponade is a paradoxical pulse, which is defined as more than a 10 mm Hg drop in systolic arterial pressure during inspiration. When severe, the paradoxical pulse may be apparent as the absence of a palpable brachial or radial pulse during inspiration. A paradoxical pulse can also occur when there are wide swings in intrathoracic pressure, pulmonary embolism (Chapter 98), or hypovolemic shock (Chapter 106). A paradoxical pulse may be difficult to recognize in the presence of severe shock.

DIAGNOSIS

Cardiac tamponade, which is a treatable cause of shock (Chapter 107), can be rapidly fatal if unrecognized. As such, cardiac tamponade should be considered in the differential diagnosis of any patient with shock or pulseless electrical activity.

Cardiac tamponade is usually suspected based on jugular venous distention, sinus tachycardia with hypotension, narrow pulse pressure, elevated (>10 mm Hg) pulsus paradoxus, and distant heart sounds. Pulsus paradoxus may be obvious by palpation; it is more accurately measured with a sphygmomanometer during slow inspiration.

The ECG often shows low voltage and sometimes electrical alternans (Fig. 77-5) when the heart swings within a large pericardial effusion. The chest radiograph shows a globular, enlarged cardiac shadow (see Fig. 53-12 in Chapter 53 and Fig. 77-4) without pulmonary venous congestion.

Echocardiography, which is the key diagnostic test for cardiac tamponade, must be performed without delay in any patient suspected of having this condition. Echocardiography visualizes pericardial effusions as an echo-free space around the heart (Fig. 77-6), demonstrates the presence and size of the pericardial effusion, and reflects its hemodynamic consequences. The inferior vena cava is almost always enlarged, right atrial and right ventricular collapse indicates cardiac compression, and enhanced respiratory variation of ventricular filling is a manifestation of increased ventricular interdependence. Right ventricular collapse is more specific for tamponade than is right atrial

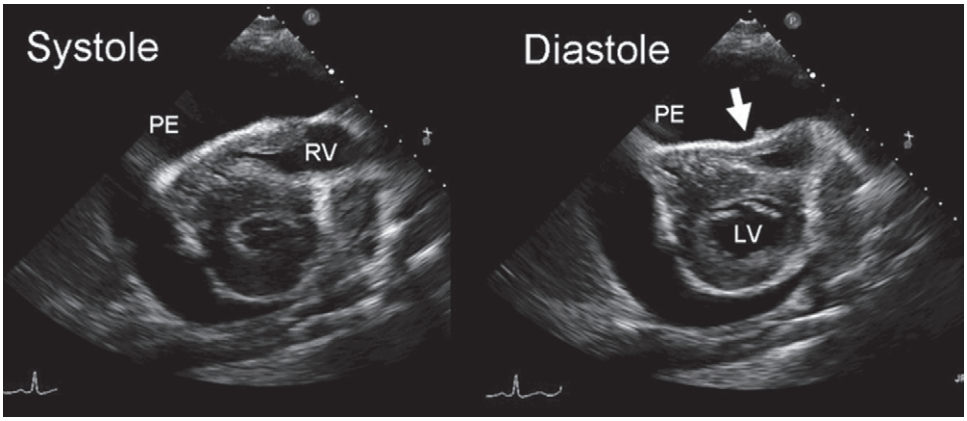

FIGURE 77-6. Two-dimensional echocardiogram from a patient with cardiac tamponade. A large pericardial effusion (PE) is apparent as an echo-free space surrounding the left ventricle (LV) and right ventricle (RV). In diastole, there is collapse of the right ventricle *(arrow)*.

collapse, but the right-sided chambers may not collapse when tamponade occurs in patients with pulmonary hypertension. Cardiac tamponade can result from a loculated pericardial effusion after cardiac surgery or trauma. A loculated effusion may not be apparent on transthoracic echocardiography, but transesophageal echocardiography and thoracic CT or MRI can delineate loculated pericardial effusions.

On Doppler study, mitral inflow velocity (especially early diastolic velocity) normally increases with expiration and decreases with inspiration; the opposite respiratory variation is seen in tricuspid inflow velocity. Doppler findings for tamponade, which are more sensitive than two-dimensional echocardiography, include augmented respiratory variation of mitral and tricuspid inflow velocities as a function of ventricular interdependence. These changes may be seen even before frank hemodynamic compromise due to pericardial effusion. Although Doppler echocardiography provides important information, it must be emphasized that cardiac tamponade is ultimately a clinical diagnosis.

The routine evaluation should include an assessment of renal function, a thyroid-stimulating hormone level, a complete blood count with differential, a platelet count, coagulation parameters, and a tuberculin skin test. Common medications that can cause a pericardial effusion include cromolyn, isoniazid, and phenytoin; hydralazine, procainamide, and reserpine are others. Blood cultures are indicated if an infectious cause is suspected. Complement levels, antinuclear antibodies, and the sedimentation rate can suggest systemic lupus erythematosus (Chapter 274), which rarely presents initially as an isolated pericardial effusion.

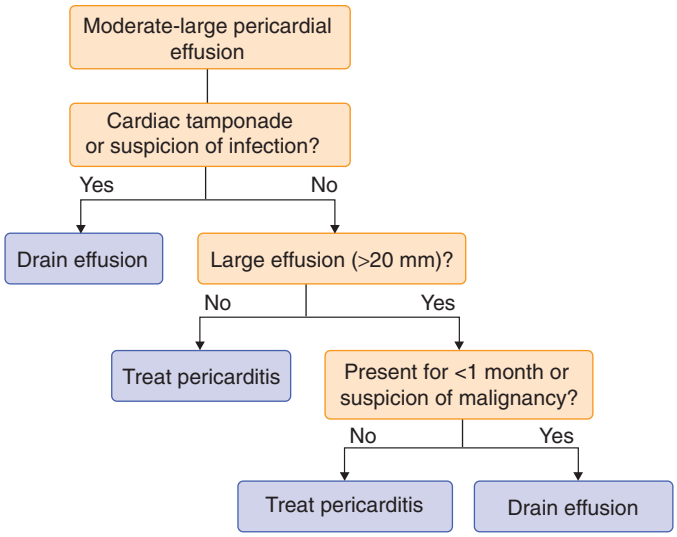

FIGURE 77-7. Algorithm for managing patients with moderate to large pericardial effusions. (Modified from Little WC, Freeman GL. Pericardial disease. *Circulation.* 2006;113:1622-1632.)

TREATMENT

Pericardial Effusion without Tamponade

Acute pericarditis is often accompanied by a small pericardial effusion that does not produce tamponade. If there is no hemodynamic compromise and the diagnosis can be established by other means, pericardiocentesis is not necessary (Fig. 77-7). Even small pericardial effusions may be related to underlying systemic illnesses such as systemic lupus erythematosus (Chapter 274), cardiac amyloid (Chapter 194), scleroderma (Chapter 275), hypothyroidism (Chapter 233), or AIDS, so it is important to consider and treat associated illnesses. Chylous pericardial effusion, which is usually related to obstruction of the thoracic duct, may require a surgical procedure for relief.

For suspected pericardial effusion, transthoracic echocardiography is the initial test of choice, although loculated effusions may be identified better by CT or MRI. If a small (0.5 to 1 cm) echolucent or "organized" pericardial effusion is observed, a follow-up echocardiogram in 1 to 2 weeks, or sooner if the patient deteriorates, is recommended. If the effusion is getting smaller, subsequent echocardiograms are not necessary unless the patient's clinical condition changes.

For moderate (1 to 2 cm) or large (>2 cm) effusions in patients who are hemodynamically stable and in whom tamponade is not suspected, a follow-up echocardiogram should be performed in 7 days and then every month until the effusion is minimal. If bacterial or malignant pericarditis is suspected, diagnostic pericardiocentesis should be performed immediately, even in the absence of clinical instability or suggestion of tamponade; tuberculous pericarditis is diagnosed best by pericardial biopsy. Anticoagulation with heparin or warfarin should be discontinued unless the patient has a mechanical heart valve or atrial fibrillation.

In hypothyroidism (Chapter 233), the effusion and the coexistent cardiomyopathy respond to hormone replacement, sometimes over several months. Uremic pericardial effusions often respond to initiation of dialysis or more intensive dialysis (Chapter 132).

Cardiac Tamponade

The treatment of cardiac tamponade is urgent drainage of the pericardial effusion, especially when there is hemodynamic compromise. Fluid resuscitation may be of transient benefit if the patient is volume depleted (hypovolemic cardiac tamponade), but inotropic agents are usually ineffective because there is already intense endogenous adrenergic stimulation. The initiation of mechanical ventilation in a patient with tamponade may produce a sudden drop in blood pressure because the positive intrathoracic pressure further impairs cardiac filling.

Echocardiographic-guided percutaneous pericardiocentesis, which can be performed at the bedside by experienced operators (Fig. 77-8), is indicated if a patient is in dire circumstances and at least 1 cm of fluid is seen anterior to the mid-right ventricular free wall throughout diastole. The ideal entry site (usually the apex) is defined using echocardiography as the minimal distance from skin to pericardial fluid without intervening structures. The pericardial space is entered with a needle and then drained through a catheter. As much fluid as possible should be removed. The pericardial fluid should be sent for pH, glucose, lactate dehydrogenase, protein, cell count, and cytology as well as staining and culture for bacteria, fungi, and tuberculosis. Continued drainage of the pericardial fluid through an indwelling catheter minimizes the risk of recurrent effusion. For hemodynamically significant effusions of less than 1 cm, organized or multiloculated effusions, and focal effusions, a limited thoracotomy-mediastinoscopy and creation of a pericardial window are advised.

Surgical drainage may be the preferred treatment if pericardial tissue is required for diagnosis or in the case of recurrent effusions or bacterial pericarditis. Malignant pericardial effusions frequently reoccur and, like other recurrent pericardial effusions, may necessitate the surgical creation of a pericardial window that allows the effusion to drain into the pleural space, preventing

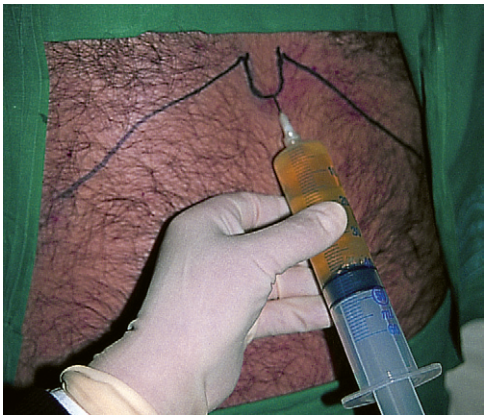

FIGURE 77-8. Aspiration of pericardial fluid is indicated in cardiac tamponade or to obtain fluid for diagnostic purposes. A wide-bore needle is inserted in the epigastrium below the xiphoid process and advanced in the direction of the medial third of the right clavicle. An alternative site is over the left ventricular apex. The procedure should be performed under echocardiographic guidance, but it may need to be performed emergently for life-saving purposes in other settings. Complications of the procedure include puncture of the heart, arrhythmias, vasovagal attack, and pneumothorax. (From Forbes CD, Jackson WF. *Color Atlas and Text of Clinical Medicine,* 3rd ed. London: Mosby; 2003.)

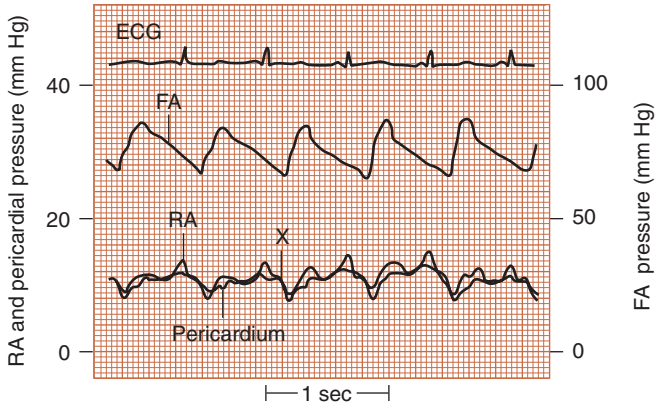

FIGURE 77-9. Right atrial (RA) pressure recording from a patient with constrictive pericarditis. Note the elevation in pressure and the prominent y descent, corresponding to rapid, early diastolic right atrial emptying. ECG = electrocardiogram; FA = femoral artery. (From Lorell BH. Profiles in constriction, restriction and tamponade. In: Baim DS, Grossman W, eds. *Cardiac Catheterization, Angiography, and Intervention,* 6th ed. Philadelphia: Williams & Wilkins; 2000: 832.)

reoccurrence of cardiac tamponade. An attractive alternative in these patients, especially if their overall prognosis is poor from the malignancy, is the percutaneous creation of a pericardial window by balloon dilation. Hemorrhagic effusions related to cardiac trauma or aortic dissection are best managed by emergency surgery.

PROGNOSIS

A pericardial effusion may recur or persist. Symptoms are usually weight loss, fatigue, dyspnea on exertion, and whatever symptoms are associated with the specific cause. Treatment of chronic or recurrent idiopathic effusions is similar to the treatment of recurrent pericarditis. If medical therapy is unsuccessful, creation of a pericardial window is indicated.

A large idiopathic, asymptomatic effusion that persists for 6 months or longer can unpredictably result in tamponade in as many as 30% of patients over long-term follow-up; diagnostic pericardiocentesis occasionally detects a neoplastic or tuberculous cause. Pericardiocentesis with prolonged drainage resolves many chronic large pericardial effusions, but pericardiectomy is often required. Long-term prognosis depends on the cause of the effusion. With pericardial tamponade, the in-hospital mortality rate is less than 10%, but the subsequent mortality rate is about 75% with a malignant effusion, compared with only 3 to 5% subsequent annual mortality for other causes.

PERICARDIAL CONSTRICTION

EPIDEMIOLOGY AND PATHOBIOLOGY

Pericardial constriction, which is usually the result of long-standing pericardial inflammation, occurs when a scarred, thickened, and/or calcified pericardium impairs cardiac filling, thereby limiting the total cardiac volume. The most frequent causes in the developed world are previous cardiac surgery, chronic idiopathic or viral pericarditis, and mediastinal radiation. Constriction may follow cardiac surgery by several weeks to months and may occur decades after chest wall irradiation. In developing countries, tuberculous pericarditis is a more common cause of constrictive pericarditis**.** Other less common causes include malignant disease, especially lung cancer, breast cancer, or lymphoma; histoplasmosis; rheumatoid arthritis; and uremia. However, a specific cause may not be identified in many patients.

With chronic constriction, the pericardium may thicken from its normal 3 mm or less to 6 mm or more, calcify, and adhere to the epicardium. In subacute constriction, the pericardium may be only minimally thickened and less calcified. Fibrous scarring and adhesions of both pericardial layers obliterate the pericardial cavity. The ventricles are unable to fill because of physical constraints imposed by a thickened, rigid, and sometimes calcified pericardium. The pathophysiologic hallmark of pericardial constriction is the exaggerated interventricular dependence and differential ventricular filling with respiration.

Although both cardiac tamponade and pericardial constriction impair diastolic ventricular filling and elevate venous pressure, the impairment in ventricular filling with constriction is minimal in early diastole until cardiac volume reaches the anatomic limit set by the noncompliant pericardium, at which time diastolic pressure rises abruptly and remains elevated until the onset of systole. This prominent y descent with an elevated plateau of ventricular pressure, which has been termed the "square root" sign (Fig. 77-9), differentiates constriction from tamponade, in which the y descent is absent. Stroke volume and cardiac output are reduced because of impaired filling, but the intrinsic systolic function of the ventricles can be normal.

CLINICAL MANIFESTATIONS

Patients with pericardial constriction typically present with manifestations of elevated systemic venous pressures and low cardiac output. Because there is equalization of all cardiac pressures (including right and left atrial pressures), systemic congestion is much more marked than pulmonary congestion. Typically, patients develop marked jugular venous distention, hepatic congestion, ascites, and peripheral edema, but their lungs remain clear. The limited cardiac output typically presents as exercise intolerance and may progress to cardiac cachexia with muscle wasting. In long-standing pericardial constriction, pleural effusions, ascites, and hepatic dysfunction may be prominent clinical features. Patients with pericardial constriction are much more likely to have left-sided or bilateral pleural effusions than right-sided effusions. Because of the prominent clinical symptoms of ascites and liver enzyme abnormalities, patients may be evaluated for hepatic disease before constrictive pericarditis is recognized.

The jugular veins are distended with prominent x and y descents. The normal inspiratory drop in jugular venous distention may be replaced by a rise in venous pressure (Kussmaul's sign). The classic auscultatory finding of pericardial constriction is a pericardial knock (Chapter 50), which is a high-pitched sound early in diastole when there is the sudden cessation of rapid ventricular diastolic filling, coinciding with the nadir of the y descent.

DIAGNOSIS

Pericardial constriction should be considered in any patient with unexplained systemic venous congestion. Pericardial calcification, seen best on the lateral plain chest radiograph, is a classic finding but is present in only 25% of patients with constrictive pericarditis, mostly in those with long-standing constriction. Similarly, most patients with pericardial constriction have a thickened pericardium (>2 mm) that can be imaged by echocardiography, CT, and MRI (Fig. 77-10). It is important to recognize, however, that pericardial constriction can be present without pericardial calcification and, in about 20% of patients, without any obvious pericardial thickening.

Transesophageal Doppler echocardiography may demonstrate pericardial thickening and calcification, but increased pericardial thickness can be missed on a transthoracic echocardiogram. Echocardiography also differentiates pericardial constriction from right heart failure caused by tricuspid valve disease and/or associated pulmonary hypertension.

FIGURE 77-10. Computed tomography in a patient with constrictive pericarditis shows a thickened pericardium *(arrow)*.

TABLE 77-6 DIFFERENTIATION OF PERICARDIAL CONSTRICTION FROM RESTRICTIVE CARDIOMYOPATHY

FINDINGS	PERICARDIAL CONSTRICTION	RESTRICTIVE CARDIOMYOPATHY
PHYSICAL EXAMINATION		
Pulmonary congestion	Usually absent	Usually present
Early diastolic sound	Pericardial knock	S_3 (low pitched)
ECHO/DOPPLER		
Respiratory variation in E wave	>25%	<20%
Mitral septal annular early diastolic velocity	>7 cm/sec	<7 cm/sec
CT/MRI		
Pericardial thickness	>2 mm (but <2 mm in 20%)	<2 mm
BIOMARKER		
B-type natriuretic peptide	<200 pg/mL	>600 pg/mL
HEMODYNAMICS		
PA systolic pressure	<60 mm Hg	>60 mm Hg
PCW-LV diastolic pressure	Respiratory variation with reduction in inspiration	No variation
Respiratory variation in RV/LV peak systolic pressure	Discordant	Concordant

CT = computed tomography; LV = left ventricular; MRI = magnetic resonance imaging; PA = pulmonary artery; PCW = pulmonary capillary wedge; RV = right ventricular.
Modified from Little WC, Freeman GL. Pericardial disease. *Circulation.* 2006;113:1622-1632.

Differential Diagnosis

The most difficult differentiation is between pericardial constriction and restrictive cardiomyopathy (Chapter 60), the clinical manifestations of which may be very similar to those of pericardial constriction (Table 77-6). Doppler echocardiography is the most useful method to distinguish constriction from restriction. Patients with pericardial constriction usually have pronounced respiratory variation (>25%) of mitral inflow, whereas patients with restrictive cardiomyopathies do not. In some patients with pericardial constriction and markedly elevated venous pressures, the respiratory variation may be present only after head-up tilt. The Doppler measurement of early diastolic septal mitral annular velocity is almost always reduced in patients with myocardial restriction, whereas it remains normal or increased in patients with pericardial constriction. A prominent diastolic reversal of hepatic vein flow velocity during expiration is characteristic of constriction, whereas the reversal flow velocity occurs during inspiration in patients with right heart failure from other causes. Patients with pericardial constriction usually have only minimally elevated (<200 pg/mL) B-type natriuretic peptide (BNP), but BNP levels are typically markedly increased (>600 pg/mL) in patients with restrictive cardiomyopathy.

Confirmation of the diagnosis of constriction may require cardiac catheterization in patients whose noninvasive evaluation is not clear-cut. Traditional invasive hemodynamic findings of equalized end-diastolic pressures in the right and left ventricles and the "dip and plateau" pattern of left ventricular diastolic pressure do not reliably differentiate constriction from restrictive cardiomyopathy. More specific invasive hemodynamic features of constriction and restriction are based on the respiratory variation in ventricular filling; the simultaneous measurement of left and right ventricular pressures demonstrates discordant changes in their systolic pressures with respiration in constrictive pericarditis. By comparison, the direction of these pressures is concordant (both left and right sides increase with expiration and decrease with inspiration) in restrictive cardiomyopathy.

All patients with documented but otherwise unexplained pericardial constriction should be evaluated for potential tuberculosis.

TREATMENT AND PROGNOSIS

Rx

In some patients with pericardial constriction of less than 3 months' duration, the symptoms and constriction may resolve over several weeks with medical therapy consisting of NSAIDs (e.g., ibuprofen 300 to 800 mg every 6 to 8 hours), colchicine (0.6 mg once or twice daily), and the cautious use of diuretics. For more chronic pericardial constriction or cases that do not respond to medical therapy, the definitive treatment is surgical pericardial decortication, with a wide resection of both the visceral and parietal pericardium. This operation is a major undertaking with substantial risk (>6% mortality even in the most experienced centers). In many patients, surgery does not immediately restore normal cardiac function; it may take weeks after removal of the constricting pericardium to return to normal. Empirical treatment of tuberculosis (Chapter 332) may be required in patients with constriction and a high suspicion of tuberculosis, even without a definitive diagnosis.

Effusive-Constrictive Pericarditis

In some patients (<10%) who present with cardiac tamponade, the elevated right atrial pressure and jugular venous distention do not resolve after removal of the pericardial fluid. In these patients, pericardiocentesis converts the hemodynamics from those typical of tamponade to those of constriction. Thus, the restriction of cardiac filling is due not only to pericardial effusion but also to pericardial constriction, predominantly involving the visceral pericardium. Effusive-constrictive pericarditis most likely represents an intermediate transition from acute pericarditis with pericardial effusion to pericardial constriction. Frequently, the symptoms resolve after several weeks of treatment with an NSAID (e.g., ibuprofen 300 to 800 mg every 6 to 8 hours).

SPECIFIC FORMS OF PERICARDIAL DISEASE

Postcardiotomy Syndrome

Postcardiotomy syndrome is acute pericarditis occurring weeks to months after open heart surgery. Patients have typical symptoms of acute pericarditis, which is associated with antimyocardial antibodies. A similar clinical picture is seen with the postperfusion syndrome caused by cytomegalovirus infection (Chapter 384) in patients who were previously uninfected but were exposed to cytomegalovirus-positive blood during cardiopulmonary bypass or transfusions. Atypical lymphocytes and elevated liver enzymes are often seen. Treatment of postcardiotomy syndrome is similar to the treatment of acute pericarditis.

Some patients who have undergone cardiac surgery develop late pericardial constriction without preceding acute pericarditis owing to bleeding in and around the open pericardium, followed by inflammation, scarring, and fibrosis. If active inflammation is present, a trial of anti-inflammatory agents may be instituted; however, surgical removal of the blood clot, usually accompanied by more extensive pericardiectomy, is typically required.

Post–Myocardial Infarction Pericarditis

Acute pericarditis can develop several days after an acute MI (Chapter 73), usually because of transmural extension of the infarction to the pericardial

surface. This syndrome is uncommon in the reperfusion era. Anticoagulation should be temporarily withheld to avoid a bloody effusion that might progress to cardiac tamponade.

A late autoimmune pericarditis, termed *Dressler's syndrome*, can develop weeks to months after MI. Diagnosis and treatment are as for acute pericarditis.

Uremic Pericarditis

Pericardial effusions develop in patients with severe renal failure, especially those on dialysis (Chapter 133). Aggressive dialysis may decrease the pericardial effusion, but sometimes the effusion persists and requires drainage or even pericardiectomy.

Infectious Pericarditis

BACTERIAL PERICARDITIS

Purulent bacterial pericarditis may result from direct extension of bacterial pneumonia, direct extension of pleural empyema, or, rarely, peritonitis or a subphrenic abscess. Most patients are acutely ill with systemic sepsis and develop acute tamponade. The most common organisms are streptococci, pneumococci, and staphylococci. Urgent pericardiocentesis, which is required for both diagnosis and therapy, shows leukocytosis and frank pus, and the fluid glucose level is markedly depressed. Persistent or recurrent drainage with an indwelling catheter or repeated taps combined with antimicrobial therapy lead to a high survival rate, but late constrictive pericarditis requiring pericardiectomy develops in 30 to 40% of patients.

TUBERCULOUS PERICARDITIS

Tuberculous pericarditis is common in developing countries but accounts for less than 5% of cases of acute pericarditis in developed countries, usually in patients who are immunosuppressed. Symptoms are often nonspecific, and acute painful pericarditis is rare. Most patients have an effusive-constrictive physiology or pericardial constriction. The chest radiograph suggests active pulmonary tuberculosis is about 30% of cases, and a pleural effusion is present in 40 to 60% of cases. The echocardiogram typically shows fibrinous strands in the pericardial effusion, with multiple echo densities adherent to the pericardial surface. Pericardiocentesis is mandatory if tuberculous pericarditis is suspected. About 75% of patients have a positive culture, and a pericardial fluid adenosine deaminase level of 40 U/L or greater is seen in 75% of patients. Polymerase chain reaction testing and pericardial biopsy are recommended when tuberculous pericarditis is strongly suspected but not otherwise confirmed.

Aggressive antituberculosis therapy (Chapter 332) yields a cure rate of about 85 to 90%. Empirical treatment may be required in patients with a consistent clinical picture but without a confirmed diagnosis.

Even with prompt treatment, 30 to 60% of patients develop constrictive pericarditis, for which surgical pericardiectomy is the treatment of choice. In cases of suspected tuberculous constriction, antituberculosis therapy (Chapter 332) should be administered before and after pericardial surgery.

FUNGAL PERICARDITIS

The most common fungal pericarditis is histoplasmosis, which usually resolves in several weeks and can be treated successfully with NSAIDs. Specific antifungal therapy (Chapter 340) is recommended only in patients with disseminated histoplasmosis.

Malignant Pericarditis

About 6% of cases of acute pericarditis that initially have no obvious cause and about 20% of cases of moderate to large pericardial effusions are related to malignant diseases; in patients with cardiac tamponade, the percentage is even higher. About 80% of malignant pericarditis is linked to breast cancer (Chapter 204), lymphoma (Chapters 191 and 192), and leukemia (Chapters 189 and 190). Melanoma (Chapter 210) is an uncommon cause of malignant pericarditis, but a large proportion of patients with melanoma have pericardial involvement.

Most patients have direct tumor extension from an adjacent malignant lesion or a tumor from hematogenous or lymphatic spread. Pericardial effusions also may be caused by pericardial irritation or compromised lymphatic drainage in patients with mediastinal lymphoma.

Pericardiocentesis is key to diagnosis and management. Fluid cytology is positive in about 85% of patients. Complete drainage with an indwelling catheter for 2 or 3 days is the treatment of choice; if the effusion does not resolve, pericardiectomy is recommended. The prognosis depends on the treatment of the underlying malignancy, but the 1-year mortality rate is 80% or higher.

Post-Radiation Pericarditis

Post-radiation pericarditis develops in about 2% of patients after mantle radiation for Hodgkin's disease (Chapter 192) and in 0.4 to 5% of patients after irradiation for breast cancer. Pericardial injury occasionally manifests during treatment, but it more commonly appears months or even a decade later. The initial pericarditis and effusion may resolve spontaneously, but constrictive pericarditis, adjacent myocarditis, and even coronary artery damage can develop. Pericardiocentesis is critical to distinguish post-radiation pericarditis from malignant pericardial disease. Pericardiectomy is recommended for recurrent pericarditis and for large recurrent pericardial effusions.

Autoimmune Pericarditis

Up to 50% of patients with systemic lupus erythematosus (Chapter 274) have pericarditis, usually during an acute flare. Patients usually present with acute pericarditis or an asymptomatic effusion; cardiac tamponade is uncommon, and constrictive pericarditis is rare. If purulent pericarditis is not suspected, pericardiocentesis is not usually required. The underlying disease should be treated aggressively.

Acute pericarditis or asymptomatic pericardial effusions can develop in patients with advanced rheumatoid arthritis (Chapter 272), scleroderma (Chapter 275), or mixed connective tissue disease (Chapter 275). The process is usually self-limited or responds to aggressive treatment of the underlying disease, although cardiac tamponade can develop.

Myopericarditis

Concomitant myopericarditis (Chapter 60) may develop in patients with pericarditis, probably owing to direct extension of the inflammatory process. It is often manifested by ECG conduction delays, ventricular arrhythmias, and elevated troponin levels. No specific treatment is available.

Acute ventricular dilation and sudden or progressive heart failure develop in some patients after pericardiectomy for constrictive pericarditis or even after drainage of a large pericardial effusion. The syndrome may be underlying myocarditis.

Congenital Abnormalities

Congenital total absence of the pericardium is asymptomatic and clinically unimportant. However, partial or localized absence of the pericardium around the left atrium can cause focal herniation and lead to strangulation. CT or MRI can establish the diagnosis. Patients may present with atypical chest pain or sudden death. Surgical repair is often recommended for a partial pericardial defect.

Benign Cysts

Benign pericardial cysts are rare and are usually asymptomatic, but they can be associated with chest pain. They are typically seen as rounded or lobulated structures adjacent to the heart on the chest radiograph or adjacent to the right atrium on transthoracic echocardiography (Chapter 55). Thoracic CT and MRI are useful for the diagnosis. Cysts rarely rupture and do not require treatment unless they become symptomatic with chest pain. In this situation, the cyst can be removed surgically or drained percutaneously or with a thoracoscope.

DISEASES OF THE AORTA

ERIC M. ISSELBACHER

The aorta is composed of three tissue layers. The intima is a thin inner layer lined with endothelial cells. The middle layer, or media, is the thickest layer of the aortic wall and is composed of sheets of elastic tissue that give the aorta tremendous tensile strength. The outermost layer, or adventitia, is composed mostly of collagen and carries the vasa vasorum, which nourish the aortic wall.

The ascending aorta is about 3 cm wide and 5 cm long and is located in the anterior mediastinum. Its most proximal portion (just above the aortic valve) is called the *aortic root* and is composed of the three sinuses of Valsalva. In the superior mediastinum, the ascending aorta meets the aortic arch and gives rise to the brachiocephalic arteries. The descending thoracic aorta courses posteriorly and is about 2.5 cm in diameter and 20 cm long. After crossing the diaphragm, it becomes the abdominal aorta, which is normally 2 cm wide and about 15 cm long; it then bifurcates into the two common iliac arteries.

AORTIC ANEURYSMS

DEFINITION

An aortic aneurysm is pathologic dilation of the aorta. Aneurysms are described in terms of their location, size, shape, and cause. The shape of an aneurysm is *fusiform* when there is symmetrical dilation of the aorta and *saccular* when the dilation involves mainly one wall. In addition, there may be a *false aneurysm* or *pseudoaneurysm* when the aorta is enlarged as a consequence of dilation of only the outer layers of the vessel wall, such as occurs with a contained rupture of the aortic wall.

EPIDEMIOLOGY

Aneurysms can involve any part of the aorta, but abdominal aortic aneurysms are much more common than thoracic aneurysms. Abdominal aortic aneurysms are 5 to 10 times more frequent in men than in women and have a prevalence of at least 3% in persons older than 50 years. Among thoracic aortic aneurysms, those of the ascending aorta are most common, followed by aneurysms involving the descending aorta; aneurysms of the aortic arch are uncommon. If a descending thoracic aortic aneurysm extends distally and involves the abdominal aorta, a thoracoabdominal aortic aneurysm is created.

Smoking is the strongest risk factor associated with the development of abdominal aortic aneurysms, followed by age, hypertension, and hyperlipidemia. In addition, there appears to be a genetic predisposition to their development because up to 28% of first-degree relatives of patients with abdominal aortic aneurysms may be similarly affected.

PATHOBIOLOGY

Atherosclerosis has long been considered the common underlying cause of abdominal aortic aneurysms. Indeed, the infrarenal aorta tends to be most severely affected by the atherosclerotic process and is accordingly a common site for aortic aneurysm formation. However, although aortic atherosclerosis clearly contributes to the process, the pathogenesis of abdominal aortic aneurysms is multifactorial, with genetic, environmental, hemodynamic, and immunologic factors all contributing to the development and progressive growth of aneurysms.

The strength of the aortic wall lies in its extracellular matrix, the most important components of which are elastin and collagen. Consequently, degradation of these structural proteins weakens the aortic wall, allowing aneurysms to develop. There is histologic evidence of inflammatory infiltrates—in particular, macrophages and T lymphocytes—within the media and adventitia of aneurysms, and this inflammation may lead to degradation of the extracellular matrix. Furthermore, matrix metalloproteinases—enzymes produced by smooth muscle and inflammatory cells that can degrade elastin and collagen—are significantly elevated in the walls of abdominal aortic aneurysms and probably contribute to their formation. As the wall begins to dilate, tension on the wall increases according to Laplace's law (tension is proportional to the product of pressure and the radius), thereby promoting further expansion of the aneurysm.

Atherosclerosis is also a common cause of aneurysms of the descending thoracic aorta. However, the most important cause of aneurysms of the ascending thoracic aorta is a process known as *cystic medial degeneration*, which histologically appears as smooth muscle cell necrosis and degeneration of elastic layers within the media. Cystic medial degeneration is found in almost all patients with Marfan syndrome (Chapter 268), who are at very high risk for thoracic aortic aneurysms. Among patients without overt evidence of connective tissue disease, a bicuspid aortic valve and familial thoracic aortic aneurysm syndrome are important congenital causes (Chapter 69). A long-standing history of hypertension is a common risk factor in older patients. Syphilis (Chapter 327), once a common cause of thoracic aortic aneurysms, is now rarely a factor. Other uncommon causes of thoracic aortic aneurysms include infectious aortitis (Chapter 76), great vessel arteritis, aortic trauma (Chapter 112), and aortic dissection (see later). Many thoracic aortic aneurysms are idiopathic.

CLINICAL MANIFESTATIONS

The large majority of abdominal and thoracic aortic aneurysms are asymptomatic and are discovered incidentally on routine physical examination or imaging study. When patients with abdominal aortic aneurysms experience symptoms, pain in the hypogastrium or lower part of the back is the most frequent complaint. The pain tends to have a steady, gnawing quality that may last hours or days. Expansion or impending rupture of an aneurysm may be heralded by new or worsening pain, often of sudden onset. With rupture, the pain is frequently associated with hypotension and a pulsatile abdominal mass.

Patients with thoracic aortic aneurysms may have chest pain or, less often, back pain. Vascular complications include aortic insufficiency (sometimes with secondary heart failure), hemoptysis, and arterial thromboembolism. An enlarging aneurysm may produce local mass effects as a result of compression of adjacent mediastinal structures, with symptoms including coughing, wheezing, dyspnea, hoarseness, recurrent pneumonia, or dysphagia.

DIAGNOSIS

Abdominal aortic aneurysms may be palpable on physical examination, although obesity can obscure even large aneurysms. Typically, abdominal aortic aneurysms are hard to size accurately by physical examination alone because adjacent structures frequently make an aneurysm feel larger than it really is. Thoracic aortic aneurysms usually cannot be palpated at all.

Definitive diagnosis of an aortic aneurysm is made by radiographic examination. Abdominal aortic aneurysms can be detected and sized by either abdominal ultrasonography or computed tomography (CT). Ultrasound is extremely sensitive and is the most practical screening method for aortic aneurysms. Screening is recommended in men aged 65 years or older and women aged 65 years or older who have smoked or have a family history. Such ultrasound screening programs are cost-effective and have been shown to reduce mortality in men aged 65 to 79.[1] CT is even more accurate (Fig. 78-1)

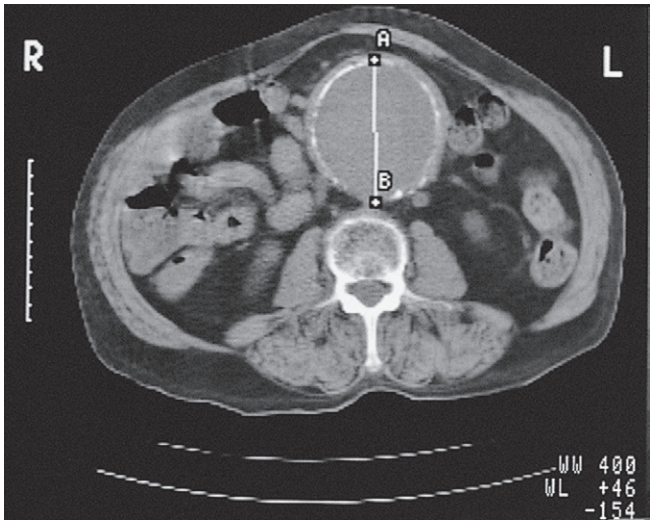

FIGURE 78-1. Abdominal aortic aneurysm on computed tomography. This sensitive imaging method allows precise measurement of size (point A to point B) and demonstrates the thickened wall of the aneurysm. (From Forbes CD, Jackson WF. *Color Atlas and Text of Clinical Medicine,* 3rd ed. London: Mosby; 2003.)

and can size an aneurysm to within a diameter of 2 mm. Although CT is less practical than ultrasound as a screening tool, it is the preferred modality for monitoring serial changes in size over time after the diagnosis has been made.

Thoracic aortic aneurysms are frequently recognized on chest radiographs; they often produce widening of the mediastinal silhouette, enlargement of the aortic knob, or displacement of the trachea from midline. CT is an excellent modality for detecting and sizing thoracic aneurysms and is particularly useful for monitoring size over time. Transthoracic echocardiography, which generally visualizes the aortic root and ascending aorta well, is useful for screening patients with Marfan syndrome, who are at particular risk for aneurysms involving this portion of the aorta.

TREATMENT

The goal of therapy for patients with aortic aneurysms is to reduce the risk for expansion and rupture of the aneurysm. Although blood pressure control is generally recommended, β-blockers do not reduce the rate of growth of abdominal aortic aneurysms. Nonrandomized data suggest a potential benefit from statins, angiotensin-converting enzyme inhibitors, and even macrolide antibiotics, which may act as matrix metalloproteinase inhibitors. However, no specific medical therapy can be recommended at the current time. Aneurysms should be monitored closely with serial imaging studies (e.g., CT) to detect any progressive enlargement over time, which may indicate the need for surgical repair.

Aortic aneurysms that produce symptoms secondary to expansion, vascular complications, or compression of adjacent structures should be repaired. Substantial evidence confirms a strong correlation between a surgeon's and hospital's aneurysm surgery volume and the outcome of abdominal aortic aneurysm repair.

Size is the major indicator for repair of asymptomatic aortic aneurysms. Abdominal aortic aneurysms larger than 5.5 cm should be repaired,[2,3] as should aneurysms larger than 5 cm in good operative candidates. Abdominal aneurysms of 3.5 to 4.4 cm should be monitored every 12 months, and those 4.5 to 5.4 cm should be monitored every 6 months. Descending thoracic aortic aneurysms larger than 6 cm should undergo surgical repair. Aneurysms of the ascending thoracic aorta should be repaired at 5.5 cm or larger, except that patients with Marfan syndrome or a bicuspid aortic valve should undergo repair when the aneurysm is 5 cm or larger because of the high risk of rupture in these patients.

Open surgical repair consists of insertion of a synthetic prosthetic tube graft. When aneurysms involve branch vessels, such as the renal or mesenteric arteries, the vessels must be reimplanted into the graft. Similarly, when a dilated aortic root must be replaced in the repair of an ascending thoracic aortic aneurysm, the coronary arteries must be reimplanted. An alternative approach for repair of abdominal aortic aneurysms (and some descending thoracic aneurysms) is the percutaneous placement of an expandable endovascular stent graft inside the aneurysm. This endovascular technique is associated with a better short-term outcome,[4,5] but there is no survival advantage after 2 years when compared with open repair.[4,6] In patients who are not candidates for open repair because of comorbid diseases or high surgical risk (Chapter 439), endovascular repair reduces aneurysm-related mortality substantially but does not reduce all-cause mortality compared with conservative medical management.[7]

PROGNOSIS

The chief concern in managing an aortic aneurysm is its tendency to rupture. Most aneurysms expand over time, and the risk for rupture increases with size.

Abdominal aortic aneurysms less than 4.0 cm have only a 0.3% annual risk for rupture, whereas aneurysms 4.0 to 4.9 cm have a 1.5% annual risk for rupture, and aneurysms 5.0 to 5.9 cm have a 6.5% annual risk for rupture. The overall mortality in patients with abdominal aortic aneurysm rupture is 80%, including 50% mortality even among those who reach the hospital.

Thoracic aneurysms smaller than 5 cm typically expand slowly and rarely rupture, but the rate of growth and risk of rupture increase significantly when thoracic aneurysms are 6 cm or larger. Similar to abdominal aneurysms, rupture of thoracic aneurysms has a high early mortality of 76% at 24 hours.

INTRAMURAL AORTIC HEMATOMA AND AORTIC DISSECTION

DEFINITION

An intramural aortic hematoma occurs when bleeding from the vasa vasorum or a tiny intimal tear causes a hematoma within the aortic media. Aortic dissection occurs when the media of the blood vessel is cleaved longitudinally to form a false lumen that communicates with the true lumen.

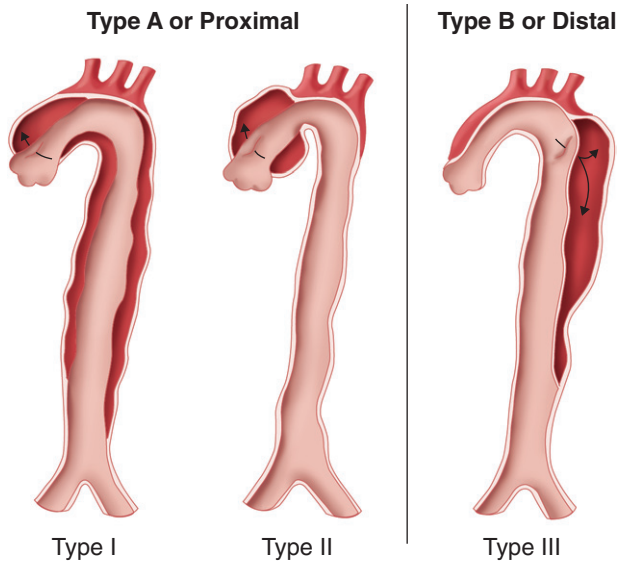

FIGURE 78-2. Classification systems for aortic dissection. (From Isselbacher EM. Diseases of the aorta. In: Braunwald E, Zipes DP, Libby P, Bonow RO, eds. *Braunwald's Heart Disease: A Textbook of Cardiovascular Medicine,* 7th ed. Philadelphia: Saunders; 2004:1416.)

The location of an intramural aortic hematoma or dissection may be described according to one of several classification systems (Fig. 78-2). Two thirds of aortic dissections are type A (proximal), and the other third are type B (distal). All the classification schemes serve the same purpose, which is to distinguish dissections that involve the ascending aorta from those that do not. Involvement of the ascending aorta carries a high risk for early rupture and death from cardiac tamponade, so the prognosis and management differ according to the extent of aortic involvement. Hematomas and dissections are also classified according to their duration: less than 2 weeks is considered acute, whereas 2 weeks or more is considered chronic.

The peak incidence of aortic dissection in patients without Marfan syndrome occurs in individuals in their 60s and 70s, and men are affected twice as often as women. A history of hypertension is present in most cases, whereas a bicuspid aortic valve or known preexisting thoracic aortic aneurysm is less common. Rarely, aortic dissection occurs in a young woman during the peripartum period. Iatrogenic trauma from intra-aortic catheterization procedures or cardiac surgery may also cause aortic dissection.

PATHOBIOLOGY

Disease of the aortic media, with degeneration of the medial collagen and elastin, is the most common predisposing factor for aortic dissection. Patients with Marfan syndrome have classic cystic medial degeneration and are at particularly high risk for aortic dissection at a relatively young age. Aortic dissection classically begins either with a tear in the aortic intima, thereby exposing the diseased medial layer to the systemic pressure of intraluminal blood, or with an intramural hematoma and subsequent rupture of the overlying intima. This hematoma may propagate longitudinally along a variable length of the aorta. If the intimal layer remains intact, the hematoma does not communicate with the aortic lumen; however, if open communication occurs, the result is no different than for a dissection that began with an intimal tear. The media cleaves into two layers longitudinally, producing a blood-filled false lumen within the aortic wall. This false lumen propagates distally (or sometimes retrogradely) a variable distance along the aorta from the site of the intimal tear.

CLINICAL MANIFESTATIONS

Pain, which is typically severe and occurs in 96% of cases of both aortic intramural hematoma and dissection, is the most common initial symptom. The pain may be retrosternal, in the neck or throat, interscapular, in the lower part of the back, abdominal, or in the lower extremities, depending on the location of the aortic hematoma or dissection. The pain may migrate as the dissection propagates distally. Thoracic pain is often of sudden onset and most severe at the start. It is sometimes described as "tearing," "sharp," or "stabbing." Although an isolated hematoma rarely causes symptoms other

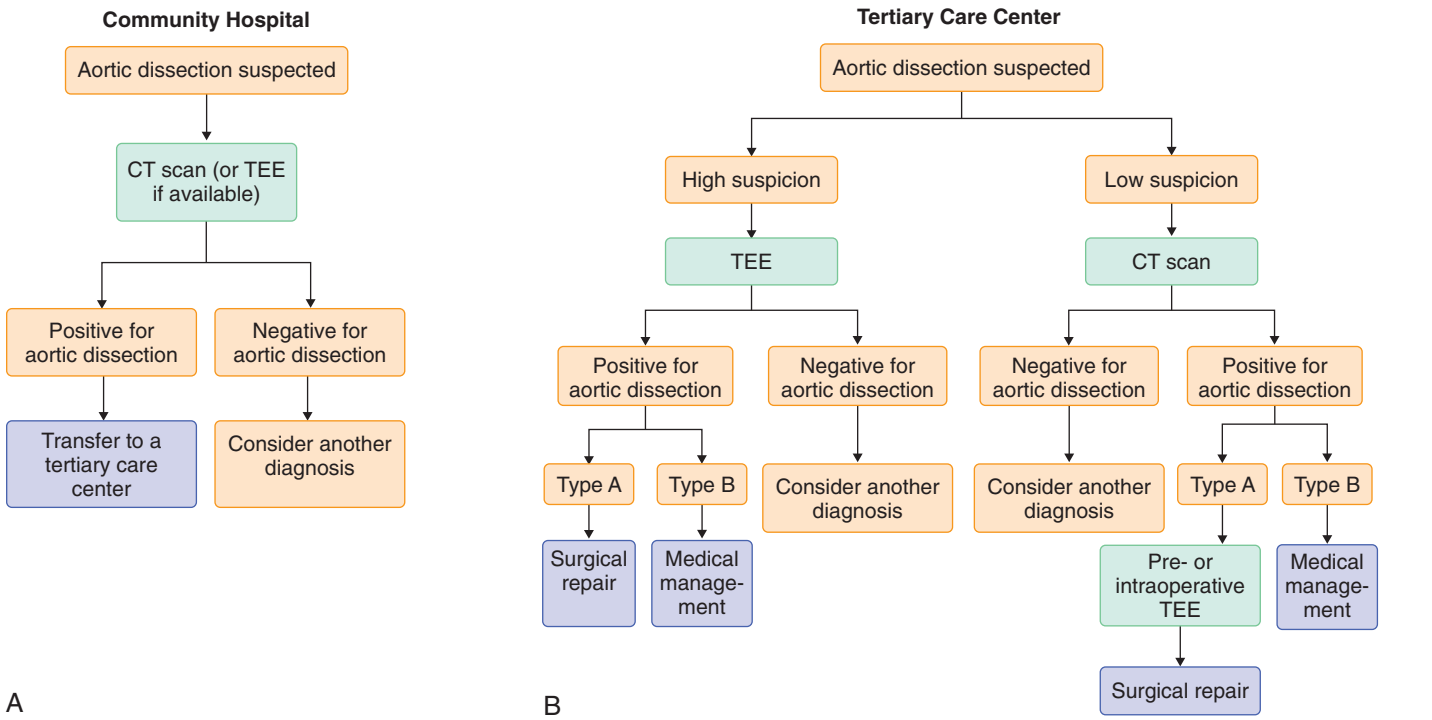

FIGURE 78-3. Algorithms for the evaluation of suspected acute aortic dissection. A, This approach is used in many community hospitals where cardiac surgery is not performed. **B,** This approach is used in many tertiary care centers where transesophageal echocardiography (TEE) and cardiac surgery are available. CT = computed tomography.

than pain, a dissection, regardless of how it starts, may also result in acute aortic insufficiency (Chapter 75), right coronary artery occlusion, hemopericardium (Chapter 77), syncope (Chapters 50 and 62), cerebrovascular accident (Chapter 414), mesenteric ischemia (Chapter 145), or ischemic peripheral neuropathy (Chapter 428).

Hypertension is a common finding on physical examination and is present in 70% of patients with distal aortic dissection. Hypotension may also occur, particularly in patients with proximal dissections, and is usually due to rupture into the pericardium or severe aortic insufficiency. Pseudohypotension occurs when a falsely low measure of upper extremity blood pressure is obtained because of involvement of the subclavian artery by the dissection. Similarly, pulse deficits are a common finding on physical examination, particularly in patients with proximal aortic dissections with involvement of the subclavian, carotid, or femoral arteries. Aortic insufficiency occurs in more than a third of patients with a proximal dissection; paradoxically, however, when acute aortic insufficiency is severe, the murmur may not be appreciable, so finding a widened pulse pressure and heart failure should raise suspicion of its presence.

Vascular complications from aortic dissection include compromise of a coronary artery, with subsequent myocardial ischemia or infarction. Involvement of the brachiocephalic arteries may produce a stroke or coma, whereas compromise of the spinal arteries may produce paraplegia. When a dissection extends into the abdominal aorta, flow to one or both renal arteries may be compromised and produce acute renal failure, which may exacerbate the hypertension. Mesenteric ischemia or frank infarction may manifest as abdominal pain. Finally, the dissection may extend distally to the aortic bifurcation and compromise or occlude one of the common iliac arteries and thereby produce a femoral pulse deficit and ischemia of the lower extremities.

An abnormality on a chest radiograph often raises the first suspicion of aortic dissection. The findings on chest radiography are nonspecific, however, and rarely diagnostic. An enlarged mediastinal silhouette is the most common finding, but it may be present in as few as 65% of patients in whom dissection is ultimately diagnosed. A left pleural effusion is commonly seen in patients with involvement of the descending thoracic aorta; when small, this typically represents an exudate from the inflamed aortic wall. A normal chest radiograph does not exclude the diagnosis of aortic dissection. Electrocardiographic findings in aortic dissection are nonspecific.

DIAGNOSIS

When there is clinical suspicion of aortic dissection, it is essential to confirm or exclude the diagnosis promptly with an imaging study (Fig. 78-3). Several imaging modalities can be used to diagnose the presence of aortic dissection accurately, including aortography, CT (Chapter 56), magnetic resonance imaging (Chapter 56), and transesophageal echocardiography (TEE; Chapter 55). Each institution must determine which of these modalities is most appropriate as an initial diagnostic approach, based on their availability and the skill and experience of the clinicians who perform and interpret the studies.

Nevertheless, when suspicion of aortic dissection is high, TEE (Fig. 78-4) is the most rapid means of providing sufficient detail to proceed directly to the operating room. When clinical suspicion is low (i.e., when the goal is to rule out aortic dissection), contrast-enhanced CT (Fig. 78-5) is preferred because it is entirely noninvasive. If TEE is not readily available, contrast-enhanced CT is the imaging modality of choice in both high-probability and low-probability patients.

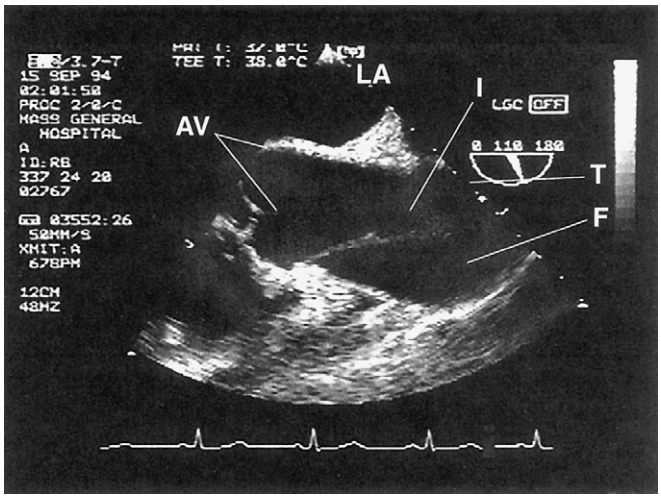

FIGURE 78-4. Transesophageal echocardiogram of the ascending aorta in the long axis in a patient with type A aortic dissection. The aortic valve (AV) is on the left, and the ascending aorta extends to the right. Within the aorta is an intimal flap (I) that originates at the level of the sinotubular junction. The true (T) and the false (F) lumens are separated by the intimal flap. LA = left atrium. (From Isselbacher EM. Diseases of the aorta. In: Braunwald E, Zipes DP, Libby P, Bonow RO, eds. *Braunwald's Heart Disease: A Textbook of Cardiovascular Medicine,* 7th ed. Philadelphia: Saunders; 2004:1423.)

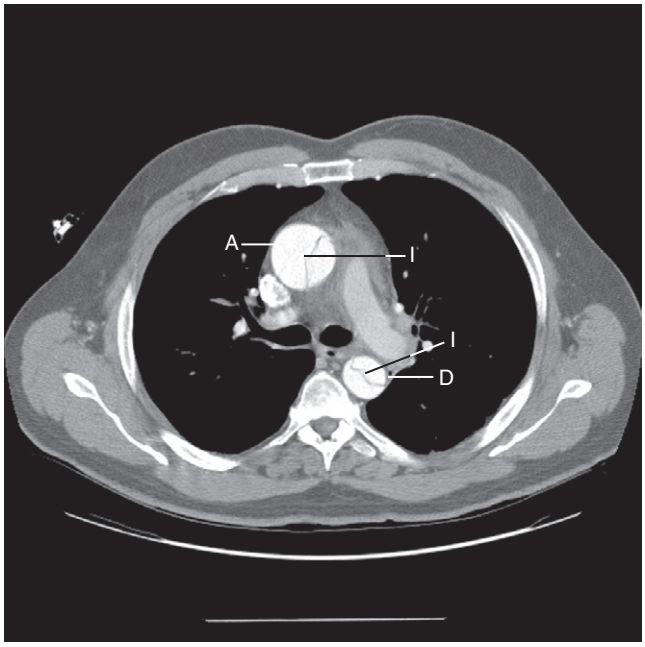

FIGURE 78-5. Aortic dissection. Contrast-enhanced computed tomography scan of the chest at the level of the pulmonary artery shows an intimal flap (I) separating the two lumens of the ascending (A) and descending (D) thoracic aorta in a type A aortic dissection.

On cross-sectional imaging, an isolated intramural hematoma appears as a crescentic thickening around the aortic wall rather than true and false lumens separated by an intimal flap (Fig. 78-6). The presence of an intramural hematoma may be missed on aortography.

TREATMENT

Rx

The goal of initial medical therapy for acute aortic intramural hematoma or dissection is to halt further progression and reduce the risk for rupture. Acute management of an isolated hematoma should be the same as for dissection because of the risk that the hematoma will propagate.

Whenever there is suspicion of aortic intramural hematoma or dissection, therapy should be instituted immediately while imaging studies are ordered, rather than waiting until the diagnosis is confirmed. The initial goal is to reduce the force of ventricular contraction and reduce systolic blood pressure to 100 to 120 mm Hg or to the lowest level that maintains cerebral, cardiac, and renal perfusion. Intravenous labetalol (20 mg administered over a 2-minute period, followed by additional doses of 20 to 80 mg every 10 to 15 minutes, up to a maximum total dose of 300 mg, and then a continuous infusion at 2 to 8 mg/minute), which acts as an α-blocker and a β-blocker, may be particularly useful in aortic dissection for controlling hypertension and contractile force. After labetalol or a pure β-blocker (e.g., intravenous propranolol at 1-mg boluses every 3 to 5 minutes to start, followed by a continuous infusion at rates up to 20 mg/hour) has been administered, intravenous nitroprusside (0.5 to 8 μg/kg/minute) should be added to titrate blood pressure minute by minute as needed. If β-blockers are contraindicated, calcium-channel blockers (e.g., intravenous diltiazem with an initial bolus of 20 mg over a 2-minute period, followed by a continuous infusion of 5 to 15 mg/hour) may be useful.

When patients have significant hypotension, pseudohypotension should be carefully excluded first. True hypotension may be due to hemopericardium and cardiac tamponade as a result of rupture of the dissection into the pericardium. These patients should be treated with volume expansion and taken to surgery as quickly as possible because early mortality is extremely high. Pericardiocentesis should be performed only as a last resort because it may precipitate hemodynamic collapse and death.

After initial medical therapy has been instituted and the diagnosis of aortic dissection confirmed, definitive therapy must be determined. Whenever an acute dissection involves the ascending aorta, surgical repair is indicated to minimize the risk of life-threatening complications such as rupture, cardiac tamponade, severe aortic insufficiency, or stroke. Patients with acute dissections confined to the descending aorta are at much lower risk for these complications and tend to fare as well with medical therapy as they do with endovascular repair or surgical repair. When a type B dissection is associated with a serious complication, however, such as end-organ ischemia, intervention is indicated with either endovascular techniques or open surgery. Patients with chronic type A dissections can often be managed medically because they have already survived the early period of high mortality associated with acute proximal dissections.

For an isolated intramural hematoma, the likelihood of progressive dissection or other complications is lower than in patients who initially have a frank dissection, especially those with smaller hematomas and normal aortic dimensions. Although the 25 to 50% risk of progression may warrant early surgery, serial imaging, with surgery reserved for progressive disease, is reasonable in patients at increased risk with surgery. For distal intramural hematomas, management is generally the same as for distal dissection.

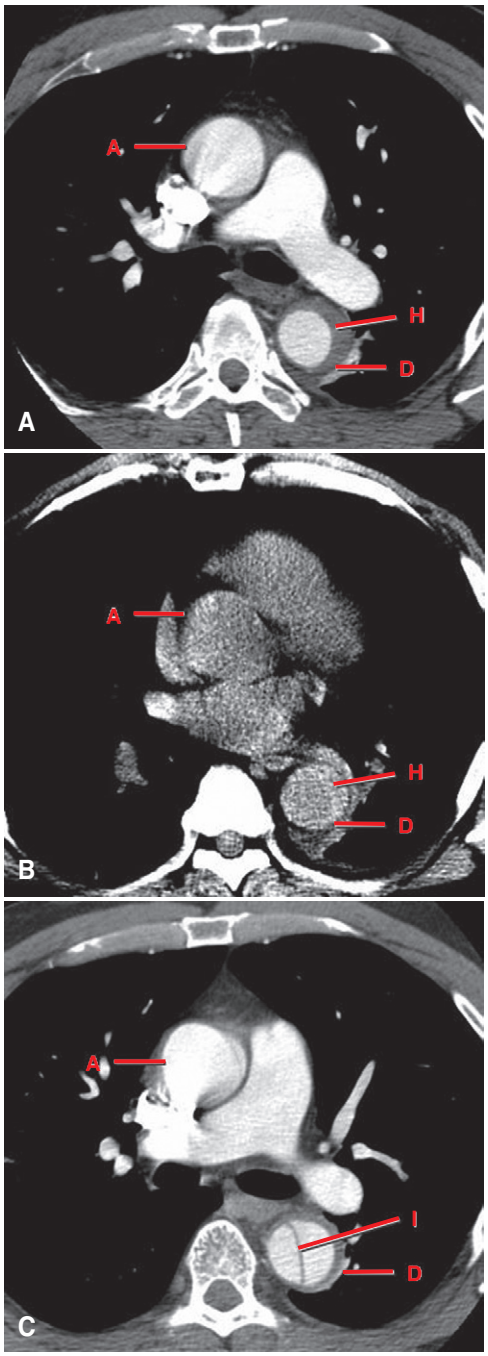

FIGURE 78-6. Intramural aortic hematoma. A, Contrast-enhanced computed tomography scan of the chest at the level of the pulmonary artery demonstrates an intramural hematoma (H) of the descending thoracic aorta (D). The hematoma appears as a crescentic thickening of the aortic wall that does not enhance from the contrast within the aortic lumen. The ascending thoracic aorta (A) is unaffected. **B,** Corresponding image from a noncontrast-enhanced computed tomography scan in which the intramural hematoma appears as a bright crescentic thickening of the aortic wall because the density of the hematoma is greater than that of the blood within the aortic lumen. **C,** Corresponding image from a contrast-enhanced computed tomography scan performed 1 week later for surveillance, in which the intramural hematoma has evolved into a classic aortic dissection with an intimal flap (I) and contrast evident within a patent false lumen.

PROGNOSIS

Acutely, the mortality rate from untreated aortic dissection is about 1% per hour. Patients with acute aortic dissection who survive the initial hospitalization generally do well thereafter, whether treated medically or surgically. Late complications such as aortic insufficiency, recurrent dissection, aneurysm formation, and aneurysm rupture can occur, however. Medications to control hypertension and reduce ventricular contractility can dramatically reduce the incidence of late complications and should be continued indefinitely. β-Blockers (e.g., metoprolol 25 to 200 mg twice daily or atenolol 25 to 200 mg/day) are the drugs of choice in this setting, but typically a second (e.g., lisinopril 5 to 40 mg/day) or third (amlodipine 2.5 to 10 mg/day or hydrochlorothiazide 12.5 to 50 mg/day) agent needs to be added to achieve the goal of systolic blood pressure less than 120 mm Hg (Chapter 67).

Patients are at highest risk for complications during the first 2 years after an intramural hematoma or aortic dissection. Progressive aortic expansion typically occurs without symptoms, so patients must be observed closely with serial aortic imaging at 6-month intervals for the first 2 years and annually thereafter, provided the anatomy is stable.

TAKAYASU'S ARTERITIS

DEFINITION

Takayasu's arteritis, which is a chronic inflammatory disease of unknown cause, involves the aorta and its branches. The mean age at onset is 29 years, with women affected eight times as often as men. It occurs more often in Asia and Africa than in Europe or North America. An early stage characterized by active inflammation involving the aorta and its branches progresses at a variable rate to a later sclerotic stage with intimal hyperplasia, medial degeneration, and obliterative changes. Most of the resulting arterial lesions are stenotic, but aneurysms may also occur. The aortic arch and brachiocephalic vessels are affected most often, and the disease tends to be most pronounced at branch points in the aorta. The abdominal aorta is also commonly involved, and the pulmonary artery is sometimes involved. The disease may be diffuse or patchy, with affected areas separated by lengths of normal aorta.

CLINICAL MANIFESTATIONS

Most patients initially have symptoms of a systemic inflammatory process, such as fever, night sweats, arthralgia, and weight loss. There is often a delay of months to years, however, between the onset of symptoms and diagnosis. At the time of diagnosis, 90% of patients have entered the sclerotic phase and have symptoms of vascular insufficiency, typically with pain in the upper (or, less often, lower) extremities. There are often absent pulses and diminished blood pressure in the upper extremities, and the condition has earned the name *pulseless disease.* There may be bruits over affected arteries. Significant hypertension (secondary to renal artery involvement) occurs in more than half the patients, but its presence may be difficult to recognize because of the diminished pulses. Aortic insufficiency may result from proximal aortic involvement. Heart failure may result from either hypertension or aortic insufficiency. Involvement of the ostia of the coronary arteries may cause angina or myocardial infarction. Carotid artery involvement may cause cerebral ischemia or stroke. Abdominal angina may result from mesenteric artery compromise.

The overall 15-year survival rate in patients diagnosed with Takayasu's arteritis is 83%, with most deaths being caused by stroke, myocardial infarction, or heart failure. The survival rate in patients with major complications of the disease is 66%; the survival rate in patients without a major complication is 96%.

DIAGNOSIS

Laboratory abnormalities during the acute phase include an elevated erythrocyte sedimentation rate, elevated C-reactive protein level, mild leukocytosis, anemia, and elevated immunoglobulin levels. The diagnosis is best made by aortography, CT angiography, or magnetic resonance angiography, which reveal stenosis of the aorta and stenosis or occlusion of its branch vessels, often with post-stenotic dilation or associated aneurysms.

TREATMENT

Rx

Corticosteroids (e.g., prednisone 60 to 100 mg/day, often for months and tapered after symptoms or evidence of inflammation subside) are the primary therapy for the acute inflammatory stage and may be effective in improving constitutional symptoms, lowering the erythrocyte sedimentation rate, and slowing disease progression. Cyclophosphamide (2 mg/kg/day) or methotrexate (15 to 25 mg/week) may be used when corticosteroid therapy alone is ineffective. It is unknown whether medical therapy reduces the risk for major complications or prolongs life.

Percutaneous balloon angioplasty can effectively dilate short stenotic lesions of the aorta and its branch arteries, although restenosis is common. Surgery may be necessary to bypass or reconstruct key segments, such as the coronary, carotid, or renal arteries, or to treat aortic insufficiency. Ideally, surgery should not be performed during the inflammatory phase.

GIANT CELL ARTERITIS

Giant cell arteritis (Chapter 279) is more common than Takayasu's arteritis. Its cause is also unclear, but it tends to occur in an older population with a mean age of 67 years. It typically affects medium-sized arteries, but in 15% of cases it involves the aorta and branches of the aortic arch. Narrowing of the aorta is rare, but weakening of the ascending aortic wall may lead to localized thoracic aortic aneurysms and secondary aortic insufficiency. Narrowing of the branches of the aortic arch produces symptoms similar to those seen in Takayasu's arteritis. Because the temporal artery is commonly involved, the diagnosis is usually made by temporal artery biopsy. Management involves high-dose corticosteroid therapy (e.g., prednisone 60 to 100 mg/day, often for months and tapered after symptoms or evidence of inflammation subside), to which the disease is usually responsive.

ATHEROSCLEROTIC PERIPHERAL ARTERIAL DISEASE

CHRISTOPHER J. WHITE

DEFINITION

Lower extremity atherosclerotic peripheral arterial disease is one subset of a larger group of peripheral vascular diseases that includes all noncoronary vascular disorders that may affect the arterial, venous (Chapter 81), or lymphatic circulation. Atherosclerotic arterial diseases are characterized by arterial narrowing or occlusion caused by the accumulation of atherosclerotic

How to Perform and Calculate the ABI

EXAMPLE

$$\frac{\text{Higher ankle pressure}}{\text{Higher arm pressure}} = \frac{92 \text{ mm Hg}}{164 \text{ mm Hg}} = 0.56$$ See ABI Chart

FIGURE 79-1. Performing pressure measurements and calculating the ankle-brachial index (ABI). To calculate the ABI, systolic pressures are determined in both arms and both ankles with the use of a handheld Doppler instrument. The highest readings for the dorsalis pedis (DP) and posterior tibial (PT) arteries are used to calculate the index.

plaque elements in the vessel wall (Chapter 70). Atherosclerotic vascular disease can also lead to aneurysm formation, which is the pathologic enlargement of arterial segments, and may result in rupture, dissection, or thromboembolism (Chapter 78).

EPIDEMIOLOGY

The prevalence of lower extremity peripheral arterial disease in the United States, Europe, and Asia continues to increase as the population ages and is exposed to atherosclerotic risk factors (Chapter 51). The presence of peripheral arterial disease is defined as an ankle-brachial index (ABI)—the ratio of the systolic blood pressure in the ankle divided by the systolic blood pressure in the arm (Fig. 79-1)—less than 0.90. Among individuals aged 40 years and older, the prevalence is 4.3% (95% confidence interval [CI] 3.1 to 5.5%), but the prevalence in diabetic individuals ranges from 20 to 30%.

Risk factors for atherosclerosis (Chapter 51) increase the likelihood of developing lower extremity peripheral arterial disease. More than 95% of individuals with peripheral arterial disease have at least one traditional cardiovascular risk factor, and most have multiple risk factors. More than one third of patients with peripheral arterial disease have significant coronary disease, and up to one quarter have carotid artery disease. As a result, the risk of heart attack, stroke, and death are increased several-fold in patients with peripheral arterial disease.

Among conventional atherosclerotic risk factors, cigarette smoking is two to three times more likely to cause lower extremity peripheral arterial disease than to cause coronary artery disease. Hypertension is also associated with lower extremity peripheral arterial disease. The development of peripheral arterial disease is more likely in patients with lipid abnormalities (elevated total and low-density lipoprotein cholesterol, decreased high-density lipoprotein cholesterol, and hypertriglyceridemia), and the risk increases by 5 to 10% for each 10 mg/dL rise in total cholesterol. Increased homocysteine levels are associated with a two- to three-fold increased risk for developing atherosclerotic peripheral arterial disease. Diabetes mellitus increases the risk of lower extremity peripheral arterial disease by two- to four-fold, and the risk of developing lower extremity peripheral arterial disease is proportional to the severity and duration of diabetes. Tight control of diabetes is important, and the risk of developing peripheral arterial disease increases by 28% for every 1% increase in glycosylated hemoglobin (Chapters 236 and 237). Diabetic patients with lower extremity peripheral arterial disease are 7- to 15-fold more likely to undergo a major amputation than nondiabetics with lower extremity peripheral arterial disease.

Peripheral arterial disease disproportionately affects older individuals (Fig. 79-2), non-Hispanic blacks, current smokers, diabetics, and those with abnormal renal function. The overall prevalence of peripheral arterial disease

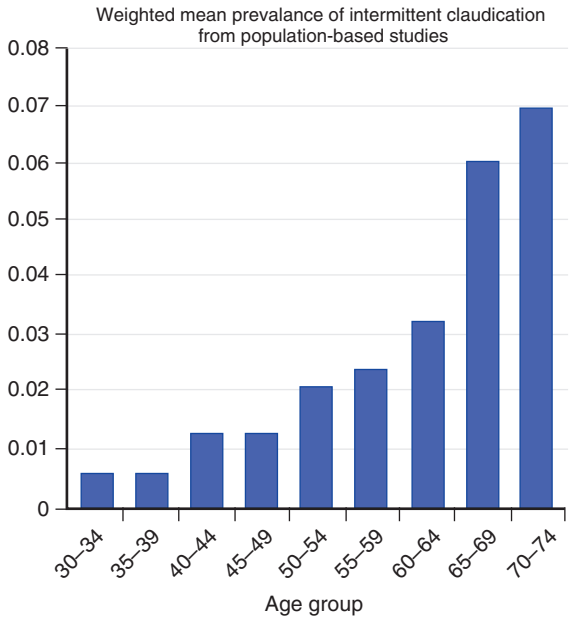

FIGURE 79-2. Weighted mean prevalence of intermittent claudication. (Modified from Dormandy JA, Rutherford RB. Management of peripheral arterial disease. TransAtlantic Inter-Society Consensus (TASC) Working Group. *J Vasc Surg.* 2000;31:S1-S296.)

in the United States among persons aged 70 years and older is 14.5% (95% CI 10.8 to 18.2%), which corresponds to approximately 4 million individuals.

PATHOBIOLOGY

Acute Limb Ischemia

Acute limb ischemia occurs when blood flow to an extremity is abruptly halted or markedly diminished, resulting in hypoperfusion that threatens the viability of the limb. Acute limb ischemia is most commonly caused by either thrombosis or embolism. Thrombosis of a lower extremity arterial bypass graft is the most common clinical scenario. Most emboli originate from the heart as a mural thrombus from a recent myocardial infarction (Chapter 73) or from the atrial appendage in a patient with atrial fibrillation (Chapter 64). A less common cause of lower extremity emboli is an atherosclerotic or aneurysmal abdominal aorta (Chapter 78) that serves as the source of cholesterol emboli (Chapter 80).

Arterial in situ thrombosis as a result of plaque rupture usually represents the final stage of a chronically diseased artery, most commonly the femoral or popliteal artery. Conditions such as severe dehydration or low-output heart failure promote thrombosis at the site of stenosis. If native artery thrombosis occurs in the absence of a preexisting stenosis, a thorough search for a hypercoagulable state should be undertaken. Acutely thrombosed femoral or popliteal aneurysms may present as acute limb ischemia.

Chronic Limb Ischemia

Chronic, stable lower extremity peripheral arterial disease, manifested by the symptoms of intermittent claudication, may be due to atherosclerosis, thromboembolism, inflammatory disease, trauma, aneurysmal disease, adventitial cysts, entrapment syndromes, or congenital abnormalities. Aneurysms may be associated with atherosclerosis, or they may be due to underlying hereditary (familial) or acquired (e.g., due to smoking or trauma) causes.

Patients with critical limb ischemia have inadequate blood flow to sustain viability in the distal tissue bed. Critical limb ischemia is most often caused by atherosclerosis, but it can also be caused by atheroembolic or thromboembolic disease, vasculitis, in situ thrombosis related to hypercoagulable states, thromboangiitis obliterans, cystic adventitial disease, popliteal entrapment, or trauma. Patients presenting with critical limb ischemia typically have multisegment disease along the length of the limb.

Inflammation plays a fundamental role in the development and progression of atherosclerosis (Chapter 70). Elevated levels of C-reactive protein (CRP) are strongly associated with the development of peripheral arterial disease. Markers of inflammation such as interleukin-6, tumor necrosis factor-α, CRP, and platelet activation are increased compared with normal subjects.

No specific genetic markers have been confirmed for peripheral arterial disease, although one study identified a linkage on chromosome 1p. The proportion of low ABIs attributable to heritability is estimated at 20%. Concordance rates among twins are about 33% for monozygotic pairs and about 31% for dizygotic pairs, suggesting a limited role for heritability. Taken together, these data studies suggest a modest but significant heritability factor for peripheral arterial disease.

CLINICAL MANIFESTATIONS

Acute Limb Ischemia

A patient with acute limb ischemia classically presents with a cool, painful extremity. Typically, the major muscle groups below the level of obstruction are symptomatic. The absence of a pulse may help localize the site of occlusion, but pulses may be normal in cases of microemboli or cholesterol emboli (Chapter 80). Venous and capillary filling is an indicator of the severity of acute limb ischemia. The leg should be carefully examined for color and temperature abnormalities. Pallor is seen early on, but with time, cyanosis is common. Poikilothermia, or coolness, is an important finding, particularly if the opposite limb is warm. A transition level for color and temperature changes, which is often clinically obvious, should be correlated with the pulses and denoted as a baseline reference at the initial examination for comparison with subsequent examinations.

Sensory changes include numbness and paresthesias. Paralysis indicates advanced, limb-threatening ischemia. The extent of any motor deficit is a good index of the degree of tissue anoxia and correlates well with the prognosis. Motor deficits progress from distal to more proximal muscle groups, so early motor weakness is seen in the intrinsic foot muscles. Complete motor paralysis is a late symptom that suggests impending irreversible injury. In due course, paralysis progresses to rigor when irreversible ischemia has developed.

Chronic Stable Lower Limb Ischemia

Patients with chronic peripheral arterial disease may be clinically stable and report no symptoms, atypical symptoms, or symptoms of exertional discomfort (claudication). If they are clinically unstable with pain at rest or with ulceration or spreading gangrene, they have critical limb ischemia that threatens the limb (Table 79-1). The majority of patients with chronic peripheral arterial disease are asymptomatic and are identified by abnormal pulse examinations, investigation of vascular bruits, or routine measurement of the ABI (see Fig. 79-1). Patients with typical symptoms of intermittent claudication are only the tip of the iceberg, representing no more than 20% of patients with objective evidence of peripheral arterial disease.

Claudication is defined as exertional discomfort, relieved with rest, in specific muscle groups at risk for ischemia during exercise. Symptoms usually begin one segment below the level of the arterial narrowing. For example, vascular blockages (occlusions or stenoses) of the iliac vessels typically cause hip, thigh, and calf pain, whereas femoral and popliteal artery obstructions typically cause symptoms in the calf and foot muscles. Claudication, which is a specific vascular syndrome, must be distinguished from other conditions that cause exertional leg pain, which have been termed *pseudoclaudication* (Table 79-2).

TABLE 79-1 FONTAINE'S AND RUTHERFORD'S CLINICAL CLASSIFICATIONS OF CHRONIC LOWER LIMB ISCHEMIA

	Fontaine	*Rutherford*		
STAGE	**CLINICAL**	**GRADE**	**CATEGORY**	**CLINICAL**
I	Asymptomatic	0	0	Asymptomatic
IIa	Mild claudication	I	1	Mild claudication
IIb	Moderate to severe claudication	I I	2 3	Moderate claudication Severe claudication
III	Rest pain	II	4	Rest pain
IV	Ulceration or gangrene	III IV	5 6	Minor tissue loss Ulceration or gangrene

TABLE 79-3 CLINICAL CATEGORIES OF ACUTE LIMB ISCHEMIA

CATEGORY	DESCRIPTION	SENSORY LOSS	MUSCLE WEAKNESS	DOPPLER ARTERIAL	DOPPLER VENOUS
I. Viable	Not immediately threatened	None	None	Audible	Audible
IIa. Threatened marginally	Salvageable if promptly treated	Minimal or none	None	Inaudible	Audible
IIb. Threatened immediately	Salvageable if immediately treated	More than toes, associated with rest pain	Mild to moderate	Inaudible	Audible
III. Irreversible	Major tissue loss inevitable	Profound, anesthetic	Profound, paralysis, rigor	Inaudible	Inaudible

Adapted from Rutherford RB, Baker JD, Ernst C, et al. Recommended standards for reports dealing with lower extremity ischemia: revised version. *J Vasc Surg.* 1997;26:517-538.

Symptoms in individual patients are remarkably variable despite similar degrees of vascular stenosis, in part owing to collateral vessel formation. A patient with superficial femoral artery occlusion but robust collateral formation via the deep femoral artery and geniculate collaterals, which supply blood to the infrapopliteal vessels, may have minimal or no symptoms. Another patient with similar anatomy but poor collaterals may have severe symptoms.

Chronic Critical Lower Limb Ischemia

Critical limb ischemia develops in about 10% of all patients with peripheral arterial disease; it presents as resting limb pain or impending limb or tissue loss, as manifested clinically by nonhealing lower extremity ulcers or the presence of gangrene. These patients' limbs are in jeopardy, and even the most minor trauma from a poorly fitting shoe or a carelessly clipped toenail may cause a nonhealing wound or infection necessitating amputation. Critical limb ischemia can be exacerbated by conditions that reduce blood flow to the microvascular bed, such as diabetes, severe low cardiac output states, and, rarely, vasospastic diseases.

DIAGNOSIS

Acute Limb Ischemia

In patients with acute limb ischemia, the history and physical examination are important steps not only in assessing the cause and severity of ischemia but also in determining the diagnostic and therapeutic path. Upon completion of the history and physical examination, the physician should be able to answer the following questions about the severity of acute limb ischemia: Is the limb viable? Is its viability immediately threatened? Are there already irreversible changes that may preclude salvage of the limb? Three findings that help differentiate "threatened" from "viable" extremities are the presence of persistent pain, sensory loss, and muscle weakness (Table 79-3).

Chronic Limb Ischemia

The clinical severity of acute and chronic limb ischemia can be semiquantitatively assessed using either the Fontaine or the Rutherford classification (see Table 79-1). The clinician must distinguish intermittent claudication from nonvascular causes that may mimic claudication (i.e., pseudoclaudication), such as neurogenic pain from spinal stenosis or nerve root compression (Chapter 407), musculoskeletal or arthritic pain, or discomfort from venous congestion or a compartment syndrome (see Table 79-2). A typical history of claudication has a low sensitivity but a high specificity for peripheral arterial disease.

Patients presenting with peripheral arterial disease should be assessed for atherosclerotic risk factors (Table 79-4) and undergo a complete vascular physical examination, including measurement of the ABI (see Fig. 79-1). In healthy adults without arterial occlusive disease, ankle systolic pressure is typically 10 to 15 mm Hg greater than arm (brachial) systolic pressure, owing to the effect of pulse wave reflection. A truly normal ABI is greater than 1.10, although peripheral arterial disease is generally defined as a resting ABI of 0.90 or less.

Imaging

Duplex imaging combines ultrasound imaging and Doppler blood velocity measurements to localize vascular obstructions and estimate lesion severity. The sensitivity and specificity of duplex ultrasound for the diagnosis of a 50% or greater stenosis in the lower extremity are 90% or higher. Duplex ultrasound has proved useful for the surveillance of post-surgical vein graft patency in the lower extremities, although the specific utility of ultrasound surveillance after synthetic bypass grafting or after endovascular therapy has not been demonstrated.

FIGURE 79-3. Aortography with distal run-off in three different patients by three different methods: digital subtraction angiography (DSA), computed tomography angiography (CTA), and magnetic resonance angiography (MRA). (From White C. Intermittent claudication. *N Engl J Med.* 2007;356:1241-1250.)

Computed tomography angiography (CTA) and magnetic resonance angiography (MRA) obtain cross-sectional images that can be reconstructed into a three-dimensional angiogram (Fig. 79-3). CTA requires iodinated intravenous contrast material and ionizing radiation, whereas MRA uses gadolinium contrast and does not expose the patient to ionizing radiation. The major toxicity of gadolinium is an uncommon but potentially lethal systemic disorder called nephrogenic systemic fibrosis or nephrogenic sclerosing dermopathy (Chapter 275); chronic kidney disease with a glomerular filtration rate of 60 mL/minute or less is the major risk factor for the development of nephrogenic sclerosing dermopathy.

FIGURE 79-4. **A,** Baseline angiogram of left leg showing occlusion *(arrowheads)* of the femoral-popliteal segment. **B,** Post-treatment angiogram after balloon angioplasty and stent placement. **C,** More than 5 years later, the patient returns with claudication and a reduced ankle-brachial index. Follow-up computed tomography angiogram shows narrowing of the superficial femoral artery between the two stents. **D,** Final angiogram following balloon angioplasty and stent placement in the femoral narrowings.

An advantage of CTA over MRA is its ability to visualize metallic stents and stent-grafts (Fig. 79-4). CTA requires only about one fourth the radiation required for invasive digital angiography, and it can be performed more quickly and with less pretreatment planning than MRA. Vascular calcification may be a source of artifact with CTA but is inconsequential with MRA. MRA tends to overestimate lesions at the ostia of arteries owing to turbulent flow, and MRA cannot be performed in patients with ferromagnetic metallic implants. In a randomized trial comparing MRA with CTA for initial imaging in peripheral arterial disease, there was no difference between the two techniques in terms of ease, clinical utility, or patient outcome, but CTA reduced total diagnostic costs.■

Invasive digital angiography remains the "gold standard" for the diagnosis and evaluation of peripheral arterial disease (see Fig. 79-3), despite the need for iodinated contrast material and the exposure to ionizing radiation. Another limitation is the two-dimensional nature of the images, given the vascular system's tortuous, three-dimensional structure and detailed morphology, which may be obscured by the overlap of side branches. Invasive angiographic procedures (Chapter 57) are associated with a relatively small but nontrivial rate of complications, including severe contrast allergy in 0.1%, access-related bleeding complications, contrast-induced nephropathy, and, very rarely, infection.

TREATMENT

Rx

The treatment of patients with atherosclerotic lower extremity peripheral arterial disease is directed at salvaging the limb, improving walking distance, and reducing the patient's risk for life-threatening cardiovascular complications of atherosclerosis. The decision to perform a percutaneous or surgical revascularization procedure for the relief of claudication is based on a risk-benefit assessment that weighs the patient's disability and discomfort against the estimated short- and long- term success and risks of the procedure. Because very few patients with claudication are in danger of losing their limbs, the primary goal of revascularization is long-lasting relief of symptoms, not limb salvage.

Revascularization strategies now emphasize percutaneous endovascular treatments rather than traditional open surgical approaches because of their lower morbidity (see Fig. 79-4). Stenting has made catheter-based procedures safer, more durable, and more predictably successful.

Acute Limb Ischemia

Patients with irreversible limb ischemia should not undergo angiography and should be scheduled for amputation (Fig. 79-5). All other patients with acute limb ischemia should undergo emergent angiography. Before angiography, anticoagulation to prevent thrombus propagation and/or embolization (e.g., unfractionated heparin 5000 IU bolus, then 1000 IU/hour infusion) and analgesia (e.g., morphine 2 mg intravenously, as needed) should be initiated, and any underlying medical comorbidities (e.g., heart failure) should be managed aggressively to stabilize the patient. The method used for direct revascularization must be tailored to the patient and to the physician's skills (operative or endovascular).

The options for prompt revascularization consist of endovascular therapies with intra-arterial thrombolysis (e.g., recombinant tissue plasminogen activator 0.5 mg/hour intra-arterially) or thrombectomy, or surgical thrombectomy with or without arterial bypass. In general, endovascular therapy is recommended for patients with an onset of acute symptoms less than 14 days earlier, and surgical revascularization is recommended for patients with a duration of symptoms greater than 14 days. These treatments are often complementary, each with its own advantages and limitations. The less invasive endovascular therapy allows simultaneous angiography to guide reperfusion therapy, but it may be difficult to pass the guidewire across a total occlusion. Surgery offers definitive restoration of blood flow with thrombectomy or bypass surgery, but it carries higher short-term risks. When choosing a treatment, consideration should be given to the location of the occlusion, the type of occlusion (thrombus or embolus), the duration of ischemia, patient-related risks, the type of conduit to be recanalized (artery or graft), and therapy-related risks and outcomes. For example, an in situ thrombus is more amenable to thrombolysis than is an embolus, which may require thrombectomy.

Chronic Stable Lower Limb Ischemia

The treatment of patients with claudication is directed at both improving the walking distance and, perhaps more importantly, reducing the patient's risk for life-threatening cardiovascular complications of atherosclerosis. Risk factor modification (Chapter 51), antiplatelet therapy (Chapter 37), and an exercise prescription are the basic elements of treating peripheral arterial disease.

Exercise Therapy

Improvement in walking distance can often be achieved with pharmacologic management, discontinuation of tobacco use, and a regular, supervised exercise program. Patients should be reassured that exercising, even though it may precipitate their claudication symptoms, is not harmful and is the preferred initial treatment.■ A meta-analysis of eight randomized trials demonstrated that a supervised, as opposed to unsupervised, exercise program improved symptoms of claudication.■ Supervised exercise commonly involves walking on a treadmill, with the initial workload set to elicit symptoms within 3 to 5 minutes of walking. The patient is permitted to rest until the symptoms resolve but then resumes exercising. Maximal benefits are associated with programs that require the patient to continue walking until the pain is near maximal and with sessions that last more than 30 minutes, occur three or more times per week, and continue for more than 6 months. It typically takes 1 to 2 months for the patient to begin to notice benefits, which gradually increase over several months.

Pharmacology

Currently, two medications are approved in the United States for the symptomatic treatment of intermittent claudication: pentoxifylline and cilostazol. In randomized clinical trials, pentoxifylline has not consistently improved treadmill walking distance, so it cannot be recommended. Cilostazol (50 to 100 mg twice daily), a phosphodiesterase inhibitor, improves maximal walking distance by 40 to 50% compared with placebo.■ Cilostazol is contraindicated in patients with heart failure. Oral vasodilating prostaglandins, vitamin E, and chelation therapy with EDTA have not been effective in improving either symptoms or walking distance.

Risk Factor Treatment

Antiplatelet therapy with aspirin (usually 81 mg/day) has an established role in the secondary prevention of cardiovascular events in patients at high risk, based on clinical evidence of either coronary artery disease or stroke (Chapter 414). However, the role of aspirin in other populations, such as those with peripheral arterial disease but no clinical evidence of coronary artery disease or stroke, has not been established. The thienopyridines, such as

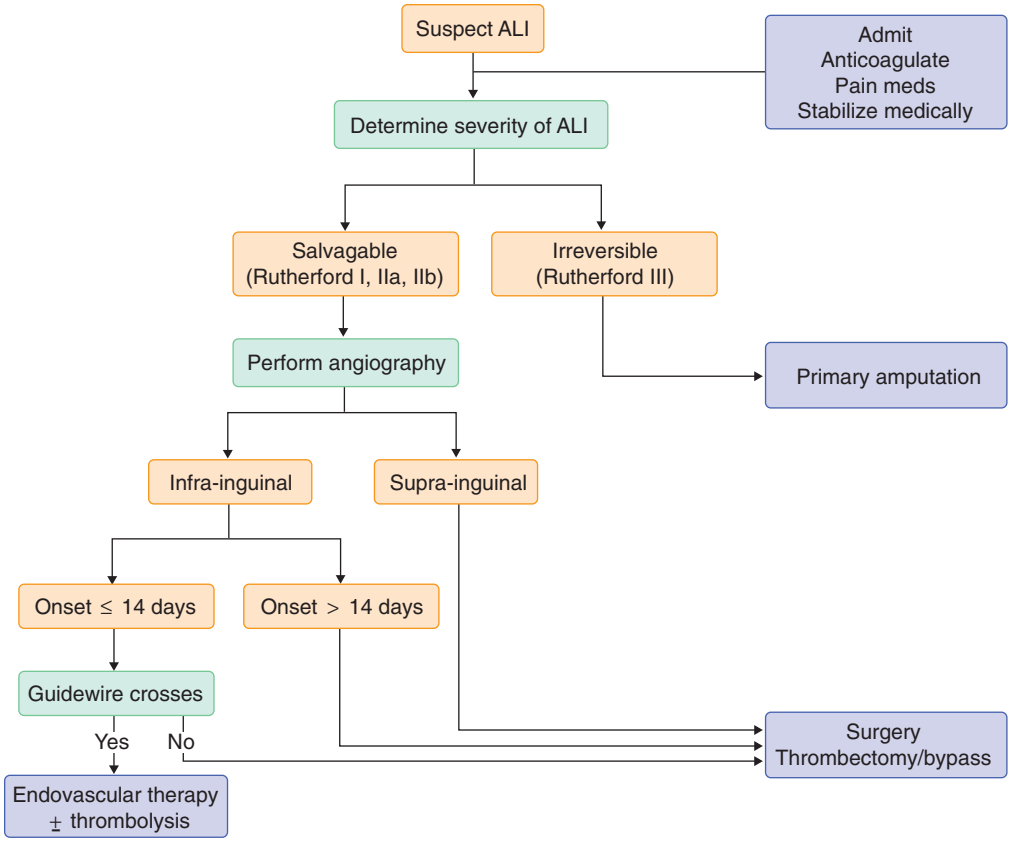

FIGURE 79-5. Treatment algorithm for acute limb ischemia (ALI). (Modified from Gray BH, Conte MS, Dake MD, et al. Atherosclerotic Peripheral Vascular Disease Symposium II: lower-extremity revascularization: state of the art. *Circulation.* 2008;118:2864-2872.)

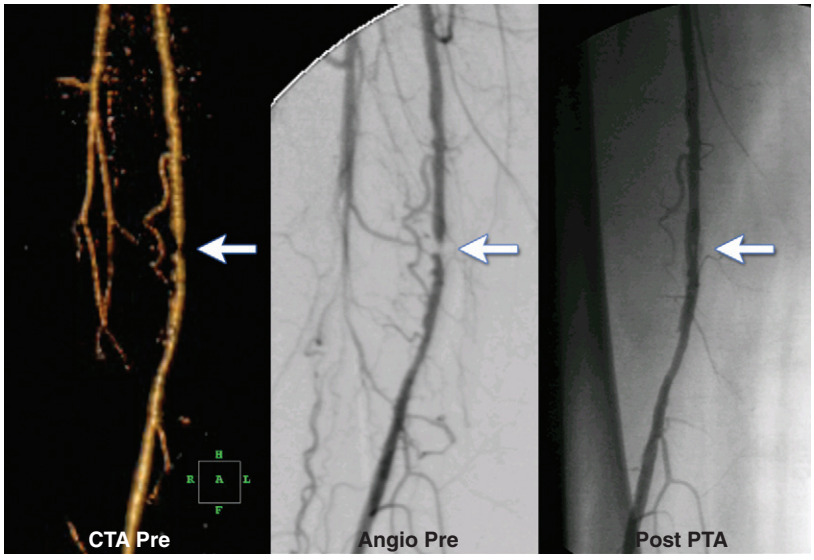

FIGURE 79-6. Discrete stenosis *(arrows)* of the left superficial femoral artery seen on computed tomography angiography (CTA; left), digital subtraction angiography (middle), and digital angiography after percutaneous transluminal angioplasty (PTA; right). (From White C. Intermittent claudication. *N Engl J Med.* 2007;356:1241-1250.)

clopidogrel (usually 75 mg/day), are indicated only if aspirin is not tolerated, based on clopidogrel's efficacy compared with aspirin among patients with peripheral arterial disease.[6]

Patients with known peripheral arterial disease should be encouraged to modify or eliminate atherosclerotic risk factors such as diabetes (Chapter 237), tobacco use (Chapter 31), hyperlipidemia (Chapter 213), and hypertension (Chapter 67) and to exercise regularly (Chapter 15). Medical therapy, dietary modification, and exercise should all be tailored to meet current guidelines for controlling hyperlipidemia (Chapter 213) and hypertension (Chapter 67).

For patients with severe peripheral arterial disease and elevated CRP levels, statin therapy substantially improves overall survival.[6] This finding in patients with peripheral arterial disease is consistent with findings in other studies of patients with a history of vascular disease, with or without peripheral arterial disease, and with either elevated low-density lipoprotein cholesterol levels or elevated CRP levels. Blood pressure control is very important, especially in patients with coexisting diabetes.[7] β-Blockers are effective antihypertensive therapy and are not contraindicated in peripheral arterial disease. Angiotensin-converting enzyme inhibitors reduce the risk of cardiovascular death in patients with peripheral arterial disease.[8]

Revascularization

Patients selected for revascularization to relieve symptoms of intermittent claudication should have significant lifestyle limitations or be unable to work and should have failed to respond to pharmacologic and exercise therapy. They should also have a favorable risk-benefit ratio and favorable vascular anatomy for the planned revascularization procedure.

Superficial femoral artery stenosis or occlusion is the most common lesion associated with claudication (Fig. 79-6). Revascularization with surgery or percutaneous transluminal angioplasty is indicated for the relief of vocational or lifestyle-limiting claudication in patients who have failed exercise and pharmacologic therapy. Angioplasty with stenting is preferred when possible in patients younger than 50 years, as they have a higher risk of surgical graft failure than do older patients.

Clinical trials comparing medical therapy and percutaneous transluminal angioplasty with and without stenting for patients with claudication and for those with femoral-popliteal arterial disease demonstrate substantially better early relief of symptoms and long-term vessel patency with angioplasty. A meta-analysis comparing exercise therapy with balloon angioplasty in claudicants found no difference in quality-of-life measures at 3 and 6 months, but

the ABI and functional capacity improved more with angioplasty than with exercise therapy.[3]

Some randomized trials comparing surgery with percutaneous transluminal angioplasty show similar rates of mortality, amputation, and patency at 4 years in patients with lower extremity ischemia. Percutaneous transluminal angioplasty is preferred in amenable lesions because of its lower periprocedural mortality and morbidity. Percutaneous transluminal angioplasty is more cost-effective than surgery if the expected 5-year patency rate of the treated vessel is 30% or greater. Outcomes following femoral-popliteal percutaneous transluminal angioplasty have improved over time, with current patency rates of 87, 69, and 55% at 1, 3, and 5 years, respectively.

Clinical success for patients with claudication caused by femoral lesions depends on obtaining a durable, long-lasting result. Although one option is angioplasty followed by provisional "bailout" stenting if the angioplasty itself is not successful, primary stenting with nitinol self-expanding stents is superior to provisional stent replacement for longer femoral lesions (7 to 10 cm) in terms of restenosis, improvement in ABI, and longer walking distance.[10] At 2 years follow-up, the benefit of primary stenting remained statistically significant, but the restenosis rate for femoral stents is about 50%. In more discrete femoral lesions (mean, 4.5 cm), a strategy of balloon angioplasty first, with stenting only for bailout, is as good as routine stenting.[11,12] The difference in outcomes for short versus long lesions is because stenting is equally good for long and short lesions, but longer lesions are more prone to restenosis after balloon angioplasty; as a result, stents improve outcomes in longer lesions. For shorter superficial femoral artery lesions, a strategy of percutaneous transluminal angioplasty with bailout stenting is preferable.

Adjunctive angioplasty devices such as atherectomy, cryotherapy, and the cutting balloon have not been meaningfully tested in any population, and there are few data to support their use versus less expensive, more conventional therapies. In randomized trials, laser angioplasty is not superior to conventional percutaneous transluminal angioplasty and/or stent placement in the superficial femoral artery. Given the substantial additional expense associated with these devices, more evidence of their efficacy is needed before widespread adoption can be justified.

Attempts to use drug-eluting stents in the femoral artery to reduce recurrence rates have failed. However, two randomized controlled trials using paclitaxel-coated balloons in femoral lesions showed lower restenosis rates compared with control balloons. Despite the small number of patients tested, these two trials provide reason for optimism.

Chronic Critical Lower Limb Ischemia

Patients with critical limb ischemia who have extensive necrosis or infectious gangrene or who are nonambulatory may best be served by primary amputation. For other patients with critical limb ischemia, the optimal treatment is prompt revascularization. The therapeutic goal is to reestablish pulsatile, straight-line flow to the distal extremity. Establishment of uninterrupted flow to at least one infrapopliteal vessel (i.e., the anterior or posterior tibial or peroneal arteries) is a prerequisite for wound healing. When treating patients with potential tissue or limb loss, transient restoration of flow to the extremity may effectively heal an ulcer. The healed ulcer usually does not recur, even if restenosis occurs after several months, if there is no recurrent injury.

In patients with critical limb ischemia caused by infrainguinal disease, percutaneous transluminal angioplasty and surgery are comparable as first-line therapies, but angioplasty is less costly and is associated with a lower morbidity.[13] Percutaneous transluminal angioplasty should be tried first if a patient is a candidate for either procedure, particularly if the patient's life expectancy is less than 2 years. Primary stenting with a drug-eluting stent may be preferable to regular angioplasty.[14] compared with percutaneous transluminal angioplasty with "provisional" bailout stenting in patients with occlusions and critical limb ischemia.

PROGNOSIS

Peripheral arterial disease is a major cause of acute and chronic illness associated with impaired functional capacity, reduced quality of life, limb loss, and increased risk of death (Fig. 79-7). Approximately two thirds of patients with peripheral arterial disease have at least one severely diseased coronary artery, and up to one quarter of patients have significant carotid artery stenosis. Consequently, patients with peripheral arterial disease face an increased risk of cardiovascular ischemic events such as myocardial infarction, ischemic stroke, and death. It is estimated that coronary and cerebrovascular adverse events occur two- to four-fold more commonly than do limb adverse events in patients with peripheral arterial disease.

The annual mortality for patients with peripheral arterial disease is about 5%, but it is higher for patients with severe disease. For example, the estimated 1-year mortality rate for patients with critical limb ischemia is 25%,

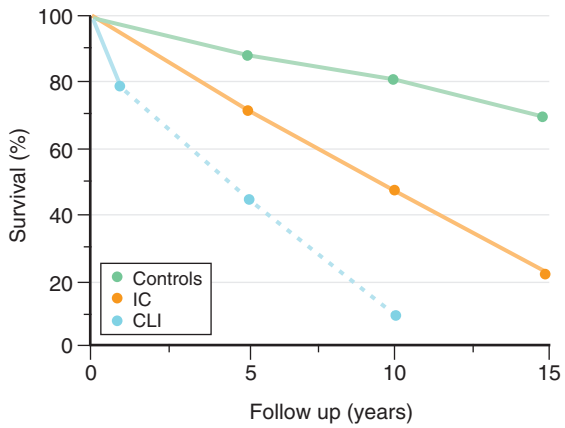

FIGURE 79-7. Survival curve of patients with intermittent claudication (IC) versus critical limb ischemia (CLI). (Modified from Norgren L, Hiatt WR, Dormandy JA, et al. Inter-society consensus for the management of peripheral arterial disease (TASC II). *Eur J Vasc Endovasc Surg.* 2007;33:S1-S75.)

but this can climb to 45% for patients requiring amputation; in contrast, annual mortality for patients with intermittent claudication is only 1 to 2%. For patients presenting with acute limb ischemia, the 30-day amputation rate is as high as 40%, and mortality rates up to 30% have been reported.

Patients with lower extremity claudication should be reassured that the risk of limb loss is low and that claudication usually does not worsen or improve at a rapid rate. Moreover, a history of claudication, by itself, only slightly increases the risk of amputation after 10 years. However, a reduced ABI and diabetes mellitus are associated with the development of ischemic rest pain and ischemic ulceration, which may lead to limb loss. Among patients with peripheral arterial disease, those who have diabetes are 15 times more likely to have an amputation than are patients without diabetes, whose annual amputation rate is about 0.6%.

80 OTHER PERIPHERAL ARTERIAL DISEASES

JEFFREY W. OLIN

LIVEDO RETICULARIS

Livedo reticularis is characterized by a reticular, fishnet, or lacy pattern on the skin of the lower extremities and other parts of the body. This pattern is red or blue and is caused by deoxygenated blood in the surrounding horizontally arranged venous plexus.

Primary or benign livedo reticularis occurs most commonly in young women between the ages of 20 and 40 years. Ulceration generally does not occur with this form of the disease, which may result from vasomotor instability or increased sensitivity (e.g., to cold, stress, tobacco) of the dermal blood vessels. It is intensified by cold exposure and is relieved by rewarming, and it may occur in association with Raynaud's phenomenon. The benign variety of livedo reticularis often needs no treatment other than measures to keep the body as warm as possible.

Secondary livedo reticularis occurs in association with atheromatous embolization (Fig. 80-1), polyarteritis nodosa (Chapter 278), systemic lupus erythematosus (Chapter 274), leukocytoclastic vasculitis (Chapter 278), cryoglobulinemia (Chapter 193), other connective tissue diseases, therapy with amantadine, and various neoplastic, neurologic, or endocrine diseases and in patients receiving large doses of vasopressors such as epinephrine, norepinephrine, and dopamine. Livedo reticularis is also one of the many skin manifestations of the antiphospholipid antibody syndrome (Chapter 179). In patients with secondary livedo reticularis, therapy should be directed at the underlying cause.

Livedoid Vasculopathy

In livedoid vasculopathy or livedoid vasculitis, extensive livedo reticularis surrounds a painful, ischemic-appearing ulceration located on the anterior or posterior portion of the lower leg (Fig. 80-2). Pathologically, thrombosis of the microvasculature occurs, with little or no active inflammatory component. Small doses of tissue plasminogen activator (10 mg intravenously daily for 14 days) may be effective in treating the ulcerations. Atrophie blanche (Fig. 80-3) is a variant of livedoid vasculopathy. These ulcerations generally occur around the ankle or foot. They have a white or yellowish base with poor granulation tissue and are exquisitely painful and difficult to heal.

ATHEROMATOUS EMBOLIZATION

DEFINITION

Atheromatous embolization (cholesterol embolization) refers to the embolization of cholesterol crystals or platelet fibrin aggregates to the extremities or to one or more organs. Atheromatous emboli usually originate from ulcerated or stenotic atherosclerotic plaques or from aneurysms that are primarily in the thoracic or abdominal aorta, iliac artery, or carotid artery.

EPIDEMIOLOGY AND PATHOBIOLOGY

Atheromatous embolization of the kidneys (Chapter 127) is a common histologic finding and may occur in 15 to 30% of patients with severe aortic atherosclerosis or aneurysm of the abdominal aorta. Increasing aortic plaque thickness, protruding aortic atheroma, and mobile aortic atheroma are associated with a high likelihood of atheromatous embolization. Atheromatous embolization may be spontaneous, but it occurs most often after percutaneous coronary, peripheral, or cerebrovascular intervention. Pathologically, biconvex cholesterol crystals lodge in the arterioles and lead to a foreign body reaction in which polymorphonuclear leukocytes, macrophages, and multinucleated giant cells appear several days to several weeks after the inciting event.

CLINICAL MANIFESTATIONS

The most common clinical manifestations are skin changes. These changes occur in more than one third of patients and are generally found in the lower extremities, but they may also be seen in the trunk, over the buttocks, and rarely in the upper extremities. These manifestations include livedo reticularis (embolization to the dermal blood vessels), purple or blue toes (see Fig. 80-1), splinter hemorrhages, gangrenous digits or ulcerations, and nodules in the presence of palpable foot pulses. The pain associated with ischemic lesions is disproportionate to the amount of tissue involvement.

FIGURE 80-2. Livedoid vasculitis. Ischemic ulceration is evident on the posterior portion of the calf, surrounded by a livedoid pattern on the skin.

FIGURE 80-1. Typical livedo reticularis on the lateral portion of the left foot and both heels. The second and fourth toes are cyanotic. These findings are typical of atheromatous embolization, and the fact that both feet are involved indicates a source above the aortic bifurcation. (From Bartholomew JR, Olin JW. Atheromatous embolization. In: Young JR, Olin JW, Bartholomew JR, eds. *Peripheral Vascular Diseases,* 2nd ed. St. Louis: Mosby; 1996.)

FIGURE 80-3. Atrophie blanche. Typical appearance of atrophie blanche. Note the pearly white plaque surrounded by prominent venules and a shallow ulceration. These lesions are quite painful and notoriously difficult to heal.

Atheroembolic renal disease is a small vessel occlusive disease leading to uncontrolled hypertension and advanced or end-stage renal disease. Atheromatous embolization may also involve the gastrointestinal tract and may produce ischemic bowel, with generalized abdominal pain, nausea, vomiting, melena, or hematochezia. Cholesterol emboli to the gallbladder may produce acute gangrenous cholecystitis, whereas emboli to the pancreas can cause acute pancreatitis.

Cardiac manifestations of atheroemboli include angina pectoris (Chapter 71) and myocardial infarction (Chapter 73). Patients may develop amaurosis fugax or blindness caused by retinal artery occlusion. A Hollenhorst plaque (yellow, highly refractile atheromatous material) may be present at the bifurcation of retinal blood vessels. Stroke, headache, confusion, organic brain syndrome, dizziness, and spinal cord infarction can occur. Constitutional signs and symptoms such as fever, weight loss, anorexia, fatigue, myalgia, headache, nausea, vomiting, or diarrhea may suggest necrotizing vasculitis, infection, or malignant disease.

DIAGNOSIS

Atheromatous embolization is frequently overlooked or misdiagnosed. No single laboratory test is diagnostic. Nonspecific findings such as elevation in the erythrocyte sedimentation rate, leukocytosis, or anemia may be present. Increased levels of serum amylase, hepatic transaminases, blood urea nitrogen, or serum creatinine may be noted if the pancreas, liver, or kidney is involved. The urine sediment may be abnormal but is nonspecific. Eosinophilia and eosinophiluria may be present early in the course, and hypocomplementemia has been reported in a small number of series. Biopsy is the most specific way to make the diagnosis, but it is often not required because the clinical findings are so highly suggestive of atheromatous embolization.

A markedly irregular and shaggy aorta may be observed on various imaging techniques. Transesophageal echocardiography may detect mobile, protruding atheroma, which are associated with a very high risk for future embolization.

Atheromatous embolization may mimic vasculitis, such as polyarteritis nodosa or leukocytoclastic vasculitis, or it may suggest an underlying malignant disease, nonbacterial thrombotic endocarditis, subacute bacterial endocarditis, multiple myeloma, antiphospholipid antibody syndrome, or atrial myxoma. A cardiac source of emboli should always be excluded.

TREATMENT Rx

The treatment of atheromatous embolization has three goals: (1) removal of the source of atheromatous material (by surgical exclusion and bypass, percutaneous transluminal angioplasty, stent implantation, or stent grafting), (2) symptomatic care of the end organs in which the emboli are located, and (3) optimal treatment of cardiovascular risk factors (Chapter 51) to prevent myocardial infarction, stroke, and cardiovascular death.

Pain control and local care of ischemic ulcers are critical to the management of patients with atheromatous embolization. Intravenous prostaglandin analogues (iloprost 0.5 to 2.0 ng/kg/minute continuously for 10 to 14 days, followed by 8-hour infusions three times a week for an additional 2 to 3 weeks) may be useful in the healing of ischemic ulcerations and in controlling pain secondary to atheromatous embolization. Patients should be given antiplatelet therapy with aspirin (81 mg/day) and clopidogrel (75 mg/day). Use of anticoagulants such as heparin or warfarin should be avoided unless a compelling reason exists to use this class of drugs. If a vasospastic component is present, a dihydropyridine calcium-channel blocker (amlodipine 2.5 to 10 mg/day or nifedipine extended release 30 to 120 mg/day) may be effective in relieving some of the symptoms. Chemical or surgical sympathectomy or spinal cord stimulators have been helpful for ulcer healing and pain relief in some patients.

Covered stents or stent grafts, which can be inserted in the thoracic or abdominal aorta for aneurysms or occlusive disease, are now the treatment of choice to prevent future embolic events when such approaches are technically feasible. In other cases, surgical bypass therapy is an alternative, although patients who are poor surgical risks may require ligation of the common femoral arteries followed by extra-anatomic bypass, such as axillobifemoral bypass.

PROGNOSIS

Patients with atheromatous embolization generally have advanced atherosclerosis and a poor prognosis. Patients should receive appropriate risk factor modification (Chapter 71) to slow the progression of atherosclerosis and to improve overall cardiac and cerebrovascular morbidity and mortality. Statins may reduce the risk of embolic events.

THROMBOANGIITIS OBLITERANS (BUERGER'S DISEASE)

DEFINITION

Thromboangiitis obliterans (Buerger's disease) is a nonatherosclerotic, segmental inflammatory disease that most commonly affects the small and medium-sized arteries and veins in the upper and lower extremities. The origin of Buerger's disease is unknown, but there is an extremely strong association with tobacco use, and progression of the disease is closely linked to continued tobacco use.

EPIDEMIOLOGY

Buerger's disease has a worldwide distribution, but it is more prevalent in the Middle East, Near East, and Far East than in North America and western Europe. The prevalence of Buerger's disease is decreasing as the consumption of tobacco products declines.

PATHOBIOLOGY

Patients with Buerger's disease may be hypercoagulable, and some patients have anti–endothelial cell antibodies, anticollagen antibodies, circulating immune complexes, and/or impaired endothelial-dependent vasorelaxation. Patients with thromboangiitis obliterans also have an increase in cellular sensitivity to type I and III collagen (normal constituents of human arteries).

In the acute phase of thromboangiitis obliterans, a highly inflammatory thrombus may affect both the arteries and the veins. The lesion is characterized by acute inflammation involving all layers of the vessel wall in association with occlusive inflammatory cellular thrombosis. Around the periphery of the thrombus, one may see polymorphonuclear leukocytes with karyorrhexis, the so-called microabscess that may contain one or more multinucleated giant cells. The acute phase lesion is followed by an intermediate phase characterized by progressive organization of the acute occlusive thrombus in the arteries and veins; a prominent, inflammatory cellular infiltrate may persist within the thrombus. The chronic phase or end-stage lesion is characterized by complete organization of the occlusive thrombus, with extensive recanalization, prominent vascularization of the media and adventitia, and perivascular fibrosis.

CLINICAL MANIFESTATIONS

Classically, Buerger's disease occurs in young male smokers, with the onset of symptoms before age 40 to 45 years; however, 20 to 30% of patients with Buerger's disease may be women. Buerger's disease usually begins with ischemia of the toes, feet, fingers, and hands (Fig. 80-4). As the disease progresses, it may involve more proximal arteries, but involvement of large arteries is unusual.

Patients may present with claudication of the feet, the legs, and occasionally the arms and hands. Foot or arch claudication may be the presenting manifestation and is often mistaken for an orthopedic problem. Seventy-five to 80% of patients present with ischemic rest pain and/or ulcerations. Two or more limbs are always involved, and angiographic abnormalities are consistently found in limbs that are not yet clinically involved. Superficial thrombophlebitis and Raynaud's phenomenon each occur in approximately 40% of patients.

A positive Allen test indicates the distal nature of thromboangiitis obliterans and its involvement of the lower and upper extremities, helping to differentiate it from atherosclerosis. In this test, the physician simultaneously occludes both the radial and the ulnar arteries. When pressure is released from either artery, one should note prompt filling from that artery, with the return of color to the hand. A positive test result occurs when color does not return to the blanched hand.

DIAGNOSIS

No specific laboratory tests aid in the diagnosis of Buerger's disease, but tests should exclude vasculitis, connective tissue diseases, hypercoagulable states, and a proximal source of emboli. On arteriography, the proximal arteries are normal, and the disease is most often infrapopliteal in the lower extremities and distal to the brachial artery in the upper extremities. Multiple vascular occlusions with collateralization around the obstruction (corkscrew collaterals) may occur, similar to what may be seen in other small vessel occlusive diseases such as the CREST syndrome (calcinosis cutis, Raynaud's phenomenon, esophageal motility disorder, sclerodactyly, and telangiectasias) or

FIGURE 80-4. Buerger's disease. Ischemic finger of a young male patient **(A)** and ischemic toe of a 28-year-old woman **(B)** with Buerger's disease.

scleroderma (Chapter 275). However, the arteriographic appearance of Buerger's disease may also be similar to that of systemic lupus erythematosus (Chapter 274), rheumatoid vasculitis (Chapter 272), mixed connective tissue diseases (Chapter 275), and antiphospholipid antibody syndrome (Chapter 179), although the diagnosis of these other diseases can usually be established or excluded by other tests. Because cocaine and cannabis use (Chapter 33) may produce a clinical and angiographic picture identical to that of thromboangiitis obliterans, a toxicology screen may be indicated if the diagnosis in not clear-cut. Patients with Takayasu's arteritis (Chapter 78) or giant cell arteritis (Chapter 279) present with proximal vascular involvement and can readily be distinguished from patients with Buerger's disease.

TREATMENT

Rx

The cornerstone of therapy for thromboangiitis obliterans is the complete discontinuation of cigarette smoking and tobacco use in any form. Patients who stop using tobacco almost always avoid amputation, whereas 40% or more of patients who continue to use tobacco progress to one or more amputations.

In a randomized trial, intravenous iloprost was superior to aspirin at 28 days in relieving rest pain and in healing ischemic ulcerations. At 6 months, 88% of patients receiving iloprost (0.5 to 2.0 ng/kg/minute, maintaining hemodynamic stability for 6 hours daily for up to 28 days) responded to therapy, compared with 21% in the aspirin-treated group; only 6% underwent amputation in the iloprost-treated group, compared with 18% in the aspirin-treated group. Other treatments such as calcium-channel blockers (amlodipine, 2.5 to 10 mg/day or nifedipine extended release 30 to 120 mg/day), antibiotics, and anticoagulants, as well as sympathectomy, are palliative.

Surgical bypass is not a viable option in most patients because they may not have a distal target vessel with which to bypass. Sympathectomy and implantable spinal cord stimulators may help some patients, but iloprost is more effective than lumbar sympathectomy. Stem cell and gene therapy have helped in healing ischemic ulcers and preventing amputation in patients with Buerger's disease. The use of intermittent pneumatic compression (arterial pump device) enhances blood flow to the foot and is useful in relieving rest pain and healing ulcers in patients with small vessel occlusive disease.

VASCULAR DISEASES ASSOCIATED WITH CHANGES IN TEMPERATURE

Raynaud's Phenomenon

DEFINITION

Raynaud's phenomenon is the abrupt onset of a triphasic color (white, blue, and red) response: well-demarcated pallor of the digits progresses to cyanosis with pain and often numbness, followed by reactive hyperemia on rewarming. This vasospastic phenomenon is often precipitated by cold exposure or stress. *Primary Raynaud's phenomenon* denotes patients who have no underlying cause, whereas *secondary Raynaud's phenomenon* is associated with or caused by some other systemic illness or disease process (Fig. 80-5).

EPIDEMIOLOGY

Raynaud's phenomenon is common in patients with connective tissue diseases. Approximately 90% of patients with scleroderma (Chapter 275) experience Raynaud's phenomenon, and it may be a presenting manifestation in many of them. Raynaud's phenomenon is also a component of the CREST syndrome. These patients have small vessel occlusive disease that may lead to digital pitting or ulceration and eventual amputation.

FIGURE 80-5. Raynaud's phenomenon in the acute phase, with severe blanching of the tip of one finger. (From Forbes CD, Jackson WF. *Color Atlas and Text of Clinical Medicine,* 3rd ed. London: Mosby; 2003.)

The β-adrenergic receptor antagonists are most commonly associated with Raynaud's phenomenon because they block the vasodilatory β-receptors and thus leave the vasoconstrictive α-receptors unopposed. Ergotamine preparations, polyvinyl chloride, and several cancer chemotherapeutic agents can also cause Raynaud's phenomenon.

Raynaud's phenomenon occurs frequently in individuals who use vibratory tools such as pneumatic hammers, chain saws, sanders, and grinders. This has been termed the *hand-arm vibration syndrome,* and the prevalence of Raynaud's phenomenon may exceed 90% at 10 years in individuals with heavy exposure. Continued use of vibratory tools can lead to chronic occlusive small vessel disease. The syndrome has also been described in typists, pianists, meat cutters, and sewing machine operators.

Trauma to the distal ulnar artery (several centimeters distal to the wrist) may occur with pounding the palm of the hand, karate, or other activities that traumatize the hypothenar eminence and lead to an aneurysm or pseudoaneurysm of the distal ulnar artery (hypothenar hammer syndrome). Thrombus within the aneurysm may then embolize to the fingers, or the distal ulnar artery may thrombose.

PATHOBIOLOGY

The initial manifestation of Raynaud's phenomenon occurs when the digits turn white as a result of the intense vasoconstriction or spasm of the digital arteries. At this point, blood flow ceases totally, and the digits are often numb and painful. As the arterial vasoconstriction abates, subsequent postcapillary venule constriction causes the blood in the capillaries and veins to become deoxygenated, producing the cyanotic appearance. When rewarming occurs, blood flow is markedly increased due to marked vasodilation, producing reactive hyperemia to the digits (red color).

The pathophysiologic factors operative in Raynaud's phenomenon include vascular, neural, and intravascular abnormalities. Vascular factors include small vessel occlusive disease, such as is seen in scleroderma, and functional abnormalities, such as impaired endothelium-dependent (nitric oxide–mediated) and endothelium-independent vasodilation, reduced production of vasodilators, and increased vasoconstriction. Neural abnormalities include impaired sympathetic nervous system activity that disturbs the balance between vasoconstriction and vasodilation. Intravascular factors such as platelet activation, impaired fibrinolysis, white blood cell activation, reduced red blood cell deformability, and oxidative stress may play important roles in some patients.

TABLE 80-1 DIFFERENTIATING PRIMARY FROM SECONDARY RAYNAUD'S PHENOMENON

CHARACTERISTICS	PRIMARY	SECONDARY
Associated diseases	No	Yes
Age at onset	Younger (<30 yr)	Older (>30 yr)
Nail-fold capillaries	Normal	Large, tortuous with "dropout"
Autoantibodies	Negative or low titers	Frequent
Endothelial cell activation	Yes	Yes
Endothelial damage	No	Frequent
Structural occlusion	No	Yes
Digital gangrene	Rare; only superficial	Common
α_2-Adrenergic activity	High	High
Calcitonin gene-related peptide	Low	Low

From Block JA, Sequeira W. Raynaud's phenomenon. *Lancet.* 2001;357:2042-2048.

CLINICAL MANIFESTATIONS

The signs of Raynaud's phenomenon may include pallor (see Fig. 80-5), cyanosis, and rubor. The triphasic color response occurs in 4 to 65% of patients. Exposure to the cold is the typical precipitating factor, but emotional lability may also cause or exacerbate attacks in some patients. Vasospastic attacks usually occur only in the fingers, but vasospasm can occur in the toes, nose, ears, lips, and other body parts.

In primary Raynaud's phenomenon, the physical examination is normal between attacks. However, in secondary Raynaud's phenomenon, pits or ulcerations on the fingertips may be present in patients with scleroderma, CREST syndrome, or thromboangiitis obliterans. An abnormal Allen test on physical examination indicates fixed arterial obstruction.

DIAGNOSIS

The diagnosis of Raynaud's phenomenon is not difficult when it is based on the patient's description of the attacks. Patients with persistent cyanosis or persistent hyperemia generally have some condition other than Raynaud's phenomenon. In primary Raynaud's phenomenon, vasospastic attacks are precipitated by exposure to the cold or emotional stimuli; there is bilateral involvement of the extremities without gangrene; and, after a careful search, no evidence indicates an underlying systemic disease that could be responsible for the vasospastic attacks (Table 80-1).

To evaluate systemic illnesses, a serologic evaluation should include a complete blood cell count, multiphasic serologic analysis, urinalysis, erythrocyte sedimentation rate, C-reactive protein, antinuclear antibody, extractable nuclear antigen (anti-Smith and ribonuclear protein), anti-DNA, cryoglobulins, complement, anticentromere antibodies, and SCL70 scleroderma antibodies. In addition, nail-fold capillaroscopy can be performed to help confirm a diagnosis of CREST syndrome or scleroderma in patients whose symptoms are not clear. Abnormal nail-fold capillaroscopy indicates that the patient does not have primary Raynaud's phenomenon.

The noninvasive vascular laboratory (pulse volume recordings) is useful in identifying the degree of digital arterial occlusive disease (fixed ischemia) and in predicting whether ischemic ulcerations on the digits will heal. Arteriography is not routinely performed.

TREATMENT

Rx

In patients with mild vasospastic attacks, reassurance about the benign nature of the disease and instructions on how to prevent attacks are often all that is needed. Patients should limit their exposure to the cold and should dress warmly and protect not only the extremities but also the entire body. Mittens are better than gloves for keeping the hands warm. Patients need to be especially careful when they handle cold objects. Hand- and foot-warming devices (battery operated or chemical) may be helpful. Smoking should be avoided because nicotine causes intense vasoconstriction. β-Blocking agents may exaggerate the symptoms of Raynaud's phenomenon. Conditioning techniques and biofeedback are sometimes helpful in controlling vasospastic episodes.

The dihydropyridine calcium-channel blockers are the most effective pharmacotherapeutic agents for Raynaud's phenomenon.[B] Patients who have infrequent attacks may benefit from a short-acting calcium-channel blocker such as nifedipine 10 to 20 mg, given 30 minutes to 1 hour before cold exposure. When vasospasm occurs more frequently, the extended-release preparations of nifedipine (30 to 120 mg/day) or amlodipine (2.5 to 10 mg/day) should be used. α_1-Adrenergic receptor antagonists such as prazosin (1 to 10 mg twice daily) or terazosin (2 to 20 mg/day) are also highly effective in decreasing the severity, frequency, and duration of vasospastic attacks. Nitroglycerin or its analogues can be used topically (0.1 to 0.8 mg/hour),[B] whereas prostacyclin can be given intravenously (0.5 ng/kg/minute for 6 hours/day for 21 days).[B] Dual endothelin receptor blockade (e.g., bosentan 62.5 to 125 mg twice daily) has been beneficial in randomized trials.[C] Angiotensin-converting enzyme inhibitors, angiotensin receptor blockers, phosphodiesterase-5 inhibitors, niacin, and papaverine are not of proven benefit. Several reports have suggested a beneficial effect from selective serotonin reuptake inhibitors such as fluoxetine (20 to 40 mg/day). Small case series suggest that cilostazol (100 mg twice daily, 30 minutes before breakfast and 30 minutes before dinner) may improve ulcer healing in patients with secondary Raynaud's phenomenon. L-Arginine (2 to 8 g/day) and sildenafil (50 mg twice daily) have been used with variable success.

Although sympathectomy may be beneficial in the short term, with about a 50% improvement rate, the vasospastic attacks may recur in 6 months to 2 years. Some patients with severe disease have had success with digital sympathectomy.

PROGNOSIS

The prognosis in patients with primary Raynaud's phenomenon is excellent. No mortality is associated with this condition. In a long-term study involving 307 patients with primary Raynaud's phenomenon, 38% had stable disease, 36% were improved, 16% were worsened, and the syndrome disappeared in 10%. The prognosis associated with secondary Raynaud's phenomenon depends on the underlying condition that caused it.

Pernio (Chilblains)

DEFINITION AND EPIDEMIOLOGY

Pernio is a Latin word that means "frostbite"; its synonym *chilblains* is an Anglo-Saxon term that means "cold sore." It is a localized inflammatory lesion of the skin caused by an abnormal response to the cold. Whereas in Raynaud's phenomenon there is acute and readily reversible vasospasm, in pernio the vasospasm is more prolonged. Pernio is frequently encountered in the temperate, humid climates of northwestern Europe and in the northern United States.

PATHOBIOLOGY

Pernio develops in susceptible individuals who are exposed to nonfreezing cold. The pathologic changes include edema of the papillodermis, vasculitis characterized by perivascular infiltration (with lymphocytes) of the arterioles and venules of the dermis, thickening and edema of the blood vessel walls, fat necrosis, and a chronic inflammatory reaction with giant cell formation.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Pernio most commonly occurs in young women between the ages of 15 and 30 years, but it may occur in older individuals or in children. Acute pernio may develop 12 to 24 hours after exposure to the cold. Single or multiple erythematous, purplish, edematous lesions appear, accompanied by intense itching or burning. These lesions may have a yellowish or brownish discoloration and may be associated with some flaking. They tend to affect the toes and dorsum of the proximal phalanges. The lesions of acute pernio are usually self-limited, although they may lead to recurrent disease. The arterial circulation is normal on physical examination and in the noninvasive vascular laboratory. Chronic pernio occurs when repeated exposure to the cold results in the persistence of lesions, with subsequent scarring and atrophy. Characteristically, the lesions begin in the fall or winter and disappear in the spring or early summer. In advanced cases, the seasonal variation may disappear, and chronic occlusive vascular disease may develop.

In the typical form, the patient develops violet or yellow-brown blisters and shallow toe ulcers that burn and itch (Fig. 80-6). The differential diagnosis of pernio includes recurrent, erythematous, nodular, and ulcerative lesions such as erythema induratum, nodular vasculitis, erythema nodosum, and cold panniculitis. The skin lesions of pernio may resemble those of atheromatous embolization (see earlier).

FIGURE 80-6. Pernio on the toes of the right foot. The lesions on the second, third, and fourth toes are the typical red, brown, and yellow scaling lesions. The lesion on the fifth toe can be confused with atheromatous embolization.

FIGURE 80-7. Frostbite of the hand in a mountaineer. On rewarming, the hand became painful, red, and edematous, with signs of probable gangrene in the fifth finger. (From Forbes CD, Jackson WF. *Color Atlas and Text of Clinical Medicine,* 3rd ed. London: Mosby; 2003.)

PREVENTION AND TREATMENT

Rx

Prevention is the best form of therapy. Cold exposure should be minimized as much as possible. In randomized trials, nifedipine (20 to 60 mg/day)■ and pentoxifylline (400 mg three times daily)■ reduce pain and facilitate the healing process. The severe itching may be treated with local application of an antipruritic agent.

Acrocyanosis

Acrocyanosis, which is a persistent blue or cyanotic discoloration of the digits, occurs most commonly in the hands and may worsen with exposure to cold and improve with rewarming. The primary form is a benign cosmetic condition, but it may also be seen in patients with connective tissue diseases, thromboangiitis obliterans, and diseases associated with central cyanosis. The exact pathophysiologic abnormality is not clear, but it may be vasospasm in the cutaneous arteries and arterioles, with compensatory dilation and oxygen desaturation in the postcapillary venules.

Ulceration or tissue loss is unusual, and the overall prognosis is excellent. Patients should be advised to keep their entire body and extremities warm. Drugs such as α-adrenergic blocking agents (prazosin 1 to 10 mg twice daily or terazosin, 2 to 20 mg/day) or calcium-channel blockers (amlodipine 2.5 to 10 mg/day or nifedipine extended release 30 to 120 mg/day) may be helpful.

Frostbite

EPIDEMIOLOGY AND PATHOBIOLOGY

Frostbite is the freezing of tissues resulting from exposure to cold. It may occur in above-freezing temperatures under circumstances such as wetness, strong wind, or high altitude.

A person's response to cold is aimed at conserving the core (internal body) temperature as well as the viability of the extremities. Heat loss is reduced by peripheral vasoconstriction caused by sympathetic stimulation and catecholamine release. Maintenance or augmentation of body heat is accomplished by muscular activity such as shivering. However, the heat production from shivering cannot be sustained for more than a few hours because of the depletion of glycogen, which is the source of heat during shivering. The extremities are also protected by the "hunting reaction," which consists of irregular, 5- to 10-minute cycles of alternating vasoconstriction and vasodilation that protect the extremities against excessive sustained vasoconstriction with minimal loss of internal body temperature. However, when the body is exposed to cold of a magnitude or a duration that threatens the internal body temperature, this mechanism fails. Because the disruption of core temperature is more deleterious to the body than is peripheral vasoconstriction, conservation of core temperature takes precedence over rewarming of the extremities, and the hunting response is replaced by continuous and more intense vasoconstriction that promotes frostbite by means of ice crystal formation, cellular dehydration, and thrombosis of the microvasculature.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Soon after exposure to the cold, pain develops and gradually progresses to numbness; the frozen part turns white because of intense vasoconstriction (Fig. 80-7). With rewarming or thawing, the circulation is restored, and the affected parts become hyperemic. Edema may first occur within hours of thawing and persist for days or weeks. Blisters appear within the first 24 hours and are reabsorbed within 1 to 2 weeks, after which a black eschar may persist. Overactivity of the sympathetic nervous system is manifested by hyperhidrosis or a burning sensation.

Seventy percent of frostbite victims develop chronic sequelae, including cold sensitivity, pain, and sensory disturbances, often resembling complex regional pain syndrome (Chapter 428). Frostbite arthritis may occur in particularly severe cases.

It is important to establish the depth of the frostbite and determine whether the tissue is viable. This may not be obvious on initial clinical examination; it is usually determined weeks or months after the cold injury, when the demarcation zone appears and the dead tissue is sloughed.

TREATMENT

Rx

In mild cases of frostbite, the only treatment necessary may be daily whirlpool baths and bedrest. However, treatment of deep frostbite should be considered a medical emergency because the early institution of therapy may reduce the amount of tissue loss. Thawing, the mainstay of therapy, should not be implemented if the patient may be exposed to cold again, because refreezing of thawed tissue promotes further tissue damage. Walking on a frozen limb produces substantially less damage than walking on a thawed limb.

After the patient's transfer to a medical facility, frozen tissue should be rapidly rewarmed in a water bath of 40 to 42° C (104 to 108° F) for 15 to 30 minutes until complete thawing has occurred. After thawing, reappearance of normal color signifies the reestablishment of blood flow. Thawing is often a painful process and may require the administration of narcotics.

After thawing, the extremity should be cleansed twice daily in a whirlpool bath with an aseptic solution at 35 to 37° C (95 to 99° F). Care should be taken to prevent and treat secondary infections. Tetanus prophylaxis should be administered. A frostbite protocol consisting of débridement of clear blisters with a topical application of aloe vera, oral ibuprofen, and daily hydrotherapy is highly effective. An important principle is to avoid early débridement or amputation, which is indicated only when infected gangrene or generalized sepsis occurs.

ERYTHROMELALGIA

DEFINITION AND EPIDEMIOLOGY

Erythromelalgia literally means "red, painful extremities." It may be classified as primary (or idiopathic) or secondary. The primary form may be nonfamilial or familial. Secondary erythromelalgia is associated with other diseases, the most common being myeloproliferative disorders such as polycythemia vera and essential thrombocythemia. Other diseases associated with secondary erythromelalgia include hypertension, diabetes, rheumatoid arthritis, gout, spinal cord disease, multiple sclerosis, systemic lupus erythematosus, cutaneous vasculitis, and viral infection; it also may result from therapy with various drugs (e.g., nifedipine, nicardipine, verapamil, bromocriptine, pergolide).

PATHOBIOLOGY

Families with autosomal dominant erythromelalgia have demonstrated mutations in the sodium channel $Na_v1.7$, which is selectively expressed

within the nociceptive dorsal root ganglion and sympathetic ganglion neurons. The histologic features vary from normal findings to arterial occlusion with thrombus formation.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Erythromelalgia is characterized by the clinical triad of erythema, burning pain, and increased temperature, usually of the extremities. The feet, especially the soles, are more commonly involved than the hands. The peripheral pulses are generally normal in the primary type and variable in secondary erythromelalgia. The symptoms may occur in "attacks" that last for minutes to hours or occasionally days and are precipitated by a warm environment. Exercise and dependency tend to exacerbate symptoms. Patients seek relief by exposing the affected extremity to a cooler environment, such as placing it in cold water, walking on a cold floor barefoot, or running an air conditioner even in the winter. This response often leads to a cold-induced vascular injury superimposed on the erythromelalgia. Erythromelalgia may precede the clinical appearance of a myeloproliferative disorder by several years, so patients older than 30 years should be monitored periodically with blood cell counts.

TREATMENT

Rx

The treatment of erythromelalgia is often difficult and frustrating. Symptoms can be so debilitating that they lead to suicide. In secondary erythromelalgia, treatment of the underlying disease (phlebotomy in patients with polycythemia vera, and normalization of the platelet count in patients with thrombocythemia) may relieve the symptoms. Aspirin (81 to 325 mg/day) is the most effective treatment available, particularly for patients with erythromelalgia secondary to myeloproliferative disorders. Other therapies with variable success in case reports include methysergide, ephedrine, nonsteroidal anti-inflammatory drugs, phenoxybenzamine, nitroglycerin, sodium nitroprusside, corticosteroids, and surgical sympathectomy. Lidocaine transdermal patches (Lidoderm) on the feet and thalamic stimulation have also been used anecdotally.

POPLITEAL ARTERY ENTRAPMENT SYNDROME

In popliteal artery entrapment syndrome, the popliteal artery is compressed by a congenital anatomic abnormality or an abnormal muscle or fibrous band. In the most common abnormality, the medial head of the gastrocnemius muscle compresses the popliteal artery and causes its medial deviation.

The clinical presentation consists of a healthy, "athletic-type" patient complaining of typical claudication symptoms in the absence of premature atherosclerosis. Disappearance of the pulse with passive dorsiflexion of the foot or active plantar flexion against resistance may suggest the diagnosis. Duplex ultrasound may help, and computed tomography or magnetic resonance imaging can confirm the diagnosis. On arteriography, the characteristic finding is medial deviation of the popliteal artery with post-stenotic dilation. Other diseases that can cause mid-popliteal occlusion include cystic adventitial disease, thrombosed popliteal artery aneurysm, and atherosclerosis of the superficial femoral and popliteal arteries. The primary treatment of popliteal artery entrapment syndrome is surgical resection of the abnormal muscle or fibrous band.

CYSTIC ADVENTITIAL DISEASE

In cystic adventitial disease, gelatinous fluid accumulates in an arterial wall cyst, and the cyst encroaches on the vessel lumen, with resulting stenosis or occlusion. The cyst arises in the outer portion of the media or subadventitial layer, most commonly in the popliteal artery. Cystic adventitial disease is an isolated lesion not associated with a systemic process, and the precise pathophysiologic mechanism is unknown.

The disease predominates in men, with an approximate male-female ratio of 5 : 1, and the mean age at diagnosis is about 45 years. Claudication is the most frequent symptom. The pulses may disappear on flexion of the knee (Ishikawa's sign). However, if the artery is occluded, no pulses are palpable.

Pulse volume recordings may show the characteristic decrease in blood pressure and the change in waveform configuration in the affected limb. A perivascular cystic structure may be visualized on duplex ultrasound, computed tomography, or magnetic resonance imaging. Computed tomography–guided needle aspiration can partially but usually not completely remove the highly viscous and gelatinous fluid. Surgical resection is indicated when claudication interferes with a patient's lifestyle or ischemic rest pain is present.

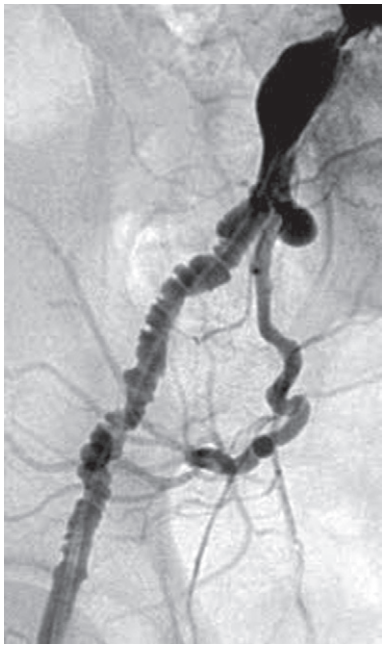

FIGURE 80-8. Fibromuscular dysplasia. Note the "string of beads" or "accordion" appearance in the external iliac artery. This radiographic appearance is diagnostic of fibromuscular dysplasia of the medial type. Also note the aneurysm proximal to the area of dysplasia.

FIBROMUSCULAR DYSPLASIA OF THE EXTREMITIES

Although fibromuscular dysplasia (in particular, medial fibroplasia) is most common in the renal and carotid arteries (Chapters 67 and 127), it may also occur in peripheral arteries of the extremity (iliac, superficial femoral, popliteal, tibial, subclavian, axillary, radial, and ulnar). These lesions may be asymptomatic, or they may produce a difference in blood pressure between the two limbs, with paresthesias, claudication, or critical limb ischemia.

The typical arteriographic appearance of a "string of beads" is virtually pathognomonic of medial fibroplasia (Fig. 80-8). Long, smooth areas of narrowing are characteristic of intimal fibroplasia, but they may also be seen in Takayasu's arteritis (Chapter 78) and giant cell arteritis (Chapters 78 and 279).

Therapy should be reserved for patients with lifestyle-interfering claudication or critical limb ischemia. Under most circumstances, percutaneous balloon dilation is the treatment of choice.

81 PERIPHERAL VENOUS DISEASE

JEFFREY GINSBERG

DEEP VEIN THROMBOSIS

DEFINITION

Deep vein thrombosis (DVT), which is the most important disease affecting the peripheral veins, has an estimated annual incidence of 0.1% in whites. Most pulmonary emboli (Chapter 98) arise from DVT of the legs. In fact, DVT and pulmonary embolism are usually considered different clinical manifestations of one disease, venous thromboembolism (VTE), because up to 50% of patients who present with proximal (popliteal vein or more proximal) DVT have abnormal lung scans suggestive of clinically silent pulmonary emboli, whereas up to 90% of patients with proven pulmonary emboli have DVT, even though only 15% of them have leg symptoms. For the most part, the cornerstones of management of DVT and pulmonary embolism are the same: immediate and long-term anticoagulation.

Superficial thrombophlebitis consists of thrombosis and inflammation of one or more superficial veins. Provided the associated thrombus has not extended into the deep veins, affected patients have a negligible risk for development of pulmonary emboli and can often be effectively managed conservatively with ice, elevation, and anti-inflammatory medication.

EPIDEMIOLOGY

In nonpregnant patients, DVT usually originates in one of the distal or calf veins, where it has little or no potential to cause clinically important pulmonary emboli. The true incidence of calf vein thrombosis is not known because many affected patients remain asymptomatic while the thrombus forms and spontaneously resolves. On the basis of results of studies of *symptomatic* patients with suspected DVT, about 10 to 25% actually have a diagnosable DVT, of whom about 15% have isolated calf DVT. Approximately one fourth of these thrombi that are initially isolated to a calf vein subsequently extend into the proximal veins, usually within 1 week of presentation, where they *then* have the potential to cause pulmonary emboli.

In pregnancy, most (~90%) thrombi occur in the deep veins of the left leg and frequently involve the ileofemoral veins but not the calf or popliteal veins. These findings suggest an anatomic predisposition to left leg ileofemoral DVT, which may be a result of compression of the left iliac vein by the fetus, an exaggeration of the "obstruction" that occurs where the right iliac artery crosses the left iliac vein, and an increase in venous webs at the left iliac vein (May-Thurner syndrome). These observations strongly suggest that most if not all of the increase in VTE during pregnancy is attributable to the increase in left iliac DVT.

From a clinical perspective, risk factors can be subdivided by duration, that is, transient and finite duration (e.g., fractured fibula treated with plaster immobilization) compared with permanent or long-term duration (e.g., congenital antithrombin deficiency, metastatic cancer), and according to the magnitude of the risk, that is, major (hip or knee replacement surgery) or minor (long-distance air travel, use of oral contraceptives). Classification of patients according to the presence or absence and type of risk factor is predictive of the risk of recurrence after a prolonged (≥3 months) course of anticoagulant therapy and provides key information that helps determine the optimal duration of anticoagulant therapy. Patients in whom DVT develops in association with a major risk factor that has resolved have a much lower risk of recurrence after a 3-month course of anticoagulants than do patients whose DVT was associated with a transient minor risk factor that has resolved or patients whose DVT was apparently idiopathic or associated with an ongoing risk factor.

PATHOBIOLOGY

Virchow's triad of hypercoagulability, venous stasis, and injury to the vessel wall provides a model for understanding many of the risk factors that lead to the formation of thrombosis. For example, in patients who have total hip or knee replacement surgery, there is venous endothelial injury caused by surgery, venous stasis due to perioperative immobilization, and hypercoagulability as a result of postoperative fibrinolytic shutdown. In other patients, an identifiable "thrombophilia" or "tendency to clot," such as congenital antithrombin (formerly antithrombin III) deficiency or the presence of factor V Leiden (Chapter 179), combined with use of oral contraceptives results in DVT in women of childbearing age. However, a relatively high proportion of patients have unexplained DVT without "clinical" risk factors that cause endothelial damage or venous stasis or identifiable thrombophilias that cause hypercoagulability. Undoubtedly, some of these patients have yet to be determined thrombophilias, but the DVT currently is labeled idiopathic.

CLINICAL MANIFESTATIONS

The clinical features of lower extremity DVT include leg pain, tenderness, swelling (Fig. 81-1), palpable cord, discoloration, venous distention, prominence of the superficial veins, and cyanosis. In most patients in whom DVT is clinically suspected, the symptoms and signs are nonspecific, and DVT is confirmed in less than 50% of cases. Conversely, patients with relatively minor symptoms and signs may have extensive DVT.

In some patients, DVT may be asymptomatic, but the patient will present with pulmonary embolism. Conversely, pulmonary embolism occurs in 50% of patients with objectively documented proximal leg vein thrombosis, but many of the emboli are asymptomatic. Usually, only part of the thrombus embolizes, so 50 to 70% of patients with angiographically documented pulmonary emboli have detectable DVT of the legs at the time of initial evaluation.

DIAGNOSIS

By itself, clinical diagnosis of DVT is inaccurate because no individual symptom or sign is sufficiently sensitive or specific for the diagnosis to be made or excluded. Clinical assessment can categorize patients according to their pretest probability of DVT with reasonable accuracy. By combining a validated prediction rule (Table 81-1) to assess this pretest probability with the results of noninvasive tests, diagnostic accuracy can be improved, thereby often limiting or eliminating the need for further investigation (Fig. 81-2).

FIGURE 81-1. Deep vein thrombosis (DVT) presenting as an acutely swollen left leg. Note the dilation of the superficial veins. The leg was hot to the touch, and palpation along the line of the left popliteal and femoral veins caused pain. Less than 50% of DVTs present in this way, and other conditions may mimic DVT, so further investigation is always indicated. Note the coincidental psoriatic lesion below the patient's right knee. (From Forbes CD, Jackson WF. *Color Atlas and Text of Clinical Medicine*, 3rd ed. London: Mosby; 2003.)

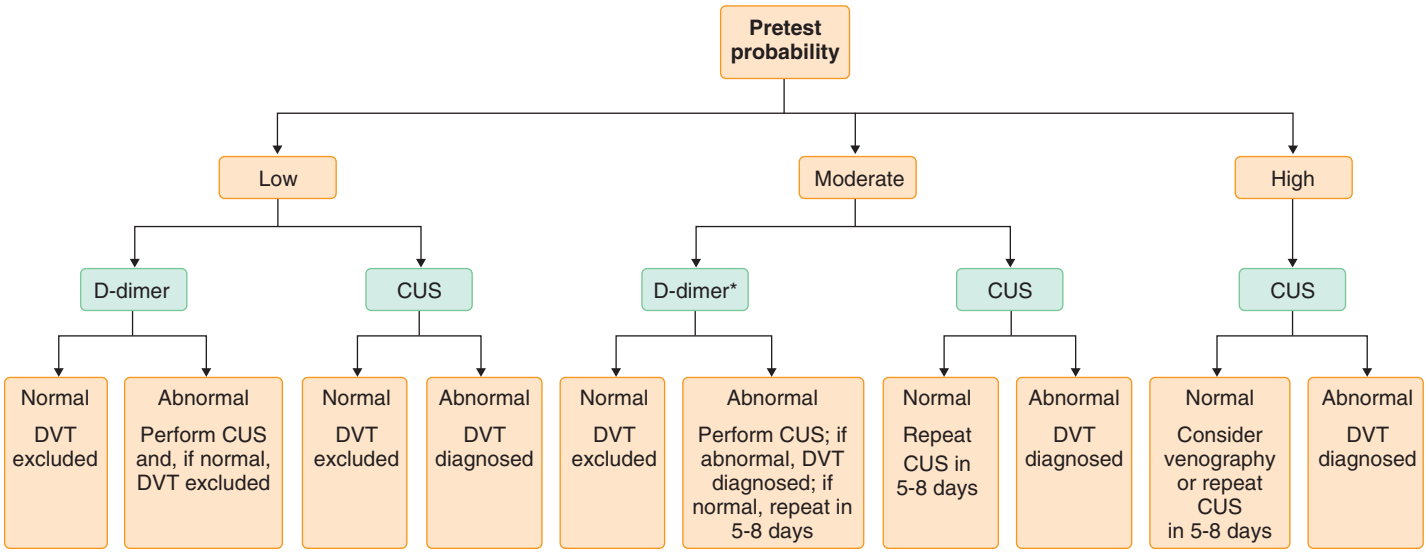

FIGURE 81-2. Diagnostic algorithm for suspected deep vein thrombosis. This algorithm uses evaluation of pretest probability based on a clinical prediction rule (see Table 81-1) and D-dimer testing to complement compression ultrasonography (CUS). The *asterisk* indicates use of a highly sensitive (>95%) D-dimer.

TABLE 81-1 PREDICTION RULE FOR DEEP VEIN THROMBOSIS

CLINICAL CHARACTERISTIC	SCORE*
Active cancer (treatment ongoing within previous 6 mo or palliative)	1
Paralysis, paresis, or recent plaster immobilization of the lower extremities	1
Recent bed rest of >3 days or major surgery within 3 mo requiring anesthesia	1
Localized tenderness of the deep veins of the leg	1
Entire leg swollen	1
Calf swelling of >3 cm larger than asymptomatic side measured 10 cm below tibial tuberosity	1
Pitting edema confined to the symptomatic leg	1
Collateral superficial veins (not varicosed)	1
Previously documented deep vein thrombosis	1
Alternative diagnosis as likely as or more likely than deep vein thrombosis	−2

*A score of 0 or less indicates low probability, 1 or 2 indicates moderate probability, and 3 or more indicates high probability.
Modified from Wells PS, Anderson DR, Bormanis J, et al. Value of assessment of pretest probability of deep-vein thrombosis in clinical management. *Lancet.* 1997;350:1795-1798.

FIGURE 81-3. Abnormal venogram demonstrates a persistent (two or more different views) intraluminal filling defect in the popliteal vein.

Imaging

Contrast Venography

Ascending contrast venography remains the "gold standard" for diagnosis, but because of its expense, discomfort to the patient, and potential for adverse experiences, venography is currently indicated in symptomatic patients only when diagnostic uncertainty persists after noninvasive testing or if noninvasive testing is unavailable. A constant intraluminal filling defect is diagnostic of acute thrombosis (Fig. 81-3), and DVT can essentially be excluded in patients who have a normal, adequately performed venogram. Minor side effects of local pain, nausea, and vomiting are not uncommon, whereas more serious adverse reactions, such as bronchospasm, are rare; however, venography itself can also induce DVT.

Compression Ultrasonography

Compression venous ultrasonography is currently the most widely used noninvasive test for suspected DVT because of its accuracy in detection of thrombus involving the popliteal or more proximal veins; absence of compressibility (Fig. 81-4) of the proximal leg veins on ultrasonography has a sensitivity of 97% and a specificity of 96% for symptomatic patients with suspected DVT. Thus, the finding of a noncompressible venous segment, particularly in the popliteal or common femoral vein, has a high positive predictive value for DVT in symptomatic patients and is an indication for treatment. Of patients with symptoms suggestive of DVT but with normal findings on initial ultrasound examination of the proximal veins, about 15% will have undetected isolated calf DVT; progression into the proximal veins occurs in a minority of patients, usually within a week of presentation. Isolated calf DVT that does not extend into the proximal veins is rarely if ever associated with clinically important pulmonary embolus. The sensitivity of ultrasonography for calf DVT is well below 90%, with a wide range of accuracies reported for different populations of patients.

Imaging of the calf veins is time-consuming and potentially inaccurate. Rather, two-point (common femoral and popliteal) or three-point (two-point plus the calf "trifurcation") ultrasonography should be performed and, if the results are normal, repeated in 1 week after the initial examination. This approach will identify the 20 to 25% of patients who have had proximal

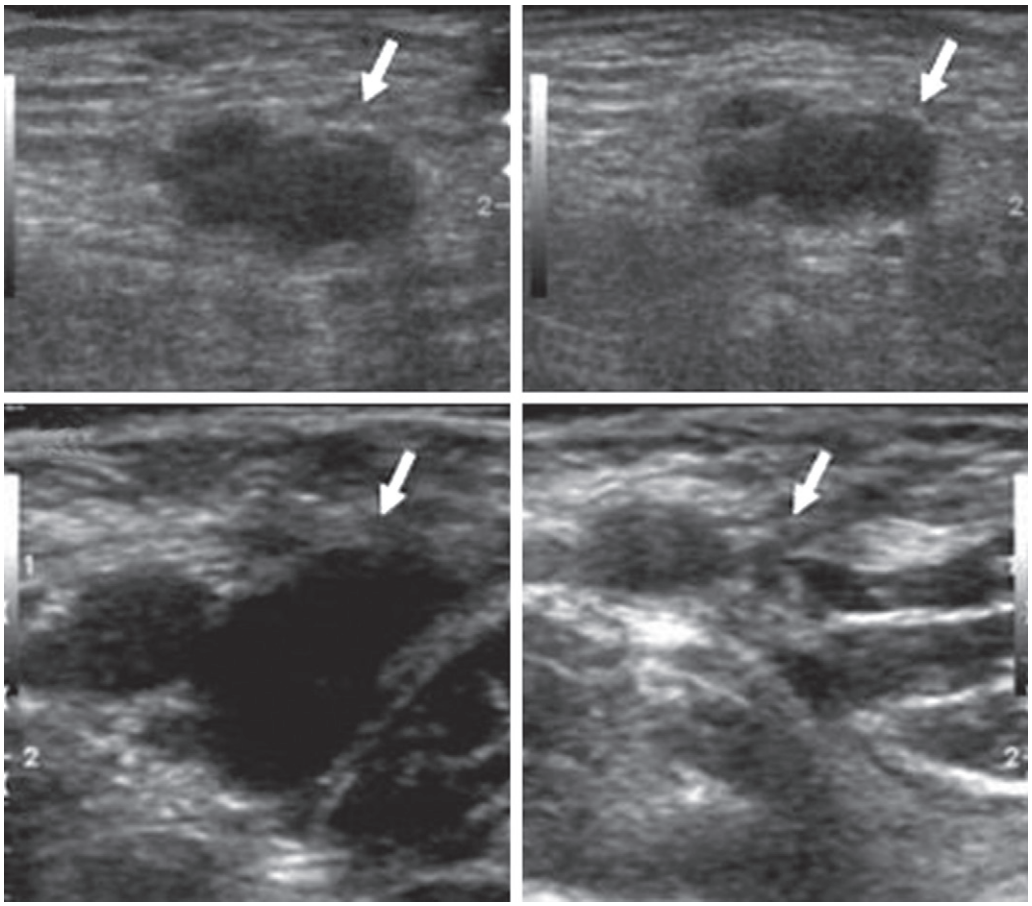

FIGURE 81-4. Compression venous ultrasonography demonstrates thrombosis of the popliteal vein. The sonograms in the *top row* demonstrate examination without *(left side)* and with *(right side)* gentle probe compression of the skin overlying the popliteal vein. The lack of compressibility is diagnostic of deep vein thrombosis. The *bottom row* shows analogous views of the femoral vein, which shows partial compressibility.

extension of distal clot in the calf veins. If the repeated ultrasound examination 1 week later also is normal, further investigation and therapy can be safely withheld. In centers with highly skilled operators, however, one normal ultrasound of the proximal and calf veins at presentation may be sufficiently accurate to exclude clinically important DVT and eliminate the need for follow-up testing, especially in patients with either a normal D-dimer test result or a low clinical pretest probability (see later).

Magnetic Resonance Venography

Magnetic resonance venography (MRV), which uses the difference in magnetic resonance signals between flowing blood and stationary clot, has a high sensitivity and specificity for proximal DVT. Recent interest has focused on magnetic resonance for direct imaging of the thrombus because a thrombus produces a positive image without the use of contrast material owing to its methemoglobin content. Although MRV is undoubtedly accurate in diagnosing and excluding DVT, it is expensive and not readily available in most centers outside of the United States.

Laboratory Findings

D-Dimer

D-dimer is a plasma protein specifically produced after lysis of cross-linked fibrin by plasmin. Levels are almost invariably elevated in the presence of acute VTE, so measurement of D-dimer levels is a sensitive test for recent DVT and pulmonary emboli. Unfortunately, numerous nonthrombotic conditions, including sepsis, pregnancy, surgery, and cardiac or renal failure, can also cause elevated levels. As a result of this nonspecificity, the role of D-dimer assays is limited to helping exclude VTE when levels are not raised.

Laboratory tests for D-dimer use enzyme-linked immunosorbent assay (ELISA) or agglutination techniques, both involving specific monoclonal antibodies. Sensitivity and cut points vary among assays, so results cannot be generalized. Highly sensitive tests, consisting of new rapid ELISA or immunoturbidimetric assays, have sensitivities of 95 to 100% for acute VTE but in general have low specificities (20 to 50%). Moderately sensitive tests, of which the SimpliRED red cell agglutination assay is the main example, have a reported sensitivity of approximately 90% but a higher specificity (~75%) for acute VTE. Serial two-point ultrasonography plus D-dimer is as good as whole-leg color-coded Doppler ultrasonography for diagnosing suspected symptomatic DVT.■ Highly sensitive D-dimer assays can be employed as "stand-alone tests" for exclusion of DVT, but clinicians must be aware of the accuracy of the assay in their institution before using the D-dimer assay to make management decisions. A point-of-care D-dimer test can help exclude DVT, which is rare in patients with less than four points using the following scale: male sex, use of hormonal contraceptives, active cancer in prior 6 months, surgery in prior month, absence of leg trauma, distention of collateral veins (1 point each); greater than 3-cm difference in calf circumference (2 points), and abnormal D-dimer assay (6 points).

D-dimer measured after a 3-month (or longer) initial treatment with warfarin also appears to be predictive of recurrent or persistent DVT. In addition, an elevated D-dimer level 1 month after stopping warfarin predicts a clinically and statistically significant higher recurrence rate than is seen in patients in whom the D-dimer levels were normal or low.

Algorithms for Diagnosis of Deep Venous Thrombosis

A number of diagnostic algorithms have been tested in prospective management trials (see Fig. 81-2).

Clinical Assessment and Venous Ultrasonography

It is safe to perform only a single ultrasound examination in patients with a low pretest probability by a validated clinical prediction rule (Table 81-2). Other patients require serial ultrasonographic testing if only clinical assessment and ultrasonography are used. Venography should be considered in patients with a high pretest probability and normal compression ultrasonography because the probability of DVT is still approximately 20% in such patients.

Clinical Assessment, D-Dimer Testing, and Venous Ultrasonography

Diagnostic imaging and treatment can be safely withheld in patients who have (1) a low pretest probability based on a validated clinical prediction rule and a negative value on a moderately sensitive D-dimer assay or (2) a low or intermediate pretest probability and a negative value on a highly sensitive D-dimer assay. Patients with a high pretest probability require ultrasonography regardless of the D-dimer result. A normal D-dimer result with use of either a moderately or highly sensitive assay can safely obviate the need for

repeated imaging in patients with normal findings on the initial ultrasound examination.

Differential Diagnosis

A number of conditions can mimic DVT (see Table 81-2), but DVT often can be excluded only by accurate diagnostic testing. In some patients, however, the cause of pain, tenderness, and swelling remains uncertain.

Suspected Recurrent Deep Venous Thrombosis

Approximately 10% of patients with unprovoked VTE will experience recurrent thromboembolism in the first year after ceasing anticoagulant therapy. In addition, many patients will have positional leg swelling and pain early during treatment as a result of venous outflow obstruction or later (≥6 months after diagnosis) because of the post-thrombotic syndrome when venous valvular incompetence is manifested. These and other nonthrombotic disorders can produce symptoms that are similar to acute recurrent DVT, so accurate diagnostic testing to confirm recurrence is mandatory. However, residual venous abnormalities are common after an initial event; persistent abnormalities are seen on compression ultrasonography in approximately 80% of patients at 3 months and 50% of patients at 1 year after a documented proximal DVT. Therefore, comparison with previous ultrasound images is required in patients with suspected recurrence. Although an increase in diameter of 4 mm or more in the compressed vein strongly suggests recurrent DVT, a new noncompressible proximal venous segment is the most reliable criterion for the diagnosis of recurrence. When compression ultrasonography is inconclusive, venography should be considered; a new intraluminal filling defect is diagnostic of acute DVT, and the absence of a filling defect excludes the diagnosis. Nonfilling of venous segments may mask recurrent DVT and is considered a nondiagnostic finding. A normal D-dimer test result is useful in excluding recurrent DVT.

Pregnancy

Symptoms of leg pain or swelling, shortness of breath, and atypical chest pain are common during pregnancy, so objective testing is needed to diagnose VTE. As in nonpregnant patients, compression ultrasonography is the initial test of choice. A normal D-dimer test is also reassuring in excluding DVT. Because isolated iliac and iliofemoral DVT is more common in pregnancy and has the potential to be missed by ultrasonography, venography should be considered when clinical suspicion is high even if the findings of the initial ultrasound examination are normal. MRV, which is sensitive for pelvic DVT, may be useful in this circumstance.

TREATMENT

Rx

Anticoagulant therapy, which is the treatment of choice in most patients with VTE, reduces the extension and recurrence of symptomatic proximal and calf DVT and reduces mortality in patients with pulmonary emboli (Fig. 81-5). Coumarin derivatives (e.g., warfarin) are usually the drugs of choice for long-term anticoagulant therapy, but such drugs have a delayed onset of anticoagulant effect (Chapter 37). Therefore, initial short-term therapy with a rapid-acting heparin or heparin derivative for approximately 1 week is necessary to provide an immediate antithrombotic effect and to reduce the risk of thrombus growth or embolization in patients with acute DVT. Initial outpatient therapy with a low-molecular-weight heparin (LMWH) or fondaparinux is preferred to inpatient treatment with intravenous unfractionated heparin whenever feasible in patients with DVT. Rarely, medical therapy is unsuccessful or cannot be tolerated; such patients may require procedural therapy.

TABLE 81-3 GUIDELINES FOR ANTICOAGULATION WITH LOW-MOLECULAR-WEIGHT HEPARIN AND FONDAPARINUX

INDICATIONS	GUIDELINES
VTE suspected	Obtain baseline aPTT, PT, CBC Check for contraindication to heparin therapy Order imaging study; consider giving IV unfractionated heparin (5000 IU) or LMWH
VTE confirmed	Give LMWH (dalteparin,* enoxaparin,† nadroparin,‡ tinzaparin,§ fondaparinux‖) Start warfarin therapy on day 1 at 5 mg and adjust the subsequent daily dose according to INR Check platelet count between days 3 and 5 Stop LMWH therapy after at least 4 or 5 days of combined therapy when the INR is >2 Anticoagulate with warfarin for at least 3 months at an INR of 2.5, range of 2-3

*Dalteparin sodium, 200 anti-Xa IU/kg/day subcutaneously. A single dose should not exceed 18,000 IU (approved in Canada).
†Enoxaparin sodium, 1 mg/kg q12h subcutaneously, or enoxaparin sodium, 1.5 mg/kg/day subcutaneously. A single daily dose should not exceed 180 mg (approved in both the United States and Canada).
‡Nadroparin calcium, 86 anti-Xa IU/kg two times a day subcutaneously for 10 days (approved in Canada), or nadroparin calcium, 171 anti-Xa IU/kg subcutaneously daily. A single dose should not exceed 17,100 anti-Xa IU.
§Tinzaparin sodium, 175 anti-Xa IU kg/day subcutaneously daily (approved in Canada and the United States).
‖Fondaparinux subcutaneously according to weight: <50 kg, 5 mg once daily; 50-100 kg, 7.5 mg; and >100 kg, 10 mg.
aPTT = activated partial thromboplastin time; CBC = complete blood count; INR = international normalized ratio; LMWH = low-molecular-weight heparin; PT = prothrombin time; VTE = venous thromboembolism.
Modified from Hyers TM, Agnelli G, Hull RD, et al. Antithrombotic therapy for venous thromboembolic disease. *Chest.* 2001;119:176S-193S.

Initial Treatment

LMWH preparations, which are produced by either enzymatic or chemical depolymerization of unfractionated heparin, have lower mean molecular weights ranging from 4000 to 6000. The reduced molecular size provides a sufficient pentasaccharide moiety to antithrombin to inhibit factor Xa but reduces the ability of LMWH to inhibit thrombin in comparison with unfractionated heparin. Therefore, LMWH has an increased ratio of anti–factor Xa to anti–factor IIa (thrombin) inhibitory activity. The reduced size of LMWH also decreases charge-related nonspecific protein binding, thereby resulting in improved subcutaneous bioavailability, more predictable anticoagulant response, and predominantly dose-independent renal clearance. These qualities have made outpatient management of DVT with unmonitored, weight-based subcutaneous LMWH feasible and preferable.

LMWH products differ in their method of production, molecular weight, and anticoagulant effect. Few trials have directly compared different LMWH preparations for treatment of acute VTE, and definitive conclusions with regard to comparative efficacy and safety cannot be made. Dosage regimens differ for the various LMWH formulations (Table 81-3), but once-daily administration of LMWH is thought to be as safe and effective as twice-daily administration.

Because the antithrombotic response to weight-based dosing of LMWH is predictable, laboratory monitoring during LMWH treatment is usually unnecessary. There are, however, three populations of patients in whom anti–factor Xa monitoring should be considered: (1) patients with renal insufficiency (calculated creatinine clearance of less than 30 mL/minute); (2) obese patients, in whom the volume of distribution of LMWH might be different, so weight-adjusted dosing might not be appropriate; and (3) pregnant women, in whom it is unclear whether the dose should be adjusted according to the woman's weight change. Levels are usually determined on blood samples drawn 4 hours after subcutaneous injection; therapeutic ranges of 0.6 to 1.0 U/mL for twice-daily administration and 1.0 to 2.0 U/mL for once-daily treatment have been proposed.

Meta-analyses have documented that unmonitored, fixed-dose subcutaneous injection of LMWH is as effective and safe as adjusted-dose intravenous administration of unfractionated heparin for the treatment of acute DVT, with a trend toward a significant difference in mortality benefit favoring

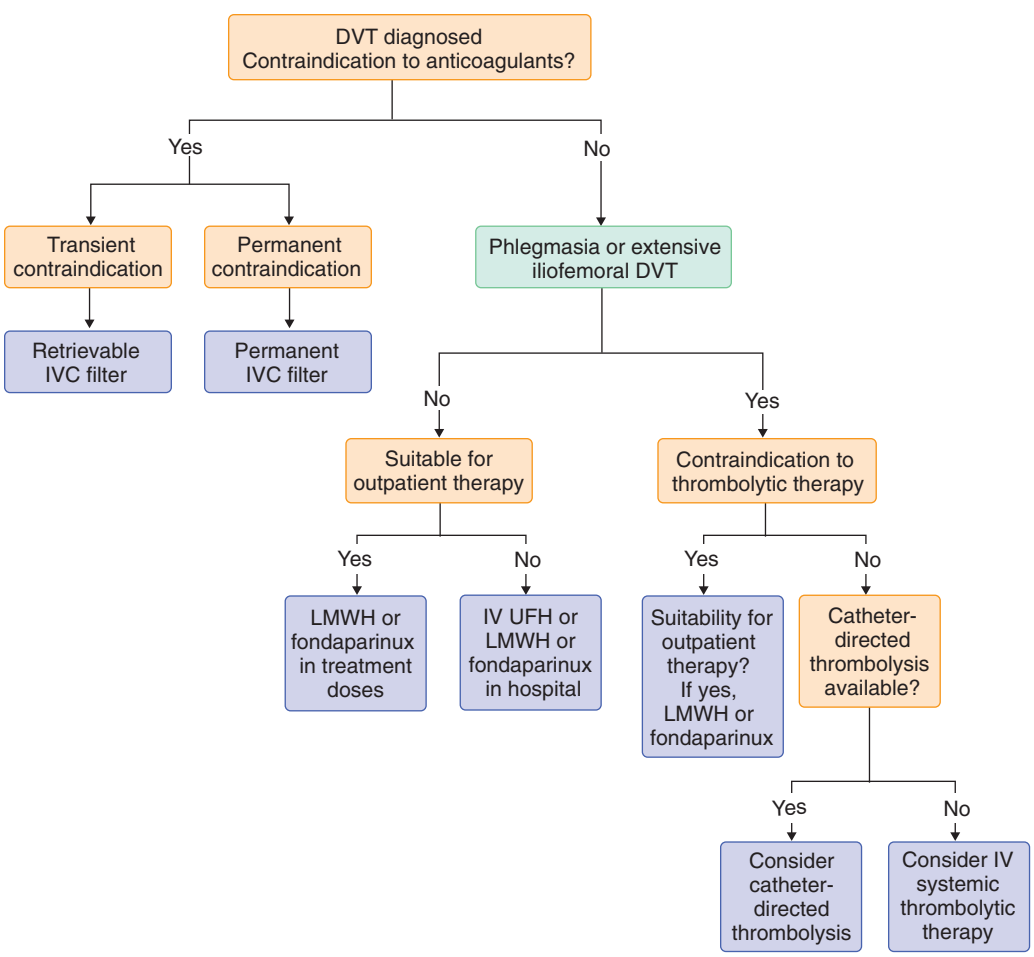

FIGURE 81-5. Guidelines for treatment of deep vein thrombosis (DVT). IVC = inferior vena cava; IV = intravenous; LMWH = low-molecular-weight heparin; UFH = unfractionated heparin.

LMWH, probably because of improved survival in patients with malignant disease. However, patients with extensive iliofemoral DVT have often been excluded from trials of LMWH, and extended-duration (i.e., more than 5 days) intravenous unfractionated heparin therapy is often administered to such patients. Outpatient therapy with LMWH is as good as inpatient treatment, thereby making LMWH more cost-effective than intravenous unfractionated heparin in most health care settings.

Fondaparinux

Fondaparinux is a synthetic analogue of the critical pentasaccharide sequence required for binding of heparin molecules to antithrombin (Chapter 37). Chemically engineered, it has minor modifications from the natural pentasaccharide moiety, thereby improving stability and resulting in enhanced binding to antithrombin. Given subcutaneously, fondaparinux demonstrates 100% bioavailability, with peak plasma concentrations occurring 1.7 hours after dosing. Once-daily subcutaneous administration of fondaparinux (5.0 mg daily if weight is less than 50 kg; 7.5 mg daily if weight is 50 to 100 kg; 10 mg daily if weight is more than 100 kg) is an effective and safe alternative to LMWH for the initial 5 to 10 days of treatment of DVT. Clearance is predominantly renal, with approximately 70% of the initial dose recovered in the urine in an unchanged form. Patients with reduced creatinine clearance, such as elderly patients, have higher peak drug levels and longer drug half-life, so their dose may need to be adjusted downward.

Unfractionated Heparin

Unfractionated heparin is a sulfated glycosaminoglycan that exerts its anticoagulant effect predominantly by binding to antithrombin and inducing a conformational change that accelerates the rate at which antithrombin inhibits coagulation enzymes (Chapter 37). It consists of a heterogeneous group of molecules ranging in molecular weight from 3000 to 30,000, and only one third of unfractionated heparin molecules contain the unique pentasaccharide sequence required for binding to antithrombin. This molecular heterogeneity, along with variable charge-related nonspecific binding of unfractionated heparin to other plasma proteins such as von Willebrand factor and platelet factor 4, contributes to the large variability in the anticoagulant response in individual patients.

Unfractionated heparin is usually administered by continuous intravenous infusion, a route that has been shown to be effective in reducing recurrence and extension of thrombus. The use of validated nomograms (Table 81-4), with either fixed initial dosing or dosing according to a patient's weight, results in more rapid achievement of therapeutic activated partial thromboplastin time (aPTT) levels and improves outcome, although adjustment according to the sensitivity of local aPTT methods is required. The initial aPTT level should be measured 6 hours after therapy is commenced. Up to 25% of patients with acute VTE have resistance to heparin, defined as a requirement for greater than expected doses of unfractionated heparin to achieve a "therapeutic" aPTT. If it is available, anti–factor Xa monitoring is recommended in patients with heparin resistance. Larger doses (front-loaded and weight-adjusted follow-up doses) of subcutaneous, 12-hourly unfractionated heparin are as safe and efficacious as LMWH without requiring monitoring of the aPTT. However, this regimen has not been widely embraced by clinicians because of a bias toward monitoring unfractionated heparin with frequent aPTT adjustments.

TABLE 81-4 WEIGHT-BASED NOMOGRAM FOR INITIAL INTRAVENOUS HEPARIN THERAPY

aPTT	DOSE (IU/kg)
Initial dose	80 bolus, then 18/h
<35 sec (<1.2×)*	80 bolus, then 4/h
35-45 sec (1.2-1.5×)	40 bolus, then 2/h
46-70 sec (1.5-2.3×)	No change
71-90 sec (2.3-3×)	Decrease infusion rate by 2/h
>90 sec (>3×)	Hold infusion 1 h, then decrease infusion rate by 3/h

*Figures in parentheses show comparison with control.
aPTT = activated partial thromboplastin time. In general, with contemporary aPTT reagents, the target therapeutic range is more than 1.2 to 2.3 times control.
Modified from Raschke RA, Reilly BM, Guidry JR, et al. The weight-based heparin dosing nomogram compared with a "standard care" nomogram: a randomized controlled trial. *Ann Intern Med.* 1993;119:874-881.

Transition to Oral Treatment

Coumarin Derivatives (Warfarin)

Warfarin is a vitamin K antagonist that inhibits the production of clotting factors II (prothrombin), VII, IX, and X as well as the naturally occurring anticoagulants protein C and protein S. In patients with DVT, the drug should be started within 24 to 48 hours of initiation of heparin with a goal of achieving

international normalized ratio (INR) results between 2.0 and 3.0 (Chapter 37). A higher target INR of 3.0 to 4.0 is associated with more bleeding but no better efficacy, even in patients with the antiphospholipid antibody syndrome (Chapter 179),[4] and lower intensity warfarin therapy (target INR, 1.5 to 1.9) is significantly less effective at preventing recurrent VTE despite similar rates of major bleeding.[5]

The dose is empirical, but a starting dose of 5 to 10 mg is suitable for most patients. Warfarin doses are adjusted according to the prothrombin time, expressed as the INR, performed daily or every other day until the results are in the therapeutic range for at least 24 hours. After initial dosing, warfarin can be monitored two or three times per week for 1 to 2 weeks and then less frequently, depending on the stability of INR results, up to intervals as long as 4 to 6 weeks. If dose adjustment is needed, such as when medications that can interact with warfarin are introduced, the cycle of more frequent monitoring is repeated until a stable dose response is again achieved.

It is now clear that pharmacogenetics have a large impact on the relatively wide range of warfarin dose requirements among different populations as well as the variability of warfarin requirements over time in any individual patient. Polymorphisms in the gene encoding cytochrome P-450 2C9 enzyme, the enzyme that primarily clears the S-enantiomer of warfarin, contribute to variable responses to warfarin; some genetic variants result in an increased sensitivity to warfarin and a lower required dose of warfarin. Vitamin K epoxide reductase (VKORC1) recycles vitamin K epoxide to the reduced form of vitamin K and is the target of warfarin. Its common genetic variants result in altered sensitivity to warfarin, and *VKORC1* polymorphisms are associated with a need for lower doses of warfarin during long-term therapy. Routine pharmacogenetic testing may ultimately be recommended in candidates for long-term (>3 months) warfarin therapy to identify individuals who are likely to require higher or lower warfarin doses.

Side Effects of Anticoagulants

Bleeding is the most common side effect of anticoagulant therapy. Major bleeding (e.g., intracranial [Chapter 415], gastrointestinal [Chapter 137], or retroperitoneal) leading to hospitalization or transfusion or death occurs in approximately 2% of patients treated with intravenous unfractionated heparin for acute VTE. Factors such as recent surgery, trauma, and concurrent aspirin or thrombolytic therapy increase the risk of bleeding.

The risk of major bleeding with warfarin in doses adjusted to achieve a target INR of 2.0 to 3.0 ranges from 1 to 3% per year and appears to be highest soon after treatment is started or if anticoagulation is difficult to control. The risk of major bleeding increases according to individual characteristics, such as older age, the presence of comorbid conditions (e.g., diabetes, hypertension, renal insufficiency, previous gastrointestinal bleeding, or cancer), and the use of concomitant drugs, in particular antiplatelet therapy.

Heparin-induced thrombocytopenia, which is a relatively common nonhemorrhagic complication of therapy with unfractionated heparin and a very uncommon complication of LMWH, is manifested typically with thrombocytopenia and new thrombosis (Chapter 37). Monitoring of the platelet count is recommended every other day until day 14 in patients receiving therapeutic unfractionated heparin but is not routinely recommended with LMWH or fondaparinux because of the extremely low risk with these newer medications.

Long-Term Treatment

The preferred long-term treatment of DVT for most patients is warfarin or another coumarin derivative (e.g., acenocoumarol), continued until the benefits of treatment for reducing recurrent VTE no longer outweigh its risks of major bleeding. The decision to prolong or to stop anticoagulation should be individualized, and a patient's preferences should be considered.

Patients with symptomatic proximal DVT or pulmonary emboli should be treated for at least 3 months, even if the VTE was associated with a transient risk factor,[6] but the optimal duration of treatment for patients whose VTE is not associated with a transient risk factor is controversial. Three months of treatment is associated with a 10 to 27% risk of a recurrence during the 12 months after anticoagulant therapy is stopped, whereas 6 months of anticoagulant therapy reduces the risk of recurrence in the first year after stopping to about 10%. In patients whose VTE developed in association with minor risk factors (e.g., air travel, pregnancy, within 6 weeks of estrogen therapy, after leg injury or immobilization), the risk of recurrence is probably lower than 10%. Continuation of treatment beyond 6 months reduces the risk of recurrent VTE during the course of therapy, but the benefit is lost after warfarin is discontinued.

The most convincing association of thrombophilia with the risk of recurrent VTE is the antiphospholipid antibody (lupus anticoagulant or anticardiolipin antibody; Chapter 179), which is associated with a two-fold increase in the risk of recurrence. Homozygous factor V Leiden, elevated levels of homocysteine, and deficiencies of antithrombin, protein C, and protein S also have been associated with an increased risk of recurrence in some reports, but other data suggest that testing for heritable thrombophilia does not predict recurrent VTE in the first 2 years after anticoagulant therapy is stopped. In the absence of randomized trials to assess different durations of anticoagulation in patients with VTE and thrombophilia, routine testing for thrombophilias need not be performed but should be considered in young (<50 years) patients, patients with venous thrombosis in unusual sites, and patients with a strong family history of VTE (i.e., one or more first-degree relatives with a history of VTE).

The decision to extend anticoagulant therapy beyond 3 months must balance the risk of recurrent VTE with the risk of bleeding. The annual risk of major bleeding when warfarin is adjusted to achieve a target INR of 2.0 to 3.0 is 1 to 3%, with a case-fatality rate of 10% when major bleeding occurs in patients who received treatment for more than 3 months. By comparison, the case-fatality rate for recurrent VTE is about 5%. In patients whose VTE was associated with a transient risk factor or who are at high risk of bleeding, treatment for 3 months is generally adequate because the risk of fatal recurrent VTE is lower than the risk of fatal bleeding if warfarin treatment is prolonged. Among patients without a reversible or transient cause, however, prolonged warfarin therapy for more than 6 months can be considered because the risk of fatal hemorrhage is counterbalanced by the risk of fatal recurrence. The argument to prolong therapy is stronger in patients with high-risk thrombophilia (e.g., homozygous factor V Leiden; antiphospholipid antibody; deficiency of antithrombin, protein C, or protein S; or combined heterozygous state for factor V Leiden and the prothrombin gene mutation). Indefinite therapy (preferably with LMWH) should be considered in patients with cancer-related VTE (Chapter 187) if the risk of bleeding is not high because the risk of recurrent VTE is more than 10% in the first year after anticoagulation is stopped. In motivated and capable patients, self-management of warfarin therapy is better than management by a physician or nurse.[7]

Alternatives to Coumarin Derivatives

For patients in whom warfarin is impractical or contraindicated and for those who have recurrent VTE while being treated with appropriate doses of oral anticoagulants, therapeutic doses of LMWH are as effective as warfarin. For patients with cancer-related VTE (DVT, pulmonary embolus, or both), weight-based LMWH that is decreased to 75% of the initial dose after 1 month of treatment reduces the risk of recurrent VTE compared with warfarin, with similar bleeding rates.[8]

Therapeutic strategies to manage patients in whom symptomatic VTE recurs while they are receiving conventional-intensity warfarin include unfractionated heparin, LMWH, higher-intensity warfarin (e.g., INR range of 3.0 to 4.0), and insertion of a vena caval filter. However, the optimal management of such patients is unknown because no randomized studies have been performed.

Thrombolytic Therapy

Although thrombolytic therapy results in increased rates of early patency of leg veins after DVT, it has not been conclusively shown to decrease the subsequent rate of post-thrombotic syndrome or pulmonary emboli. Except for patients who have life-threatening limb ischemia due to massive thrombosis, thrombolysis is not recommended in patients with DVT. An ongoing trial of catheter-directed thrombolysis versus "standard therapy" should provide the definitive evidence about the relative efficacy of catheter-directed thrombolysis for the prevention of post-thrombotic syndrome.

Vena Caval Filters

In a randomized trial of 400 patients with DVT, the incidence of pulmonary emboli at day 12 was lower in patients who received an inferior vena caval filter plus therapeutic anticoagulation than in those who received anticoagulation alone. However, filters did not reduce early or late mortality and are not recommended in patients who can receive therapeutic anticoagulation because this benefit did not persist at 2 years and was offset by an almost doubling of the risk of recurrent DVT. Inferior vena caval filters should be used in patients who have contraindications to anticoagulant therapy or develop major bleeding while receiving it as well as in patients who develop recurrent VTE while receiving appropriate anticoagulation. Retrievable or removable inferior vena caval filters can be retrieved and removed within 14 days to several weeks after insertion or can be left in permanently. These filters are ideal for a patient who has a reversible cause of or the potential for major bleeding (e.g., DVT after craniotomy, DVT late in pregnancy).

Oral Direct Thrombin and Factor Xa Inhibitors

Ximelagatran is an oral direct thrombin inhibitor that does not require anticoagulant monitoring. When it is used for the acute and long-term treatment of patients with acute VTE, ximelagatran is as effective and safe as unfractionated heparin or LMWH followed by warfarin in preventing recurrent VTE. However, elevation in liver enzymes, especially the alanine aminotransferases, has been reported in 5 to 10% of patients with long-term use. Although the clinical implications of these elevated levels, which may decrease to normal with continued treatment, are unclear, the drug has been removed from the market by the manufacturers.

Rivaroxaban, an oral factor Xa inhibitor, is effective at 15 mg twice daily for 3 weeks then 20 mg daily for up to 12 months, but it also is associated with elevated aminotransferase levels. These and other thrombin inhibitors are under development for acute and chronic treatment of VTE. Although none has yet been approved for use in North America for the treatment of DVT and pulmonary embolism, some have already been approved for other indications.

PREVENTION

In one large randomized trial, rosuvastatin reduced the rate of DVT by 55%.[1] It is unknown at present whether this benefit can be achieved with other statins. Despite the plethora of large randomized trials demonstrating the efficacy and safety of mechanical and pharmacologic measures in reducing the risk of VTE in a wide range of hospitalized populations of patients, prophylaxis remains grossly underused. Factors that increase the risk of DVT include surgery (particularly major hip and knee surgery, as well as neurosurgery; Chapters 439 and 441), major trauma (Chapter 112), prolonged bed rest or immobilization, previous episodes of VTE, presence of malignant disease, paralysis, morbid obesity, and increasing age.

Comprehensive consensus guidelines have been developed for the prevention of VTE in different populations of patients (see Table 37-2 in Chapter 37). In general, mechanical prophylaxis (antiembolic stockings and intermittent pneumatic compression) should be used as an adjunct to pharmacologic prophylaxis or in patients with a high risk of bleeding. For general medical patients admitted to the hospital with a major illness and in whom mobility is likely to be reduced for 72 hours or longer, low-dose unfractionated heparin or LMWH (see Table 37-2 in Chapter 37) should be considered. In patients who undergo major hip or knee surgery, warfarin (to an INR of 2.0 to 3.0), subcutaneous LMWH, subcutaneous fondaparinux (2.5 mg once daily), or oral rivaroxaban (10 mg once daily) should be used for at least 7 to 14 days postoperatively. In patients with continued immobility, prophylaxis should be considered until the patient regains preoperative mobility.

Management of Deep Vein Thrombosis in Pregnancy

The management of pregnant women with DVT (Chapter 247) is problematic because all coumarin derivatives cross the placenta and have the potential to cause warfarin embryopathy, consisting of nasal hypoplasia and epiphyseal stippling, if the newborn is exposed to warfarin between 6 and 12 weeks of gestation. Consequently, parenteral unfractionated heparin and LMWH, which do not cross the placenta and are safe for the fetus, are the agents of choice. The easiest approach is to initiate therapy with weight-adjusted "treatment" doses of LMWH (see Table 81-3), continued for the duration of the pregnancy. Although it is not proved, it is likely that the dose of LMWH can be safely decreased to approximately 80% of the therapeutic dose after 3 months of therapy. As pregnancy progresses, women normally gain weight and generally require higher doses of LMWH to achieve an anti–factor Xa level similar to that achieved at the time of diagnosis. The adequacy of the dose can be assessed by measuring a 4-hour postinjection anti–factor Xa level and targeting the dose to achieve a level of 0.5 to 1.0 U/mL for twice-daily LMWH and 0.8 to 1.5 U/mL for once-daily LMWH. Alternatively, the dose of LMWH can simply be adjusted periodically on the basis of the woman's weight.

Unfractionated heparin is less attractive than LMWH because it is associated with a greater reduction of bone density and a higher risk of heparin-induced thrombocytopenia. Unfractionated heparin can be initiated either by continuous intravenous infusion in doses adjusted to maintain an aPTT in the therapeutic range, followed by 12-hourly subcutaneous injections, or simply with 12-hourly subcutaneous injections throughout the course of pregnancy. The dose should be adjusted to target a mid-interval (6-hour postinjection) aPTT in the therapeutic range.

Pregnant women with a DVT should probably be treated for the duration of pregnancy and for at least 6 weeks postpartum. If the DVT occurred early in pregnancy, elective induction of delivery at about 37 weeks with discontinuation of the heparin 24 hours earlier is recommended. If the DVT occurs in the latter part of the third trimester, intravenous heparin should be administered by continuous infusion until approximately 6 hours before the expected time of delivery. Intravenous unfractionated heparin or subcutaneous LMWH should be started postpartum as soon as hemostasis has been achieved. Maternal warfarin therapy is safe for the breast-fed infant because warfarin and its metabolites are not secreted into breast milk in doses sufficient to cause an anticoagulant effect. Consequently, warfarin (with bridging LMWH or unfractionated heparin until the INR is 2.0 or higher) can be used after delivery.

Venous Thrombosis of the Upper Extremities

DVT of the upper extremities (including the arm and the axillary, subclavian, and internal jugular veins as well as the superior vena cava) is much less common than DVT of the legs, but it is not rare. Factors associated with upper extremity DVT include central venous catheters, acquired or hereditary thrombophilias, and anatomic (cervical rib) and physiologic (muscular individuals) impingement of the vein. The incidence of clinically important post-thrombotic syndrome is not high if patients are treated with anticoagulants alone.

Contrast venography is the gold standard for the diagnosis of upper extremity DVT, but venous ultrasonography is accurate and less invasive. Because it is not feasible to test for compression of the subclavian vein, a diagnosis of subclavian DVT by ultrasonography is based on flow abnormalities or direct visualization of thrombus by B-mode ultrasonography. Upper extremity DVT can cause pulmonary emboli, although the exact frequency is not known.

Considerable controversy exists about the management of patients in whom DVT develops in association with a central venous catheter. If the line is not necessary or is nonfunctional, some recommend simply removing the line without subsequent anticoagulant therapy, whereas others treat with full-dose anticoagulants (a heparin-related compound, followed by 1 to 3 months of warfarin). If the line is functional and must stay in place (e.g., no alternative venous access), full-dose anticoagulants should be given. Otherwise, anticoagulant therapy should be given in all patients with upper extremity DVT, with medications, doses, regimens, and durations identical to those for treatment of DVT of the leg.

SUPERFICIAL THROMBOPHLEBITIS

Superficial thrombophlebitis usually presents with pain, swelling, redness, and tenderness of superficial veins. Varicose veins (Fig. 81-6) can be red, warm, and clustered in a circumscribed area. When superficial thrombophlebitis occurs in the short or long saphenous veins, there is usually redness, tenderness, and often linear induration that follow the course of the involved vein (medial calf or thigh). Superficial thrombophlebitis can also occur at the insertion site of an intravenous catheter. Invariably, superficial thrombophlebitis is associated with thrombosis of the corresponding vein, and particularly when the long saphenous vein is involved, venous ultrasonography should be performed to exclude extension into the deep veins, which occurs in up to 19% of patients.

Nonsteroidal anti-inflammatory drugs and either moderate or full doses of LMWH are each about 70% better than placebo for treating superficial thrombophlebitis.[2] LMWH relieves symptoms more quickly and prevents growth of thrombus more effectively than do nonsteroidal anti-inflammatory drugs. Fondaparinux, 2.5 mg daily for 45 days, reduces the risk of DVT or pulmonary embolism from about 1.3% to 0.2% without adverse effects.[3] Thus, it is reasonable to use moderate doses of LMWH or fondaparinux for the initial treatment of acute, symptomatic superficial thrombophlebitis, particularly for patients with severe symptoms, proximal

FIGURE 81-6. Varicose veins are a risk factor for deep vein thrombosis and may result from it. (From Forbes CD, Jackson WF. *Color Atlas and Text of Clinical Medicine*, 3rd ed. London: Mosby; 2003.)

saphenous vein thrombosis, recurrent disease, or evidence of thrombophilia. Alternatively, and particularly for intravenous catheter-induced superficial thrombophlebitis, a nonsteroidal anti-inflammatory drug can be tried.

POST-THROMBOTIC SYNDROME

The initial pain and swelling in many patients with DVT are due to the venous obstruction or the inflammatory process mediated by the acute thrombus. Once anticoagulant therapy is initiated, the acute obstruction usually resolves during a period of several months as recanalization occurs and collateral venous channels develop, thereby leading to initial improvement in pain and swelling. However, in the long term, probably because of venous valvular incompetence produced when the thrombosed venous segments recanalize and sometimes because of residual chronic obstruction, venous hypertension and sometimes pain and swelling can recur.

This post-thrombotic syndrome develops in up to 50% of patients with proximal DVT, usually within the first 1 to 2 years after DVT. The syndrome is often a chronic, progressive disease with pain, swelling, and occasionally ulceration of the leg in patients with previous DVT.

PREVENTION AND TREATMENT

Rx

The use of below-knee graduated compression stockings for 2 years after acute DVT reduces the risk of the post-thrombotic syndrome by about 50%.[12] Some experts recommend routine stocking therapy in all patients with DVT. Others recommend waiting until the acute inflammatory process and acute outflow obstruction have subsided (usually up to 6 months) and then prescribing stockings if the patient's symptoms persist at that time. The use of graduated compression stockings does not significantly reduce DVT after stroke, however, and results in adverse skin events.[13]

However, stockings are hot in the summer, relatively expensive, difficult for many patients to put on in the morning, and cosmetically unappealing to many patients. In addition, simple lifestyle alteration (such as frequent leg elevation, avoidance of prolonged standing or sitting, and occasional use of analgesics) suffices in relieving symptoms in many patients. If symptoms are severe, it is usually because of extensive thrombus causing massive edema. In such patients, a lightweight stocking (such as support hose) can be helpful until the edema improves. If symptoms persist or worsen despite these measures, or if ulceration seems imminent (as evidenced by severe skin changes), a full-strength stocking (30 to 40 mm Hg of pressure at the ankle) can be prescribed. However, if symptoms subside and the patient remains asymptomatic or has only trivial persistent signs or symptoms with little or no effect on quality of life, stockings can be avoided, and the patient can be observed for clinically important signs and symptoms of the post-thrombotic syndrome.

VENOUS ULCERS

Venous ulcers, which are the most severe complication of post-thrombotic syndrome, typically occur in the perimalleolar area of the leg. The best management is prevention by application of graduated compression stockings either at the time of diagnosis of DVT or, at the latest, when skin changes develop in association with leg swelling. When an ulcer occurs, treatment with an emollient and regular wrapping should be commenced. Once the ulcer heals, the patient should be prescribed graduated compression stockings and watched for recurrent ulceration. Surgical closure or removal of the incompetent saphenous veins plus dressing management in patients with chronic venous ulceration does not reduce healing time of the acute ulcer compared with dressing management alone but significantly reduces the rate of recurrent ulceration for at least the next 4 years.[14]

CARDIAC TRANSPLANTATION

MARIELL JESSUP

Cardiac transplantation is the treatment of choice for suitable patients with refractory heart failure (Chapters 59, 60, and 107). The number of heart transplantation procedures worldwide reached a peak of about 4500 in 1994 but has subsequently declined because the rate of identification of potential donors has not kept pace with the increased number of patients on waiting lists, where the annual mortality is 10 to 20% (Fig. 82-1). Because newer therapeutic options have usually failed and they now lack other alternatives, patients referred for heart transplantation are becoming progressively older and more ill, with increasing medical comorbidities, which have significantly increased the risk of cardiac transplantation. In many institutions, at least one third of patients are sustained on a ventricular assist device while awaiting transplantation. At the same time, the selection criteria for donors have been broadened to increase the number of organs available. As a result, sicker recipients are now receiving less ideal organs than in the past.

POPULATION OF PATIENTS

Evaluation of the Potential Recipient

The purposes of heart transplantation are to prolong life and to improve quality of life, so the referring physician must understand the potential benefits of transplantation as well as comorbidities that may portend an unsatisfactory outcome. Suitable patients for consideration have cardiogenic shock requiring mechanical support or high-dose inotropic or pressor drugs (Chapter 107); stage D heart failure symptoms despite maximal therapy (Chapter 59); recurrent life-threatening arrhythmias despite maximal interventions, including implanted defibrillators (Chapters 63 and 65); or, rarely, refractory angina without the potential for revascularization (Chapter 71) (Table 82-1). The most potent predictor of outcome in ambulatory patients with heart failure is a symptom-limited metabolic stress test to calculate peak oxygen consumption; a peak of less than 12 mL/kg/minute indicates a lower survival with medical therapy than after transplantation.

An extensive medical and psychosocial evaluation must be performed to exclude contraindications to transplantation. In the setting of fixed

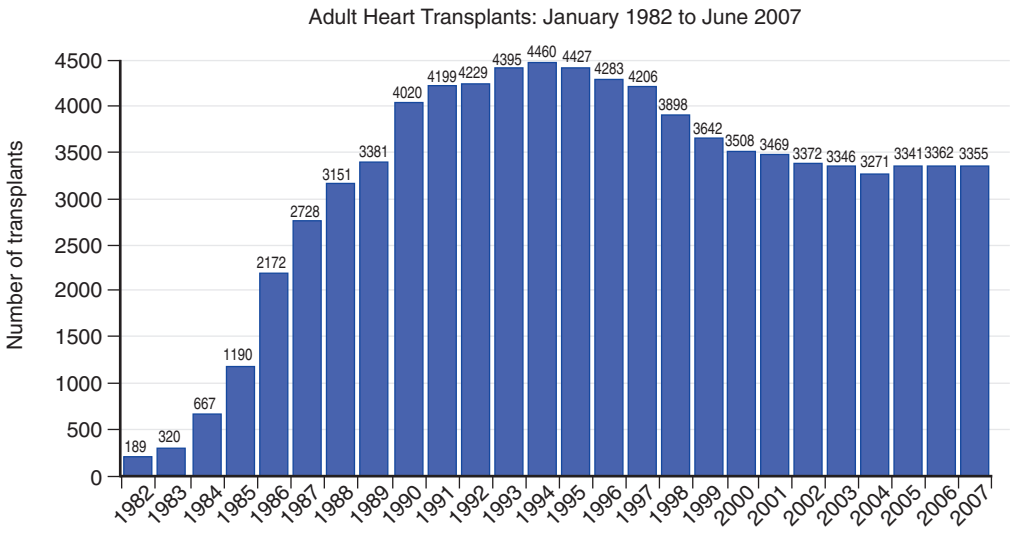

FIGURE 82-1. The number of heart transplantation procedures by year. (Data from the Registry of the International Society for Heart and Lung Transplantation. Reproduced with permission.)

TABLE 82-1 EVALUATION OF THE POTENTIAL HEART TRANSPLANT RECIPIENT

INDICATIONS FOR HEART TRANSPLANTATION		
Cardiogenic shock requiring mechanical support or high-dose inotropic drugs Stage D heart failure symptoms despite maximal therapy Recurrent life-threatening arrhythmias despite maximal interventions and implanted defibrillator Refractory angina without potential for revascularization		
CONTRAINDICATIONS TO HEART TRANSPLANTATION		
	ALTERNATIVE TREATMENT	**OPTIONS**
Age > 70 yr	Consider permanent mechanical support	End-of-life considerations or investigational therapy
Active or recent malignant disease	End-of-life considerations or investigational therapy	
Diabetes with severe end-organ damage	Consider permanent mechanical support	End-of-life considerations or investigational therapy
FEV/FVC < 40%	Consider heart-lung transplantation	End-of-life considerations or investigational therapy
BMI < 20 or BMI > 35	Nutritional modification; BMI > 35, consider permanent mechanical support or weight loss	
Irreversible pulmonary hypertension (≥4 Wood units)	Consider heart-lung transplantation	End-of-life considerations or investigational therapy
Other comorbidities: cirrhosis, vascular disease, addictions, hepatitis C, human immunodeficiency virus infection, social or psychiatric disorders	Individual transplantation team decisions	

BMI = body mass index; FEV = forced expiratory volume; FVC = forced vital capacity.

pulmonary hypertension, such patients are occasionally considered for combined heart-lung transplantation.

An immunologic evaluation includes determination of ABO blood type, antibody screen, panel-reactive antibody level, and human leukocyte antigen (HLA) typing. Using virtual crossmatch methods, flow cytometry–based single-antigen bead assays can identify prospective donors with undesirable antigens without the need for a prospective crossmatch, thereby allowing for matches outside the recipient's geographic area.

Management of the Patient Waiting for Cardiac Transplantation

A patient's priority status according to the United Network for Organ Sharing is based on the recipient's acuity status, blood type, body size, and duration of time at a particular status level. Patients who can be managed successfully outside the hospital are the lowest priority. Intermediate priority is given to patients who require hospitalization and some continuous inotropic support. The highest priority, status 1A, is given to patients requiring high-dose inotropic support or mechanical support, such as intra-aortic balloon counterpulsation or ventricular assist device. Hearts are offered geographically, by the location of the donor, and limited by an ischemic time of approximately 4 hours. Patients who are waiting for transplantation are regularly reevaluated for a change in status or the development or worsening of a comorbidity that would preclude transplantation.

THE CARDIAC TRANSPLANTATION PROCEDURE

The Cardiac Donor

Relevant history for the assessment of cardiac donors includes the presence or absence of thoracic trauma, hemodynamic stability, pressor and inotropic requirements, duration of cardiac arrest, need for cardiopulmonary resuscitation, and assessment of hypotensive episodes. In many potential donors, brain death causes hemodynamic deterioration that requires inotropic support and substantial fluid administration. Donors up to the age of 50 to 55 years are considered safe by most centers. The final decision to accept a heart for transplantation is made at the time of harvest, after direct examination for myocardial infarction, trauma, and coronary calcification.

Currently, the acceptable cold ischemia time between explant and implant is approximately 4 hours. One of the main reasons for early graft failure after transplantation is inadequate myocardial protection during prolonged ischemic periods.

Surgical Considerations

The biatrial anastomosis technique consists of four suture lines: left atrium, pulmonary artery, aorta, and right atrium. The bicaval anastomosis technique, introduced to minimize distortion of the heart and to preserve atrial conduction, has five anastomoses: left atrium, pulmonary artery, aorta, inferior vena cava, and superior vena cava. To date, there has been no prospective trial to establish the superiority of either technique. Failure to wean a heart transplant recipient from cardiopulmonary bypass is most commonly the result of right-sided heart failure, which is evidenced by low cardiac output in the face of a rising central venous pressure. Native heart pacemakers and cardiac defibrillators are usually surgically removed at the end of the operation after the chest has been closed.

POSTOPERATIVE MANAGEMENT

Early Postoperative Management

Cardiovascular Issues

Management of the heart transplant recipient early after surgery does not differ substantially from management after other cardiac procedures

(Chapter 74). Cardiac transplant patients typically need chronotropic and inotropic support for a few days in the intensive care unit.

Because the donor heart is denervated, bradycardia is a frequent problem. It is usually treated with titrated isoproterenol to maintain a heart rate above 90 beats per minute for the first several days after transplantation. Temporary pacing leads are necessary for all patients, and as many as 10 to 15% of patients require a permanent pacemaker after transplant surgery.

Inhaled nitric oxide, in a usual dose of 20 to 60 parts per million, is a potent vasodilator that has a selective effect on the pulmonary vasculature, reduces pulmonary vascular resistance, and improves right ventricular function in patients with pulmonary hypertension. Intravenous epoprostenol, an alternative, is typically used at 5 to 50 ng/kg/minute.

Immunosuppression

Most immunosuppressive regimens begin with the simultaneous use of three classes of drugs: glucocorticoids, calcineurin inhibitors, and antiproliferative agents. In addition, patients may receive a variety of drugs during induction therapy (Chapter 48).

Perioperative Induction Therapy

The goal of perioperative induction therapy is to inhibit only those T cells that respond to donor antigen, thus achieving immunologic unresponsiveness to the transplant in the face of a fully functioning immune system, called donor-specific tolerance. Agents include the polyclonal anti-thymocyte antibodies, the interleukin-2 receptor antagonists daclizumab and basiliximab, and, less often, the anti-CD3 antibody OKT3.

Acute and Maintenance Immunosuppression

Patients initially receive high doses of intravenous corticosteroids (e.g., 500 mg of intravenous [IV] methylprednisolone at the end of cardiopulmonary bypass, followed by 150 mg IV every 8 hours for three additional doses), then oral steroids that are gradually tapered during the next 6 months in an attempt to minimize side effects (Chapter 34). Corticosteroids also are usually the drug of first choice to treat acute rejection.

The calcineurin inhibitors tacrolimus and cyclosporine act specifically on the immune system and do not affect other rapidly proliferating cells. In a meta-analysis, tacrolimus was as good as cyclosporine in terms of survival and significantly reduced episodes of acute rejection.■ Important and often limiting side effects include nephrotoxicity, which occurs in up to 40 to 70% of patients, and hypertension. Target therapeutic levels 2 hours after a dose improve outcome.

Mycophenolate mofetil has replaced azathioprine as the first-line antiproliferative drug, with several randomized trials demonstrating superiority to azathioprine.■ Mycophenolate mofetil may cause leukopenia, debilitating diarrhea, and nausea.

Sirolimus (often called rapamycin) and everolimus are complementary to calcineurin inhibitors, and both drugs have been used as alternatives to standard maintenance immunosuppression and as rescue drugs for rejection. In one randomized trial using cyclosporine and steroids, addition of sirolimus halved the number of patients with acute rejection and reduced the development of vasculopathy in the donor heart compared with addition of azathioprine.■

Other Potential Management Issues

The transplant recipient is often debilitated or malnourished. Depression (Chapter 404) is common, and many patients exhibit a marked emotional lability that is aggravated by high-dose steroids. Successful heart transplantation teams must include dedicated physical therapists, nutritionists, and social workers or psychologists, in addition to the nurses and physicians, so that all these needs may be addressed.

Long-Term Care of the Cardiac Transplant Recipient

Rejection

Rejection is categorized histologically and immunologically into three major types: hyperacute, acute (cellular or humoral), and chronic. Hyperacute rejection, which results when an abrupt loss of allograft function occurs within minutes to hours after circulation is established in the allograft, is rare in modern-day transplantation. The phenomenon is mediated by preexisting antibodies to allogeneic antigens on the vascular endothelial cells of the donor organ. These antibodies fix complement, which promotes intravascular thrombosis, leading to rapid occlusion of graft vasculature and swift rejection.

Acute cellular rejection, which is a predominantly lymphocytic mononuclear inflammatory response directed against the cardiac allograft, commonly occurs from the first week to several years after transplantation. The key event in both the initiation and the coordination of the rejection is T-cell activation. The risk of acute cellular rejection in the first 6 months is 40 to 70%. Acute cellular rejection after 6 months occurs most often in patients who have had substantial rejection early after transplantation, recent reduction in immunosuppression, intercurrent infection, or noncompliance with medication.

Acute humoral rejection occurs days to weeks after transplantation and is initiated by alloantibodies directed against donor HLA or endothelial cell antigens rather than by T cells. Patients at greatest risk for humoral rejection are women and patients with a high panel-reactive antibody screen or a positive crossmatch. It is estimated that significant humoral rejection occurs in about 7% of patients, but the rate may be as high as 20%.

Chronic rejection, or late graft failure, is an irreversible gradual deterioration of graft function occurring in many allografts months to years after transplantation. It is characterized by intimal thickening and fibrosis, which lead to luminal occlusion of the graft vasculature; it is often called cardiac allograft vasculopathy.

DIAGNOSIS

Allograft rejection is most frequent within the first month after cardiac transplantation and declines progressively thereafter. Clinical symptoms of rejection are often vague and relatively late in terms of immune injury to myocytes. Endomyocardial biopsy has been the "gold standard" for the diagnosis of rejection. Biopsies are performed by a transjugular approach weekly for 3 or 4 weeks, then every other week for several months; monthly biopsies continue for 6 to 12 months in many transplant programs. Biopsy grading of cellular rejection is based on the severity of lymphocyte infiltration and myocyte necrosis (Table 82-2). In one randomized trial, gene expression profiling of peripheral blood reduced the number of biopsies and provided equivalent outcomes over a mean follow-up of 19 months among patients who were stable 6 months to 5 years after transplantation.■

Humoral rejection is usually suspected clinically when there is evidence of suboptimal graft function but the endomyocardial biopsy specimen shows either no evidence of cellular rejection or only mild rejection. The pathologic markers of humoral rejection identifiable in endomyocardial biopsy tissue include deposits of immunoglobulin M, immunoglobulin G, or complement in the microvasculature or myocytes. In particular, C4d, which is a degradation product of the classic complement pathway and which binds to the endothelial and collagen basement membrane, is increasingly used as a marker of antibody-mediated rejection. Evidence for antibodies in the circulation with specificity for non-HLA antigens on the graft also supports the diagnosis of humoral rejection.

PROGNOSIS

Acute rejection causes approximately 12% of deaths in the first year after transplantation, but cardiac allograft vasculopathy represents a substantial portion of annual mortality beyond 3 years. Moreover, efforts to avert rejection with potent immunosuppressive therapy are responsible for other common complications after cardiac transplantation.

Infection

Infections cause approximately 20% of deaths within the first year after transplant surgery and continue to be a common cause of morbidity and mortality throughout the recipient's life. Infections of any type during the first month after transplantation also increase the risk of a subsequent fatal cytomegalovirus (CMV) infection (Chapter 384).

TABLE 82-2 STANDARDIZED CARDIAC BIOPSY GRADING: ACUTE CELLULAR REJECTION* 2004

Grade 0 R	No rejection
Grade 1 R, mild	Interstitial and/or perivascular infiltrate with up to one focus of myocyte damage
Grade 2 R, moderate	Two or more foci of infiltrate with associated myocyte damage
Grade 3 R, severe	Diffuse infiltrate with multifocal myocyte damage, ± edema, ± hemorrhage, ± vasculitis

*International Society for Heart and Lung Transplantation.

Prophylaxis against CMV infection, *Pneumocystis jiroveci* pneumonia, herpes simplex virus infection, and oral candidiasis is now routine during the first 6 to 12 months after transplantation. As a result, the most common infections seen in the first month after surgery are nosocomial bacterial and fungal infections related to mechanical ventilation, catheters, the surgical site, and residual infections from prior implantation of ventricular assist devices.

The prophylactic use of trimethoprim-sulfamethoxazole, typically for the first year after transplantation, has virtually eliminated *P. jiroveci* pneumonia (Chapter 349) and also prevents nocardial infections and toxoplasmosis. The combination drug is generally reinstituted during subsequent episodes of increased risk, such as enhanced immunosuppression. Aspergillosis and candidiasis (Chapters 346 and 347) are the most common fungal infections after heart transplantation; oral nystatin solution or clotrimazole troches are routinely used in the first 6 to 12 months. Viral infections, especially CMV infection (Chapter 384), can increase immunosuppression, resulting in additional opportunistic infections. Prophylactic intravenous ganciclovir or oral valganciclovir is generally given for variable amounts of time in the CMV-seronegative recipient of a CMV-positive donor.

Health Maintenance

After 5 years, 95% of recipients have hypertension, 81% have hyperlipidemia, and 32% have diabetes. In addition, 25% to 50% have cardiac allograft vasculopathy, and up to 33% have renal insufficiency. Lifelong immunosuppression makes all recipients more susceptible to a number of malignant neoplasms, so careful follow-up is mandatory.

In many centers, recipients are given daily aspirin to reduce vascular disease, but no randomized trial has evaluated the benefits of antiplatelet therapy in heart transplant patients. Likewise, most recipients are given vitamins, stool softeners, iron supplements, and proton pump inhibitors early after surgery on an empirical basis.

Surveillance

New Health Problems

Because osteoporosis (Chapter 251) is a major problem, in part related to use of corticosteroids, prophylaxis with calcium and vitamin D is usually initiated. Depression occurs in up to 25% of recipients. A number of antidepressants may be used, but the potential for adverse drug interactions must be considered. The management of gout is difficult because colchicine may increase the risk of myoneuropathy, nonsteroidal anti-inflammatory drugs often worsen renal insufficiency and hyperkalemia, and allopurinol used with azathioprine can cause life-threatening neutropenia. Minimizing diuretic use and judicious use of colchicine with allopurinol will usually alleviate most patients' symptoms.

Risk factors for malignant disease (Chapter 183) include impaired immunoregulation, a synergistic effect with other carcinogens such as nicotine or ultraviolet light exposure, and oncogenic causes such as Epstein-Barr virus and papillomavirus. The cumulative amount of immunosuppression is positively correlated with risk for malignant change. Lymphoproliferative diseases, skin and lip cancers, and Kaposi's sarcoma are particularly common. Malignant neoplasms account for 24% of deaths after 5 years.

TRANSPLANT VASCULOPATHY

EPIDEMIOLOGY AND PATHOBIOLOGY

Transplant vasculopathy remains the most daunting long-term complication of heart transplantation, with an annual incidence rate of 5 to 10%. After the first postoperative year, cardiac allograft vasculopathy becomes increasingly important as a cause of death. The risk of transplant vasculopathy increases as the number of HLA mismatches and the number and duration of rejection episodes increase. CMV infection and ischemia-reperfusion injury also increase the risk, as do classic risk factors for atherosclerotic disease (Chapter 51), such as smoking, obesity, diabetes, dyslipidemia, and hypertension. Transplant vasculopathy can develop as early as 3 months after transplantation and is detected angiographically in 20% of grafts at 1 year and in 40 to 50% at 5 years.

CLINICAL MANIFESTATIONS

In contrast to eccentric lesions seen in atheromatous disease, cardiac allograft vasculopathy produces concentric narrowing from neointimal proliferation of vascular smooth muscle cells and affects the entire length of the coronary tree, from the epicardial to the intramyocardial segments, leading to rapid tapering, pruning, and obliteration of third-order branch vessels. Most patients will not experience anginal symptoms because of denervation of coronary arteries, so the first clinical manifestation may be myocardial infarction, heart failure, ventricular arrhythmia, or sudden death. As a result, most transplantation centers screen patients annually for possible transplant vasculopathy.

DIAGNOSIS

Intravascular ultrasonography, which is currently the most sensitive imaging technique to study early transplant vasculopathy, provides quantitative data on intimal thickness, luminal cross-sectional area, and external elastic membrane cross-sectional area. An increase in intimal thickness of at least 0.5 mm in the first year after transplantation is a reliable indicator of both cardiac allograft vasculopathy and 5-year mortality. However, increased invasiveness and cost of intravascular ultrasonography preclude its widespread application. Dobutamine stress echocardiography (Chapter 55) has a high sensitivity (83 to 95%) and specificity (between 53 and 91%) compared with angiography. Most transplantation centers do one of the screening tests on an annual basis to assess the risk of new cardiac allograft vasculopathy.

TREATMENT Rx

The only definitive treatment of transplant vasculopathy is repeated transplantation. The statins pravastatin and simvastatin repress the induction of class II major histocompatibility complex antigen expression by interferon-γ and thereby inhibit T-cell proliferation and have a direct influence on the expression of genes for growth factors that are essential for the proliferation of smooth muscle cells. Randomized controlled trials have shown that either drug significantly reduces rates of severe rejections and transplant vasculopathy while also significantly reducing cholesterol levels and improving survival (see later). It is not clear whether all statin drugs have the same benefit in this population. Sirolimus and everolimus are also being evaluated to prevent the development or progression of cardiac allograft vasculopathy, but their role has not yet been determined.

Diabetes

Diabetes (Chapter 237) occurs in 32% of transplant recipients, and patients who develop new-onset diabetes mellitus after transplantation are at increased risk for morbidity and mortality. Although impaired B-cell function appears to be the primary mechanism of calcineurin inhibitor-induced new-onset diabetes, impaired peripheral glucose use also appears to contribute to insulin resistance and abnormal glucose metabolism. Risk factors include obesity, increased age, family history of diabetes, abnormal glucose tolerance, and African American or Hispanic descent. Management is generally similar to that of the nontransplant patient.

Hypertension and Renal Insufficiency

The 5-year incidence of hypertension (Chapter 67) in the population of cardiac transplant recipients is 95%. Excess risk of hypertension is attributable primarily to the use of calcineurin inhibitors because of both direct effects and the associated renal insufficiency. Treatment often requires a combination of agents and is generally as in the nontransplant patient.

The risk of chronic renal failure is about 16% at 10 years, largely related to direct calcineurin inhibitor–mediated renal arteriolar vasoconstriction, increased levels of endothelin-1, decreased nitric oxide production, and alterations in the kidney's ability to adjust to changes in serum tonicity. Once early renal insufficiency occurs, no single treatment has yet been shown to be effective.

Hyperlipidemia

Hyperlipidemia (Chapter 213) occurs in more than 80% of cardiac transplant recipients and is associated with the development of cardiac allograft vasculopathy, cerebrovascular disease, and peripheral vascular disease. Characteristically, total cholesterol, low-density lipoprotein cholesterol, apolipoprotein B, and triglyceride levels increase by 3 months after transplantation and then generally fall somewhat after the first year. Corticosteroids, cyclosporine, sirolimus, and mycophenolate mofetil all have unfavorable effects on lipid levels, whereas tacrolimus probably causes less hyperlipidemia.

In heart transplant recipients, pravastatin and simvastatin have been associated with better outcomes, but there are no long-term data in this population demonstrating that lowering of low-density lipoprotein cholesterol levels to less than 100 mg/dL (compared with 100 to 130 mg/dL) with more potent

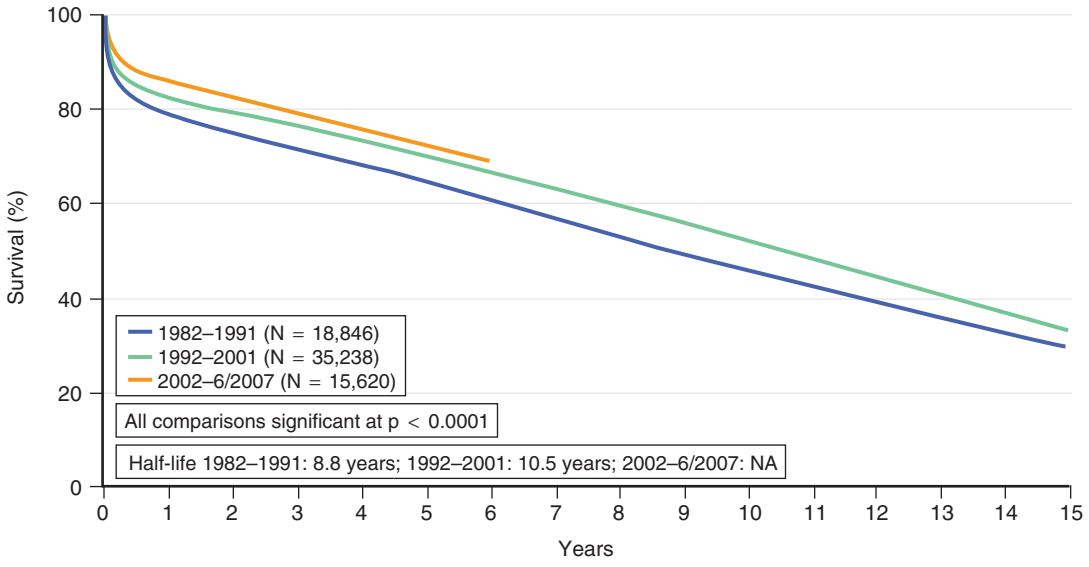

FIGURE 82-2. The Kaplan-Meier survival by era for heart transplantations performed between January 1982 and June 2007. The graph shows a significant improvement in survival over time. (Data from the Registry of the International Society for Heart and Lung Transplantation. Reproduced with permission.)

or higher-dose statin therapy improves outcomes. Different statins are metabolized differently, so caution must be exercised in the prescription of statins beyond the doses used in the randomized trials: simvastatin, 20 to 40 mg daily, and pravastatin, 10 to 20 mg daily.

OUTCOME OF TRANSPLANTATION

During the first year after transplantation, early causes of death are graft failure, infection, and rejection, with an overall survival of 87.7% at 1 year and 79.1% at 3 years (Fig. 82-2). The percentage of patients dying of early graft failure, malignant disease, and infection has remained relatively stable during the past decade. After 5 years, cardiac allograft vasculopathy and late graft failure (33% together), malignant disease (23%), and non-CMV infection (11%) are the most prominent causes of death. With advances in immunosuppression, the average half-life of the cardiac allograft increased approximately 15 months (8.8 years to 10.5 years) from 1986-1990 to 1992-2001.

Hemodynamic and Functional Outcomes

The transplanted heart markedly improves cardiac hemodynamics, but there may be a slightly diminished maximal cardiac output during exercise secondary to denervation, limited atrial function, decreased myocardial compliance from rejection or ischemic injury, and donor-recipient size mismatch. Immediately after surgery, a restrictive hemodynamic pattern is frequently observed, but it gradually improves during a few days to weeks. Some 10 to 15% of recipients develop a chronic restrictive cardiomyopathy (Chapter 60) that may produce fatigue and breathlessness during exercise. Because parasympathetic innervation, which normally lowers the heart rate, is absent, the typical resting heart rate of a recipient is 90 to 115 beats per minute.

At 1 year, 90% of surviving patients report no functional limitations, and approximately 35% return to work. Adapting to life after transplantation depends on many factors, including the patient's condition and duration of illness before transplantation and the patient's personality, intelligence, social support, and financial well-being.

Other Key Long-Term Issues for the Nontransplantation Physician

Drug Interactions

The physician outside the transplanting hospital may be reluctant to interact at all with the heart transplant recipient, a fear that complicates the comprehensive care of these patients. Often a phone call placed to the transplantation center to clarify any proposed medications or new symptoms will obviate the need for the recipient to travel to the transplanting hospital. The most common errors made by nontransplantation physicians are the addition of new drugs that result in adverse drug interactions; examples include acyclovir, allopurinol, amlodipine, antacids, antidepressants, cimetidine, clarithromycin, clotrimazole, colchicine, diltiazem, erythromycin, felodipine, ganciclovir, grapefruit juice, iron, ketoconazole, phenobarbital, phenytoin, primidone, rifampin, statin drugs, St. John's wort, trimethoprim-sulfamethoxazole, valganciclovir, and verapamil. In addition, the index of suspicion must be higher in evaluating the possibility of infection in a transplant recipient (Chapter 289).

FUTURE DIRECTIONS IN CARDIAC TRANSPLANTATION

It is not surprising that uniform agreement has not been achieved among transplantation centers regarding the precise indications for and timing of listing for cardiac transplantation. The basic tenet of organ allocation embraces two axioms that are at times contradictory: equity, or equal access of all patients to donor organs, with priority given to patients closest to death; and utility, an allocation policy for organs that maximizes survival of the patient and graft. As newer therapies, such as cell transplantation and better permanent mechanical devices, become available, the role of heart transplantation will need to be redefined.

83 APPROACH TO THE PATIENT WITH RESPIRATORY DISEASE

MONICA KRAFT

Respiratory symptoms, which are among the most common reasons why patients seek medical care, are responsible for about 20% of office visits to a primary care physician. Key common respiratory complaints include cough, wheezing, dyspnea, and hemoptysis.

APPROACH TO THE PATIENT WITH COUGH

Cough is the single most common respiratory complaint for which patients seek care. Referrals of patients with persistently troublesome chronic cough of unknown etiology account for 10 to 38% of outpatient visits to respiratory specialists.

For acute cough, defined as coughing that has been present for less than 8 weeks, a careful medical history and physical examination will usually reveal the diagnosis (Table 83-1). Although most acute coughs are of minor consequence, cough can occasionally be a sign of a potentially life-threatening illness, such as pulmonary embolism (Chapter 98), pneumonia (Chapter 97), or heart failure (Chapter 58).

Up to 98% of all cases of chronic cough, defined as a cough that persists for more than 8 weeks, in immunocompetent adults are caused by eight common conditions: postnasal drip syndrome from a variety of rhinosinus conditions (Chapter 259), asthma (Chapter 87), gastroesophageal reflux disease (GERD) (Chapter 140), chronic bronchitis (Chapter 88), eosinophilic bronchitis, bronchiectasis (Chapter 90), use of angiotensin-converting enzyme (ACE) inhibitors, and postinfectious cough. Postinfectious cough is usually nonproductive and lasts for 3 to 8 weeks following an upper respiratory infection; patients have a normal chest radiograph. Uncommon causes of chronic cough include bronchogenic carcinoma (Chapter 197), chronic interstitial pneumonia (Chapter 92), sarcoidosis (Chapter 95), left ventricular failure (Chapter 58), and aspiration (Chapter 94).

DIAGNOSIS

In chronic cough (Fig. 83-1), the character and timing are not of diagnostic help. A chest radiograph should be obtained in all patients, but other tests should not be ordered in current smokers or patients taking ACE inhibitors until the response to smoking cessation or discontinuation of the drug for at least 4 weeks can be assessed. Sinus radiographs, barium esophagography, methacholine challenge, esophageal pH, and bronchoscopy can be ordered as part of the initial evaluation, depending on the history and physical examination (Table 83-2; see Fig. 83-1). If a test points toward a possible diagnosis, a trial of treatment for that condition is needed to confirm the diagnosis.

TREATMENT Rx

The specific cause of cough can be diagnosed and treated successfully 84 to 98% of the time, so nonspecific therapy aimed to suppress the cough per se is rarely indicated. There is no strong evidence that nonspecific therapies such as antitussives, mucolytics, decongestants, or antihistamine-decongestant combinations are efficacious for acute cough in the setting of an upper respiratory tract infection. For nonspecific persistent cough, effective treatment of chronic gastroesophageal reflux disease with a proton pump inhibitor (Chapter 140) provides no more than modest benefit, with about one in five patients improving.

APPROACH TO THE PATIENT WITH WHEEZING

Wheeze is a continuous musical sound that lasts longer than 80 to 100 msec, likely generated by flow though critically narrowed collapsible bronchi. Although expiratory wheezing is a common physical finding in asthma (Chapter 87), the many causes of wheezing (Table 83-3) (e.g., chronic obstructive pulmonary disease [COPD; Chapter 88], pulmonary edema [Chapter 58], bronchiolitis [Chapter 92], bronchiectasis [Chapter 90], and less common entities such as carcinoid [Chapter 240] and parasitic infections) often can be distinguished based on the history, physical examination, and pulmonary function testing (Chapter 85).

DIAGNOSIS

On pulmonary function testing, the shape of inspiratory and expiratory flow-volume loops provides key information about the presence of airway obstruction and whether the obstruction is extrathoracic or intrathoracic (Fig. 83-2). An important cause of extrathoracic obstruction is vocal cord lesions (Chapter 196). Variable intrathoracic obstruction can be caused by tracheomalacia, whereas fixed upper airway obstruction can be caused by a proximal tracheal tumor.

TREATMENT Rx

Treatment of the specific cause will usually lead to complete or at least partial resolution of wheezing. However, treatment of associated asymptomatic or minimally symptomatic gastroesophageal reflux disease is not beneficial.

APPROACH TO THE PATIENT WITH DYSPNEA

Dyspnea is the sensation of difficult, labored, or unpleasant breathing. The word *unpleasant* is very important to this definition because the labored or difficult breathing encountered by healthy individuals while exercising does not qualify as dyspnea because it is at the level expected for the degree of exertion. The sensation of dyspnea is often poorly or vaguely described by the patient. The physiology of dyspnea remains unclear, but multiple neural pathways can be involved in processes that lead to dyspnea.

In acute dyspnea, or shortness of breath of sudden onset, the history, physical examination, and laboratory testing must first focus on potential life-threatening conditions, including pulmonary embolism (Chapter 98), pulmonary edema (Chapters 58 and 59), acute airway obstruction from anaphylaxis or foreign bodies, pneumothorax (Chapter 99), or pneumonia (Chapter 97). For chronic dyspnea, specific conditions to consider include COPD (Chapter 88), asthma (Chapter 87), interstitial lung disease (Chapter 92), heart failure (Chapter 58), cardiomyopathy (Chapter 60), GERD (Chapter 140), other respiratory diseases, or hyperventilation syndrome.

DIAGNOSIS

A chest radiograph, electrocardiogram, pulmonary function testing, and an exercise test with electrocardiographic (ECG) monitoring and pulse oximetry at rest and during exercise are key tests to assess patients with unexplained dyspnea (Fig. 83-3). For acute dyspnea, B-type natriuretic peptide testing can be extremely helpful in distinguishing heart failure from other causes. The utility of more detailed pulmonary testing with maximal inspiratory and expiratory pressures, flow-volume loops, with or without methacholine challenge, computed tomographic screening of the chest, and echocardiography depends on history and physical examination and the results of these tests. When GERD is a suspected cause of dyspnea, a modified barium esophagogram or 24-hour esophageal pH monitoring, or both, should be considered (Chapter 140). Other more invasive tests such as cardiac catheterization or lung biopsy may be indicated when the results of less invasive tests have not been conclusive.

TREATMENT Rx

Whenever possible, the final determination of the cause of dyspnea is made by observing which specific therapy eliminates it. Because dyspnea may be simultaneously due to more than one condition, it may be necessary to treat more than one condition.

APPROACH TO THE PATIENT WITH HEMOPTYSIS

Hemoptysis is the expectoration of blood from the lung parenchyma or airways. Hemoptysis may be scant, with just the appearance of streaks of bright red blood in the sputum, or massive, with the expectoration of a large volume of blood. Massive hemoptysis, which is defined as the expectoration of at least 600 mL of blood in 24 to 48 hours, may occur in 3 to 10% of

patients with hemoptysis. Dark red clots may also be expectorated when the blood has been present in the lungs for days.

Pseudohemoptysis, which is the expectoration of blood from a source other than the lower respiratory tract, may cause diagnostic confusion when patients cannot clearly describe the source of their bleeding. Pseudohemoptysis can occur when blood from the oral cavity, nares, pharynx, or tongue clings to the back of the throat and initiates the cough reflex, or when patients who have hematemesis aspirate into the lower respiratory tract. When the oropharynx is colonized with *Serratia marcescens*, a red-pigment-producing aerobic gram-negative rod, the sputum can also be red and be confused with hemoptysis.

Hemoptysis can be caused by a wide variety of disorders. Virtually all causes of hemoptysis (Table 83-4) may result in massive hemoptysis, but massive hemoptysis is most frequently caused by infection (e.g., tuberculosis [Chapter 332], bronchiectasis and lung abscess [Chapter 90], and cancer [Chapter 197]). Infections with aspergilloma (Chapter 347) and in patients with cystic fibrosis (Chapter 89) also are associated with massive hemoptysis. Iatrogenic causes of massive hemoptysis include rupture of a pulmonary

TABLE 83-1 SPECTRUM OF CAUSES AND FREQUENCIES OF COUGH IN IMMUNOCOMPETENT ADULTS

COMMON	LESS COMMON
ACUTE COUGH	
Common cold	Asthma
Acute bacterial sinusitis	Pneumonia
Pertussis	Heart failure
Exacerbations of COPD	Aspiration syndromes
Allergic rhinitis	Pulmonary embolism
Environmental irritant rhinitis	Exacerbation of bronchiectasis
CHRONIC COUGH	
Rhinosinus conditions	Bronchogenic carcinoma
Asthma	Chronic interstitial pneumonia
Gastroesophageal reflux	Sarcoidosis
Chronic bronchitis	Left heart failure
Eosinophilic bronchitis	
Bronchiectasis	
ACE inhibitors	
Postinfection	

ACE = angiotensin converting enzyme; COPD = chronic obstructive pulmonary disease.

TABLE 83-2 TESTING CHARACTERISTICS OF DIAGNOSTIC PROTOCOL FOR EVALUATION OF CHRONIC COUGH

TESTS	DIAGNOSIS	POSITIVE PREDICTIVE VALUE, %	NEGATIVE PREDICTIVE VALUE, %
Sinus radiograph	Sinusitis	57-81	95-100
Methacholine inhalation challenge	Asthma	60-82	100
Modified barium esophagography	GERD, esophageal stricture	38-63	63-93
Esophageal pH*	GERD	89-100	<100
Bronchoscopy	Endobronchial mass/ lesion	50-89	100

TABLE 83-3 DIAGNOSIS OF SELECTED WHEEZING ILLNESSES OTHER THAN ASTHMA

	DISTINGUISHING FEATURES
UPPER AIRWAY DISEASES	
Postnasal drip syndrome	History of postnasal drip, throat clearing, nasal discharge; physical exam shows oropharyngeal secretions or cobblestone appearance to mucosa.
Epiglottis	History of sore throat out of proportion to pharyngitis. Evidence of supraglottitis on endoscopy or lateral neck radiographs.
Vocal cord dysfunction syndrome	Lack of symptomatic response to bronchodilators, presence of stridor plus wheeze in absence of increased $P(A\text{-}a)o_2$; extrathoracic variable obstruction on flow-volume loops; paradoxical inspiratory and/or early expiratory adduction of vocal cords on laryngoscopy during wheezing. This syndrome can masquerade as asthma, be provoked by exercise, and often coexists with asthma.
Retropharyngeal abscess	History of stiff neck, sore throat, fever, trauma to posterior pharynx; swelling noted by lateral neck or CT radiographs.
Laryngotracheal injury due to tracheal cannulation	History of cannulation of trachea by endotracheal or tracheostomy tube; evidence of intrathoracic or extrathoracic variable obstruction on flow-volume loops, neck and chest radiographs, laryngoscopy, or bronchoscopy.
Neoplasms	Bronchogenic carcinoma, adenoma, or carcinoid tumor is suspected when there is hemoptysis, unilateral wheeze, or evidence of lobar collapse on chest radiograph or combinations of these; diagnosis is confirmed by bronchoscopy.
Anaphylaxis	Abrupt onset of wheezing with urticaria, angioedema, nausea, diarrhea, and hypotension, especially following insect bite, in association with other signs of anaphylaxis such as hypotension or hives, or administration of drug or IV contrast, or family history.
LOWER AIRWAY DISEASES	
COPD	History of dyspnea on exertion and productive cough in cigarette smoker. Because productive cough is nonspecific, it should only be ascribed to COPD when other cough-phlegm syndromes have been excluded, forced expiratory time to empty more than 80% of vital capacity >4 sec, and there is decreased breath sound intensity, unforced wheezing during auscultation, and irreversible, expiratory airflow obstruction on spirometry.
Pulmonary edema	History and physical exam consistent with passive congestion of the lungs, ARDS, impaired lung lymphatics; abnormal chest radiograph, echocardiogram, radionuclide ventriculography, cardiac catheterization, or combinations of these.
Aspiration	History of risk for pharyngeal dysfunction or gastroesophageal reflux disease; abnormal modified barium swallow and/or 24-hr esophageal pH monitoring.
Pulmonary embolism	History of risk for thromboembolic disease, positive confirmatory tests.
Bronchiolitis	History of respiratory infection, connective tissue disease, transplantation, ulcerative colitis, development of chronic airway obstruction over months to a few years rather than over many years in a nonsmoker; mixed obstructive and restrictive pattern on PFTs and hyperinflation; may be accompanied by fine nodular infiltrates on chest radiograph.
Cystic fibrosis	Combination of productive cough, digital clubbing, bronchiectasis, progressive COPD with *Pseudomonas* species colonization and infection, obstructive azoospermia, family history, pancreatic insufficiency, and two sweat chloride determinations of >60 mEq/L; some patients are not diagnosed until adulthood, in one instance as late as age 69 yr; when sweat test is occasionally normal, definitive diagnosis may require nasal transepithelial voltage measurements and genotyping.
Carcinoid syndrome	History of episodes of flushing and watery diarrhea; elevated 5-hydroxyindoleactic acid level in 24-hr urine specimen.
Bronchiectasis	History of episodes of productive cough, fever, or recurrent pneumonias; suggestive chest radiographs or typical chest CT findings; ABPA should be considered when bronchiectasis is central.
Lymphangitic carcinomatosis	History of dyspnea or prior malignancy; reticulonodular infiltrates with or without pleural effusions; suggestive high-resolution chest CT scan; confirmed by bronchoscopy with biopsies.
Parasitic infections	Consider in a nonasthmatic patient who has traveled to an endemic area and complains of fatigue, weight loss, fever; peripheral blood eosinophilia; infiltrates on chest radiograph; stools for ova and parasites for nonfilarial causes; blood serologic studies for filarial causes.

ABPA = allergic bronchopulmonary aspergillosis; ARDS = acute respiratory distress syndrome; COPD = chronic obstructive pulmonary disease; CT = computed tomography; IV = intravenous; $P(A\text{-}a)o_2$ = alveolar-arterial oxygen tension gradient; PFTs = pulmonary function tests.

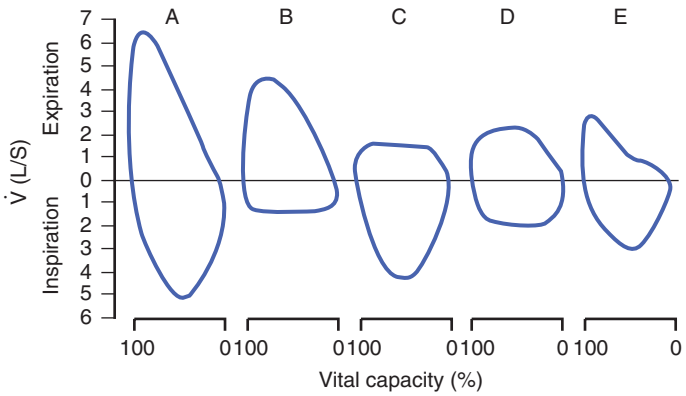

FIGURE 83-2. Schematic flow-volume loop configurations in a spectrum of airway lesions. *A* is normal; *B* is variable extrathoracic upper airway obstruction; *C* is variable intrathoracic upper airway lesion; *D* is fixed upper airway obstruction; and *E* is small airway obstruction. L/S = liters per second; V̇ = ventilation.

artery after less than 0.2% of cases of balloon-guided flotation catheterization and tracheal artery fistula as a complication of tracheostomy.

In nonmassive hemoptysis, the etiology is bronchitis in more than one third of cases (Chapter 88), bronchogenic carcinoma (Chapter 197) in one fifth of cases, tuberculosis (Chapter 332) in 7%, pneumonia (Chapter 97) in 5%, and bronchiectasis in 1% (Chapter 90). Using a systematic diagnostic approach (see later), the cause of hemoptysis can be found in 68 to 98% of cases. The remaining 2 to 32% have idiopathic or central hemoptysis, which occurs most commonly in men between the ages of 30 and 50 years. Prolonged follow-up of idiopathic hemoptysis almost always fails to reveal the source of bleeding, even though 10% continue to have occasional episodes of hemoptysis.

DIAGNOSIS

The diagnostic evaluation for hemoptysis begins with a detailed medical history and a complete physical examination. Information on the amount of bleeding should be obtained, as well as details about the frequency, timing, and duration of hemoptysis. For example, repeated episodes of hemoptysis occurring over a period of months to years suggest a bronchial adenoma or bronchiectasis as the cause, whereas small amounts of hemoptysis occurring every day for weeks are more likely to be caused by bronchogenic carcinoma. A travel history can suggest coccidioidomycosis (Chapter 341) and histoplasmosis (Chapter 340) in the United States, paragonimiasis and ascariasis (Chapter 366) in the Far East, and schistosomiasis (Chapter 363) in South America. Orthopnea and paroxysmal nocturnal dyspnea suggest heart failure (Chapter 58), especially from mitral stenosis (Chapter 75). In patients who have occupational exposure to trimellitic anhydride, which occurs when heated metal surfaces are sprayed with a corrosion-resistant epoxy resin, hemoptysis can be part of the postexposure syndrome. In a patient with the triad of upper airway disease, lower airway disease, and renal disease, Wegener's granulomatosis (Chapter 278) should be suspected. Pulmonary hemorrhage may also be a presenting manifestation of systemic lupus erythematosus (Chapter 274). Goodpasture's syndrome, which typically occurs in young men, is also associated with renal disease (Chapter 123). Diffuse alveolar hemorrhage occurs in 20% of cases during autologous bone marrow transplantation (Chapter 181) and should be suspected in patients who have undergone recent bone marrow transplantation (Chapter 181) when they present with cough, dyspnea, hypoxemia, and diffuse pulmonary infiltrates.

On physical examination, inspection of the skin and mucous membranes may show telangiectasias suggesting heredity hemorrhagic telangiectasia (Chapter 176) or ecchymoses and petechiae, suggesting a hematologic abnormality (Chapter 175). Pulsations transmitted to a tracheostomy cannula should heighten suspicion of a tracheal artery fistula. Inspection of the thorax should show evidence of recent or old chest trauma, and unilateral wheeze or rales may herald localized disease such as a bronchial adenoma or carcinoma. Although pulmonary embolism (Chapter 98) cannot be definitively diagnosed on physical examination, tachypnea, phlebitis, and pleural friction rub suggest this disorder. If rales are heard on the chest examination, heart failure as well as other diseases causing diffuse pulmonary hemorrhage (see earlier) or idiopathic pulmonary hemosiderosis (Chapter 92) should be considered. Careful cardiovascular examination may help diagnose mitral stenosis (Chapter 75), pulmonary artery fistulas, or pulmonary hypertension (Chapter 68).

Routine laboratory studies should include a complete blood count, urinalysis, and coagulation studies. The complete blood count may suggest an infection, hematologic disorder, or chronic blood loss. Urinalysis may reveal hematuria and suggest the presence of a systemic disease (e.g., Wegener's granulomatosis, Goodpasture's syndrome, systemic lupus erythematosus) associated with renal disease. Coagulation studies may uncover a hematologic disorder that is primarily responsible for hemoptysis or that contributes to excessive bleeding from another disease. The ECG may help suggest the presence of a cardiovascular disorder. Although as many as 30% of patients

with hemoptysis have a normal chest radiograph, routine chest radiographs may be diagnostically valuable.

Bronchoscopy can localize the bleeding site in up to 93% of patients by fiberoptic bronchoscopy and in up to 86% with rigid bronchoscopy. It may establish sites of bleeding different from those suggested by the chest radiograph. The best results are obtained when bronchoscopy is performed during or within 24 hours of active bleeding, and rates of diagnosis fall to about 50% by 48 hours after bleeding. When there is no active bleeding, bronchoscopy with bronchoalveolar lavage can be helpful in patients thought to have diffuse intrapulmonary hemorrhage. Typical findings include bright red or blood-tinged lavage fluid from multiple lobes in both lungs or a substantial number of hemosiderin-laden macrophages (i.e., at least 20% of the total number of alveolar macrophages).

Depending on the results of the initial evaluation and the likely categories of hemoptysis, additional diagnostic tests can be helpful (Table 83-5). Bronchoscopy may not be needed in patients who have stable chronic bronchitis (Chapter 88) with one episode of blood streaking or who have acute tracheobronchitis (Chapter 88). Bronchoscopy may also not be needed with obvious cardiovascular causes of hemoptysis, such as heart failure and pulmonary embolism.

TREATMENT

Rx

Treatment is targeted toward the cause of hemoptysis. Bronchoscopic approaches (Chapter 101) are increasingly used for endobronchial lesions.

84 IMAGING IN PULMONARY DISEASE

PAUL STARK

IMAGING OF THE LUNGS, MEDIASTINUM, AND CHEST WALL

EPIDEMIOLOGY

Worldwide, chest radiography is the most commonly performed imaging procedure; more than 75 million chest radiographs are performed every year in the United States alone. Chest radiographs provide useful information about the patient's anatomy and disease at a minimal monetary cost and with radiation exposure that most experts agree is negligible. Although many novel imaging techniques are available, the plain chest radiograph remains invaluable in the initial assessment of disorders of the lung, pleura, mediastinum, and chest wall.

Imaging Techniques

Chest radiographs, although classically obtained with cassettes and x-ray film, are now commonly acquired by digital imaging with electronic display at workstations and distribution of data through networks. Regardless of the image processing approach used, the standard chest radiograph is performed at 2 m from the x-ray tube focal spot to the image detector, in frontal and lateral projections. If possible, the radiographs should be obtained with the patient inhaling to total lung capacity. These images provide views of the lungs, mediastinum, and chest wall simultaneously.

Portable Radiography

Although bedside or portable radiography accounts for a large number of chest radiographs, the images obtained are generally of lower technical quality, cost more, and are more difficult to interpret. Lung volumes are low, thereby leading to crowding of vascular structures, and the low kilovoltage technique required for the mobile equipment yields radiographs with overexposed lungs and an underpenetrated mediastinum. The anteroposterior projection and the slightly lordotic angulation of the x-ray beam combine to distort the basal lung structures and magnify the cardiac silhouette. Recumbent studies also make recognition of pleural effusions or pneumothoraces more difficult.

Computed Tomography

Computed tomography (CT) has multiple advantages over conventional radiography. It displays cross-sectional anatomy free of superimposition, with a ten-fold higher contrast resolution. Multislice CT scanners acquire a continuous, volumetric, isotropic data set with possibilities for high-quality two-dimensional or three-dimensional reformatting (volume rendering) in any plane. High-resolution CT of the lung parenchyma is an important application; narrow collimation of the beam combined with an edge-enhancing high spatial frequency algorithm results in exquisite detail of normal and abnormal lungs, and correlation with pathologic anatomy is high.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) depends on the magnetic properties of hydrogen atoms. Magnetic coils and radio frequency coils lead to induction,

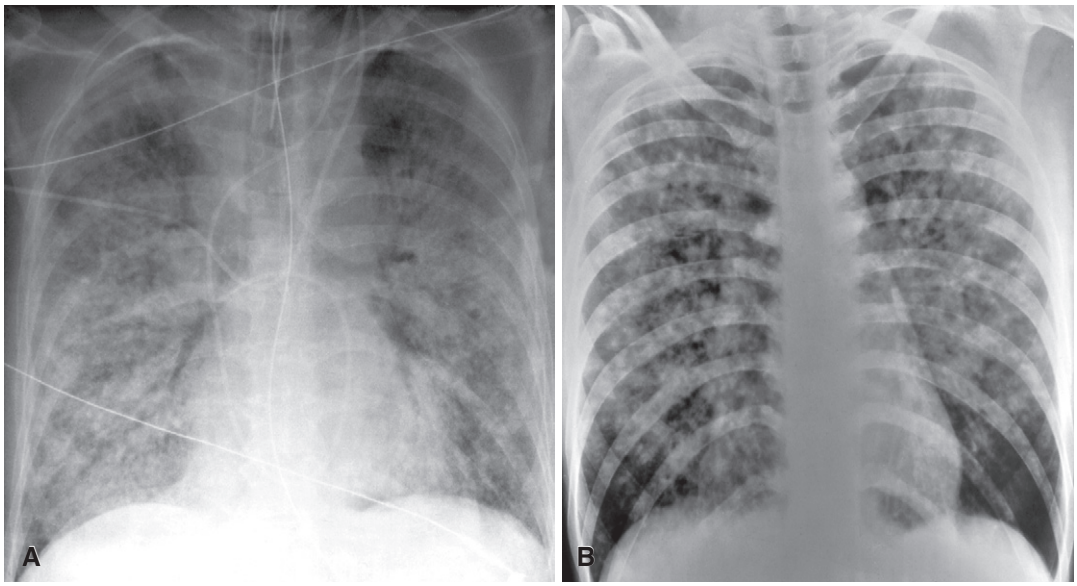

FIGURE 84-1. A, Patient with diffuse alveolar damage. Chest radiograph shows diffuse homogeneous opacification of both lungs with clearly visible air bronchograms. **B,** Patient with acute varicella pneumonia. Chest radiograph demonstrates multiple "acinar" nodules with tendency for confluence, yielding multifocal patchy parenchymal opacification.

excitation, and eventual readout of magnetized protons. The molecular environment of hydrogen atoms will affect the rate at which they release energy; this energy yields a spatial distribution of signals that is converted into an image by computer algorithms, similar to CT. Because of its soft tissue specificity, MRI has applications in the assessment of chest wall invasion, mediastinal infiltration, and diaphragmatic involvement by lung cancer or malignant mesothelioma.

Positron Emission Tomography

Fluorodeoxyglucose positron emission tomography (FDG-PET) uses labeled fluorodeoxyglucose to image the glycolytic pathway of tumor cells or other metabolically active tissues with affinity for glucose. This technique has proved helpful in studying intrathoracic tumors and has facilitated the work-up of solitary pulmonary nodules. Integrated PET-CT scans have improved the diagnosis and staging of intrathoracic tumors.■

Ultrasonography

Outside the heart, ultrasonography plays only a limited role in thoracic imaging. Its primary use is to localize pleural effusions and to guide their drainage.

Evaluation of Chest Images

Images of the chest are best evaluated by examining regions of the lung for specific findings and relating these findings to known diagnostic groups. A number of critical radiographic features should be considered, with an appreciation for the known causes of these changes.

Diffuse Lung Disease

Diffuse lung disease is an overall term for a number of related abnormal parenchymal radiographic patterns. Although radiologists have attempted to separate alveolar from interstitial lung disease radiographically, this distinction is no longer recommended because the correlation between the radiographic localization to a compartment and the actual histopathologic findings is relatively poor. For example, nodular patterns can be produced by either interstitial or alveolar disease. Conversely, so-called alveolar disease processes can induce an interstitial reaction. Ground-glass opacities can be induced by either alveolar or interstitial disease. Air bronchograms, the presumed paradigm of air space disease, can be identified in a small percentage of patients with predominantly interstitial lung disease, such as sarcoidosis, pulmonary lymphoma, and pulmonary calcinosis.

Because of such limitations, a graphically descriptive approach that combines analysis of predominant opacities, assessment of lung expansion, and distribution and profusion of disease yields a differential diagnosis. The term *infiltrate* should be avoided; instead, pulmonary opacities are classified as large (i.e., >1 cm in largest dimension) or small (i.e., <1 cm in diameter).

TABLE 84-1 CLASSIFICATION OF LARGE PULMONARY OPACITIES

Diffuse homogeneous
Multifocal patchy
Lobar without atelectasis
Lobar with atelectasis
Perihilar
Peripheral

Large Opacities

Large opacities (Table 84-1) are characterized according to their distribution. Diffuse homogeneous opacities are typical for diffuse alveolar damage (Fig. 84-1A), increased permeability (noncardiogenic) pulmonary edema, diffuse viral pneumonia, or *Pneumocystis jirovecii* pneumonia. Multifocal patchy opacities (see Fig. 84-1B) are found in multifocal bronchopneumonia, recurrent aspiration, or vasculitis. Lobar opacities without atelectasis are typically seen in lobar pneumonia. Lobar opacities with atelectasis often result from obstruction of a lobar bronchus by foreign bodies, tumors, or mucous plugs. Perihilar opacities are seen in hydrostatic pulmonary edema due to left-sided heart failure (Fig. 84-2), renal failure, volume overload, or pulmonary hemorrhage.

Small Opacities

In contrast to the large pulmonary opacities, a number of radiographic patterns characterize small pulmonary opacities in diffuse lung disease. It is helpful to differentiate small nodular, linear, reticular, or combined patterns (Table 84-2). Micronodular opacities, which include nodules 1 mm and smaller in diameter, can result from talc granulomatosis in intravenous drug abusers (Chapter 33), alveolar microlithiasis, rare cases of silicosis, talcosis, coal workers' pneumoconiosis (Chapter 93), and beryllium-induced lung diseases (Chapter 93) as well as from occasional cases of sarcoidosis (Chapter 95) or hemosiderosis. The nodular pattern includes nodules up to 1 cm in diameter. Frequent causes include infections or inflammatory granulomas such as miliary tuberculosis (Chapter 332), sarcoidosis (Chapter 95), fungal diseases, extrinsic allergic alveolitis, and Langerhans cell histiocytosis (Chapter 92).

Linear Patterns

Linear patterns, also called Kerley's lines, are mostly a reflection of thickened interlobular septa. Kerley's A lines, which radiate 2 to 4 cm from the hilum toward the pulmonary periphery and particularly toward the upper lobes (Fig. 84-3), reflect thickening of the axial interstitial compartment and can be a feature of left ventricular failure or allergic reactions. Kerley's B lines,

FIGURE 84-2. Patient with hydrostatic pulmonary edema due to left-sided heart failure. Chest frontal radiograph demonstrates classic "batwing" distribution of pulmonary edema.

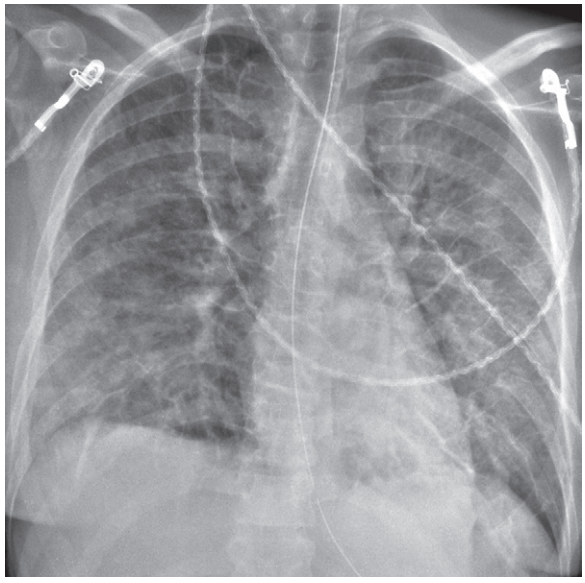

FIGURE 84-3. Patient with known transfusion reaction. Chest radiograph displays ground-glass opacification of both lungs and bilateral Kerley's A lines, presenting as long linear structures extending from the hilar regions into the pulmonary periphery.

which reflect thickening of the subpleural interstitial compartment, typically are about 1 cm in length and 1 mm in thickness and usually found in the periphery of the lower lobes, abutting the pleura. The B lines are characteristic of subacute and chronic left ventricular failure (Chapter 58), mitral valve disease (Chapter 75), lymphangitic carcinomatosis, viral pneumonia, and pulmonary fibrosis (Chapter 92). Kerley's C lines, which are rarely diagnosed by radiologists, result from thickening of the lung parenchymal interstitium and form a reticular pattern on chest radiographs.

FIGURE 84-4. Diffuse reticular lung disease. Chest radiograph in a 94-year-old patient with diffuse reticular opacities due to idiopathic pulmonary fibrosis with honeycombing and traction bronchiectases. The lung volumes are typically reduced by a decreased pulmonary compliance.

Reticular Patterns

Reticular patterns are small polygonal, irregular, or curvilinear opacities on chest radiographs (Fig. 84-4). The differential diagnosis varies according to the timeline of the pathologic change. Acute onset of a reticular pattern can occur in interstitial edema (e.g., due to left-sided heart failure), atypical pneumonitides (e.g., viral or mycoplasmal pneumonia), early exudative changes in a connective tissue disorder (e.g., systemic lupus erythematosus; Chapter 274), and acute allergic reactions (e.g., transfusion reactions [Chapter 180] or reactions to *Hymenoptera* stings). The common chronic processes resulting in a reticular pattern are idiopathic interstitial pneumonias (Chapter 92), connective tissue diseases (particularly scleroderma and rheumatoid lung), asbestosis (Chapter 93), radiation fibrosis (Chapter 92), end-stage hypersensitivity pneumonia (Chapters 92 and 93), drug reactions, lymphangitic spread of cancer, end-stage granulomatous infection, lymphoma in its bronchovascular form, Kaposi's sarcoma in its bronchovascular manifestation, and sarcoidosis.

Honeycombing

Honeycombing, which is an indication of end-stage interstitial lung disease (Chapter 92), reflects a restructuring of pulmonary anatomy accompanied by bronchiolectasis. Honeycombs form a multilayer of small subpleural spaces between 3 and 10 mm in diameter. They can be distinguished from paraseptal emphysema by their thicker wall and multiple layers.

Alveolar Pattern

An alveolar (Chapter 91) or air space pattern is characterized by acinar nodules, 0.6 to 1 cm in diameter. These nodules encompass more than the acinus, in the strict anatomic sense, with surrounding peribronchiolar lung tissue. Other patterns include ground-glass opacities (a reflection of incomplete alveolar filling), coalescent large opacities, consolidation involving whole lobes or segments, opacification in a bronchocentric distribution, air bronchograms, and air alveolograms. These radiographic features are helpful in placing a disease into a particular radiologic category, but the radiographic pattern called *alveolar* does not simply correspond to exclusive histologic alveolar filling because the interstitial compartment is involved as well in most cases. A more accurate description is parenchymal rather than alveolar opacification or consolidation.

Bronchial Patterns

Bronchial patterns, as best depicted by diffuse bronchiectasis (Chapter 90), are seen on conventional radiographs as linear, tubular, or cystic lucencies and opacities that follow the expected path of bronchi, so-called tramlines because they resemble tram tracks. Mucoid impaction, as seen in patients with asthma, allergic bronchopulmonary aspergillosis, or plastic bronchitis, leads to opacities described as toothpaste, cluster of grapes, or finger-in-glove. The "dirty lung" pattern seen in smokers with chronic bronchitis (Chapter 88) results from bronchial wall thickening, peribronchial fibrosis, respiratory bronchiolitis, and pulmonary arterial hypertension.

FIGURE 84-5. Patient with left ventricular failure. Chest frontal radiograph shows cephalization of pulmonary blood flow.

FIGURE 84-7. Patient with severe emphysema. Chest radiograph shows hyperexpansion of both lungs with bullous changes at the right lung base and leftward mediastinal shift.

FIGURE 84-6. Patient with primary pulmonary arterial hypertension. Chest frontal radiograph shows centralization of flow with pulmonary artery aneurysms and peripheral pulmonary oligemia.

Neurofibromatosis
Emphysema with pulmonary fibrosis

Vascular Patterns

Arterial patterns reflect changes in pulmonary perfusion. The term *caudalization* reflects the normal blood flow distribution pattern in an upright person in which the basilar pulmonary vessels are two to three times wider than the upper lobe vasculature. *Cephalization,* in which the ratios of diameters of vessels are reversed, is frequently seen in recumbent persons, in whom it may be considered normal; however, when it is present in individuals imaged in the upright position, it indicates left ventricular failure, mitral valve disease, or basilar emphysema (Fig. 84-5). Equalization, or balanced flow with well-demonstrated vessels to upper and lower lung zones, is found in hyperkinetic circulation due to anemia, obesity, pregnancy, Graves' disease, or left-to-right shunts. Equalization or balanced flow with oligemia can be seen in hypovolemia, diffuse emphysema, or right-to-left shunts. Centralization reflects dilation of central pulmonary vessels, with accompanying normal or diminished peripheral circulation. Typically, it is seen in pulmonary arterial hypertension (Fig. 84-6). Lateralization of flow, favoring one lung over the other, also called *asymmetrical perfusion*, is visible with unilateral emphysema, unilateral bronchiolitis obliterans (Swyer-James-McLeod syndrome), or unilateral obstruction of the pulmonary artery. Locally enlarged vessels occur in patchy emphysema, multiple pulmonary emboli, arteriovenous malformations, and nonuniform bronchiolitis obliterans. This pattern produces a mosaic perfusion on high-resolution CT scanning.

Lung Volume

Conventional radiographs and CT scans are taken during a breath hold at full inspiration. Low lung volumes are inferred by the high position of the diaphragm and the crowding of basal vascular structures (Table 84-3). Lung volumes larger than expected are commonly found in patients with diffuse emphysema (Fig. 84-7) (Chapter 88), chronic asthma (Chapter 87), or diffuse bronchiolitis and in highly trained athletes. With a few rare exceptions, chronic diffuse infiltrative lung diseases (Chapter 92) lead to loss of volume.

Anatomic Distribution

The anatomic distribution of disease can significantly facilitate the approach to diagnosis (Table 84-4 and Fig. 84-8). Upper-zone lung disease predominates in tuberculosis, fungal disease, sarcoidosis, pneumoconiosis (except asbestosis), Langerhans cell histiocytosis, ankylosing spondylitis, cystic fibrosis, cystic *P. jirovecii* pneumonia, radiation pneumonitis, and end-stage hypersensitivity pneumonia. Basal lung disease is preferentially found in bronchiectases, aspiration, desquamative interstitial pneumonia, nonspecific interstitial pneumonia, usual interstitial pneumonia, drug reactions, asbestosis, scleroderma, and rheumatoid arthritis. However, any diffuse lung

process will eventually progress to involve both lungs irrespective of zonal boundaries.

Lymph Nodes

Enlarged lymph nodes that are visible on chest CT scans and, when larger, on chest radiographs can provide diagnostic information (Table 84-5). The following entities can be associated with diffuse lung disease and concurrent enlarged lymph nodes: sarcoidosis (Chapter 95); lymphoma; fungal disease; tuberculosis (Chapter 332); pneumoconioses (Chapter 93), particularly silicosis and beryllium-associated lung disease; lung cancer; and metastatic malignant disease other than lung cancer.

Pulmonary Nodules

Solitary pulmonary nodules are covered in Chapter 197. Most patients with multiple pulmonary nodules larger than 1 cm in diameter have metastatic disease from primary cancers either within or outside the lung (Fig. 84-9). These lesions have a predilection for subpleural lung regions, including the interlobar fissures. In patients with human immunodeficiency virus infection, Kaposi's sarcoma and lymphoma can induce the formation of such nodules. Infectious processes that present with multiple nodules include multiple abscesses from recurrent aspiration (Chapter 94) or septic emboli (Chapter 76); tuberculous and nontuberculous mycobacterial granulomas (Chapters 332 and 333); fungal processes, including histoplasmosis (Chapter 340), coccidioidomycosis (Chapter 341), and cryptococcosis (Chapter 344); and infection with flukes, such as *Paragonimus westermani* (Chapter 364). Noninfectious inflammatory conditions that can present with multiple pulmonary nodules include Wegener's granulomatosis (Chapter 278), rheumatoid nodules (Chapter 272), sarcoidosis (Chapter 95), and amyloidosis (Chapter 194).

Pleural Disease

Pleural diseases are covered in Chapter 99. Abnormalities of the pleural space easily can be displayed by conventional radiographic methods supplemented by CT scanning. The volume of pleural effusions can be reliably estimated on standard posteroanterior films: 75 mL obscures the posterior costophrenic sulcus, 150 mL obscures the lateral costophrenic sulcus, 200 mL produces a

FIGURE 84-10. Patient with known prior occupational asbestos exposure. Chest radiograph shows extensive bilateral calcified plaques seen en face, in profile, and along the diaphragmatic contour.

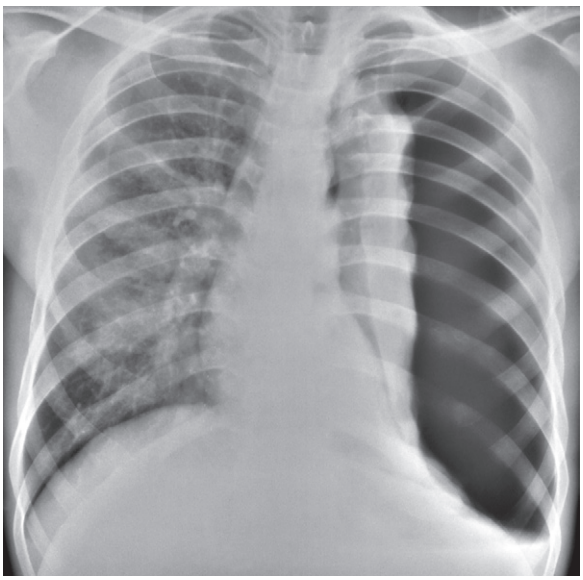

FIGURE 84-11. Patient with spontaneous tension hydropneumothorax. Chest radiograph shows complete atelectasis of the left lung with a large pneumothorax and a left basilar gas-liquid level. The patient had primary tuberculosis.

rind of 1 cm in thickness on decubitus films, 500 mL obscures the diaphragm and is visible on supine radiographs, and 1000-mL effusions reach the level of the fourth anterior rib on upright chest radiographs. An effusion of 200 mL or more can be sampled by thoracentesis. The smallest amount visible on decubitus radiographs is 10 mL. With care, as little as 175 mL of effusion can be detected on supine images. Free layering effusions produce a veil of opacity or filter effect superimposed on the aerated lung; pulmonary vessels are clearly visible through the added opacity generated by the effusion, and air bronchograms are absent.

Subpulmonic Effusions

Subpulmonic effusions elevate the lung base, mimicking a high-riding hemidiaphragm. The highest curvature point of the pseudodiaphragm is shifted laterally. Large effusions can lead to diaphragmatic inversion. Separation of the lung base from the gas-containing stomach is indicative of a subpulmonic effusion, particularly when the stomach gas bubble is displaced inferomedially. Loculated pleural effusions suggest the presence of pleural adhesions. Such encapsulated collections have obtuse angles of interface with the chest wall and have a sharply defined border with the adjacent lung.

Pleural Plaques

Pleural plaques result from parietal pleural accumulation of hyalinized collagen fibers (Fig. 84-10); their presence suggests asbestos exposure (Chapter 93). Plaques preferentially involve the parietal pleura adjacent to ribs six through nine and the diaphragm. They are less pronounced in the intercostal spaces and spare the costophrenic sulci as well as the apices. Calcifications are visible on chest radiographs in 20% and on CT scans in 50% of individuals with plaques. Imaged in profile, pleural plaques produce focal areas of apparent pleural thickening. Over the diaphragm, they appear as curvilinear calcifications or scalloping. Pleural plaques viewed en face can simulate lung disease. Their appearance has been likened to holly leaves, sunburst patterns, "geographic" patterns, or stippled or irregular structures. Rare visceral pleural plaques that occur in interlobar fissures can mimic pulmonary nodules.

Diffuse Pleural Thickening

Diffuse pleural thickening is a response observed after exposure to any of a number of stimuli including infection, inflammation, trauma, tumor, thromboembolism, radiation, and asbestos. Severe involvement results in formation of a generalized pleural peel with smooth margins, usually less than 2 cm in thickness. Radiologically diffuse pleural thickening is characterized by a smooth, noninterrupted pleural opacity involving at least one fourth of the chest wall circumference, obliterating the costophrenic sulci and encompassing also the apices. The CT criteria for diffuse pleural thickening include a thickness of at least 3 mm.

Malignant Disease

Malignant tumors of the pleura are more common than benign ones, and metastatic disease is more frequent than primary pleural mesothelioma. Primary tumors originate from pleural membranes. Pleural invasion by lung cancer, subpleural plaques in lymphoma, hematogenous dissemination to the pleura, and direct pleural seeding are other mechanisms of pleural involvement by tumor. Benign pleural tumors include lipomas, fibrous tumors, and neurogenic tumors. Lipomas are most common; their diagnosis is facilitated by CT scanning. Fibrous tumors of the pleura originate from pluripotent mesenchymal cells found in the visceral pleura or, less commonly, in the parietal pleura. They can induce paraneoplastic syndromes such as hypertrophic osteoarthropathy (Chapter 187) or hypoglycemia and only rarely invade or metastasize. In nearly half of these patients, the tumor can be on a pedicle and be mobile as a patient changes position.

Pneumothorax

Pneumothorax means gas in the pleural space (Chapter 99). The most important radiologic feature of a pneumothorax is a visceral pleural line or edge that is convex or straight toward the chest wall and produces a lucent separation of the visceral and parietal pleura (Fig. 84-11). In most cases, no pulmonary vascular structures are visible beyond the visceral pleura. On upright chest radiographs, gas is primarily found in the apicolateral pleural space. Expiratory chest radiographs are not necessary for the detection of small pneumothoraces because all pneumothoraces are visible on inspiratory films. On supine chest radiographs, pleural gas accumulates in a subpulmonic location; it outlines the costophrenic sulcus, forming the deep sulcus sign. A tension pneumothorax leads to a marked shift of the mediastinum to the contralateral side and to flattening or inversion of the ipsilateral hemidiaphragm.

Imaging of the Mediastinum

The mediastinum encompasses midline thoracic structures that are delineated by mediastinal pleura, the diaphragm, the sternum, the spine, and the thoracic inlet. The mediastinum is commonly divided into an anterior compartment, a visceral middle compartment, and a paraspinal, posterior mediastinal compartment (Table 84-6). Each compartment contains specific pathologic entities.

Imaging Techniques

On well-penetrated chest radiographs, the anterior junction line, the posterior-superior junction line, the azygoesophageal stripe, the pleuroesophageal stripe, the paratracheal stripe, and the para-aortic and the paraspinal stripes or lines should be assessed (Fig. 84-12). Mediastinal masses need to be detected and localized first. Their obtuse angles of interface with the

mediastinal pleura, as well as extension into both hemithoraces, indicate the mediastinal origin of such lesions.

CT facilitates localization of a mass to a specific mediastinal compartment. When it is known whether the mass is predominantly fat, cystic, soft tissue, or calcified, the differential diagnosis can be limited. MRI of the mediastinum has a role in diagnosis of vertebral disease or neurogenic tumors with extension into the spinal canal. It is as good as CT in diagnosis of aortic aneurysms and dissections (Chapter 78).

Mediastinal Compartments

The anterior mediastinum is actually a potential space that may contain the fatty replaced thymus and small normal lymph nodes. Space-occupying lesions in this compartment typically include thymomas, lymphomas, teratomas and other germ cell tumors, substernal thyroid goiters, lipomas, and other connective tissue tumors as well as hemangiomas or lymphangiomas (Fig. 84-13A).

TABLE 84-6 CLASSIFICATION OF MEDIASTINAL COMPARTMENTS

ANTERIOR MEDIASTINUM
Retrosternal
MIDDLE MEDIASTINUM—VISCERAL COMPARTMENT
Subcarinal space Paratracheal region Retrotracheal space Aortic-pulmonic window Retrocardiac space
POSTERIOR MEDIASTINUM
Paraspinal region

The middle mediastinum is subdivided into the subcarinal space, paratracheal region, retrotracheal region, aortic-pulmonic window region, and retrocardiac space. Characteristic lesions are enlarged lymph nodes and bronchopulmonary foregut malformations (see Fig. 84-13B).

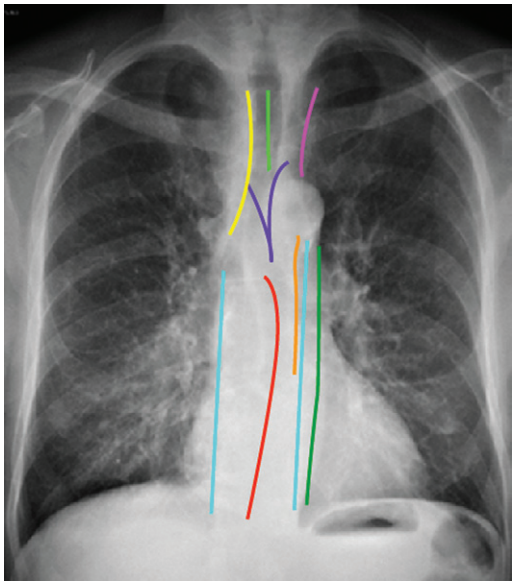

FIGURE 84-12. Chest radiograph with superimposed mediastinal stripes. *Yellow:* right paratracheal stripe. *Light blue:* right and left paraspinal stripes. *Red:* azygoesophageal stripe. *Brown:* pleuroesophageal stripe. *Purple:* anterior junction line complex. *Pink:* left subclavian artery border. *Light green:* posterior-superior junction line. *Dark green:* para-aortic line.

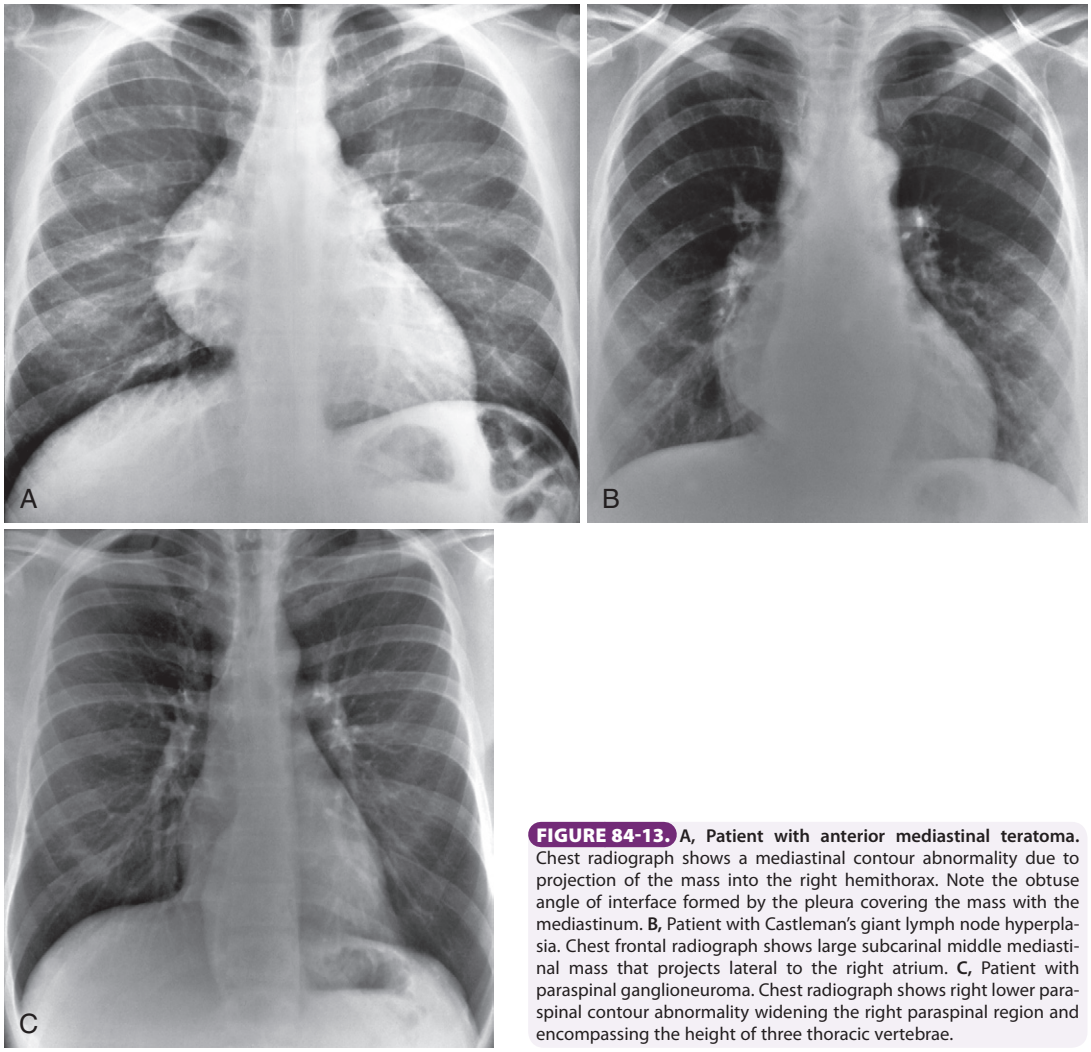

FIGURE 84-13. A, Patient with anterior mediastinal teratoma. Chest radiograph shows a mediastinal contour abnormality due to projection of the mass into the right hemithorax. Note the obtuse angle of interface formed by the pleura covering the mass with the mediastinum. **B,** Patient with Castleman's giant lymph node hyperplasia. Chest frontal radiograph shows large subcarinal middle mediastinal mass that projects lateral to the right atrium. **C,** Patient with paraspinal ganglioneuroma. Chest radiograph shows right lower paraspinal contour abnormality widening the right paraspinal region and encompassing the height of three thoracic vertebrae.

In the retrotracheal region, aberrant right subclavian arteries, posterior descending goiters, esophageal tumors, diverticula, or thoracic duct cysts can be found. In the aortic-pulmonic window, ductus diverticula, bronchopulmonary foregut malformations, or aortic or pulmonic artery aneurysms can form compartment-specific space-occupying lesions.

The paraspinal region is considered radiologically to belong to the posterior mediastinum. Important masses in that space include neurogenic tumors that originate from the sympathetic chain or from segmental nerve roots (see Fig. 84-13C). Extramedullary hematopoiesis in patients with severe anemia can result in paravertebral masses formed by hypertrophied bone marrow that extrudes from ribs or vertebral bodies. Enlarged lymph nodes due to lymphoma or metastatic disease are occasionally seen in a paraspinal location. Vertebral disease, including bacterial or tuberculous spondylitis, tumors, and post-traumatic hematomas, can widen the paraspinal region and produce contour abnormalities.

RESPIRATORY STRUCTURE AND FUNCTION: MECHANISMS AND TESTING

HERBERT Y. REYNOLDS

The lungs are designed for oxygen uptake and carbon dioxide elimination through the process of ventilation and molecular diffusion. To maintain health, purified air must be presented to the alveolar epithelial surface to aerate pulmonary capillary blood. Ambient air, which contains environmental debris, microbes, and possibly solubilized toxins and is admixed at times with aspirated oropharyngeal secretions, must be cleansed. Inspired ambient air encounters a system of host defenses that usually removes these contaminants mechanically (by sneezing, rhinorrhea, coughing, and mucociliary clearance), through innate (natural) immunity mechanisms, or immunologically through adaptive (acquired) immunity. This nonventilatory function can be missing (primary host defects) or compromised by systemic illness or the side effects of other medical therapy. Because ventilation and nonventilatory function are so intertwined, both are described together; methods for assessment of clinical function then follow.

RESPIRATORY STRUCTURE AND FUNCTION

Respiratory Tract Structure

Although the respiratory tract is a continuum of branching tubes leading to the air exchange-alveolar surface, it functionally has four distinct anatomic segments: naso-oropharynx or upper airways, conducting airways (larynx, trachea, and bronchi that branch to terminal bronchioles), respiratory bronchioles, and alveolar ducts and alveoli. Vascular and neural structures are integral to each segment; lymphatic channels begin at the level of respiratory bronchioles and flow upward or cephalad into the hilar nodes. But much still remains unknown about various cell lineages contributing to development of the lung, the phenotype and function of perhaps half of the approximately 40 resident cells that compose the human respiratory tract, and the roles of neuroendocrine cells and various progenitor cells that can replenish structural cells after injury.

The airways and their accompanying blood supply develop from an evagination of the foregut and primitive esophagus. The conducting airways form a continuum of approximately 14 generations of branches, which are extended by another 10 or so branches within the acinar airways, finally ending as alveolar sacs. This anatomic structure has been described as a tree with irregular, dichotomously branching tubes. Later developments in the fetus initiate progressive thinning of the mucosal epithelial layer in distal bronchi and then the respiratory bronchioles to a single cell surface, which defines the beginning of the gas exchange unit within the acinar-alveolar structures. Mechanisms to cleanse inspired air are dispersed along the entire tract.

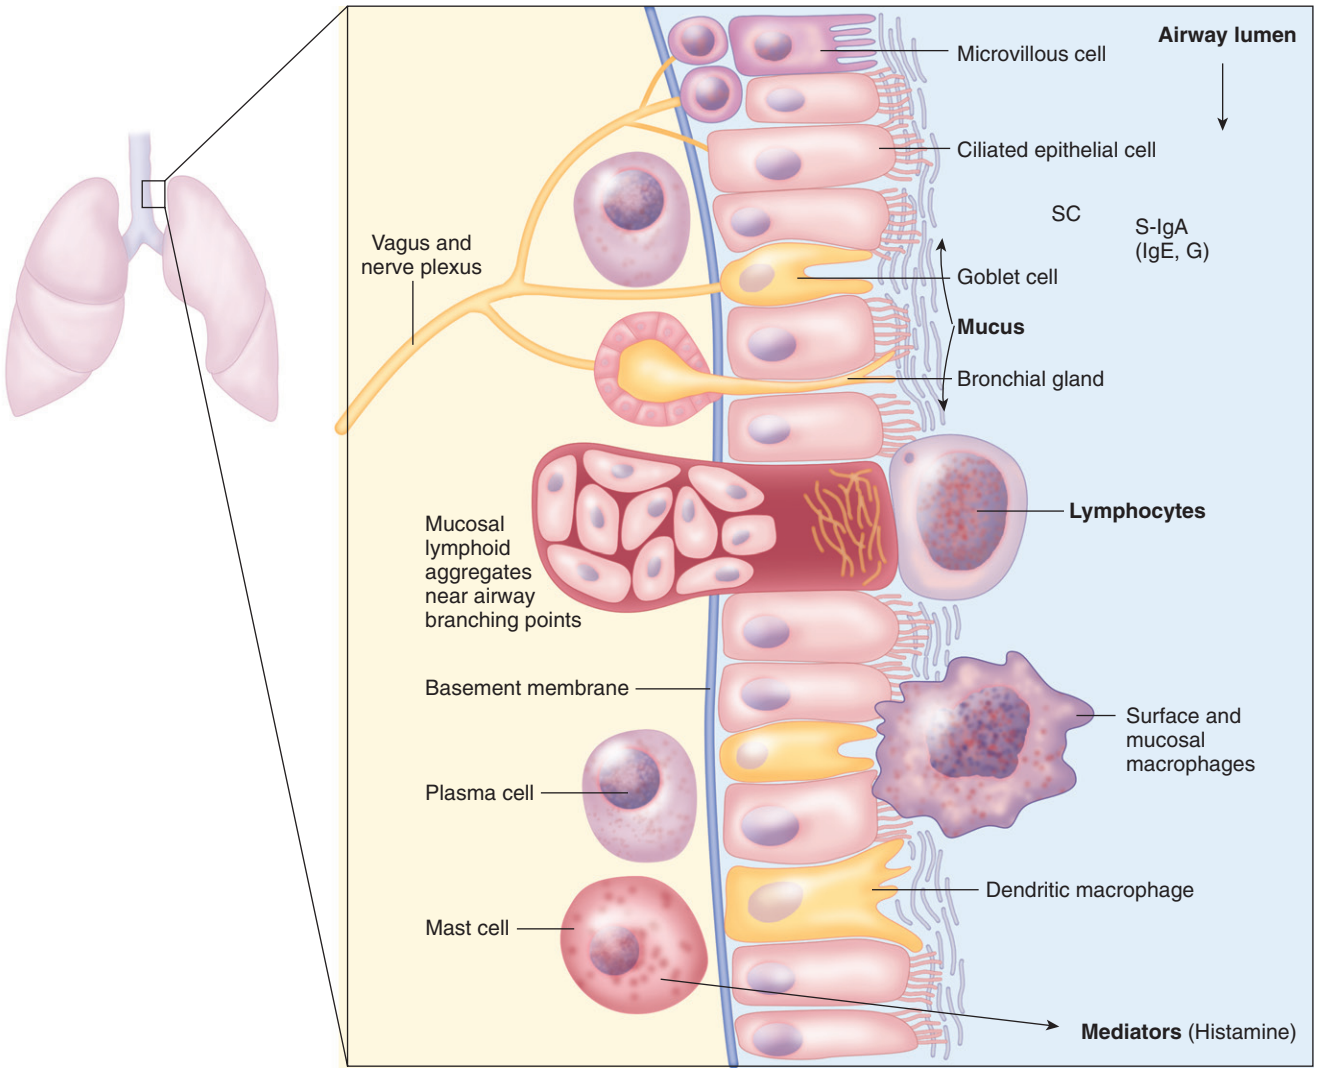
The *naso-oropharynx* includes the upper airways and associated sinuses (Chapter 434). It begins at the nares and lips and extends back through a richly vascular, undulant mucosal covering of the nasal passage, through the glottis, into the extrathoracic trachea. Nasal hairs and turbinates filter out large particles (>10 μm diameter) as inspired air passes over the nasal surface in a turbulent flow pattern. In this process, air is humidified and warmed as it passes through the nose and over the soft palate; it typically is fully conditioned before it reaches the posterior pharynx. Because sinus and posterior nasal secretions can collect in the posterior pharynx, deglutition and respiration are coordinated exquisitely by the epiglottis and laryngeal musculature to direct fluids and food into the esophagus and air into the subglottic trachea. Control is not perfect, however, and microaspiration can occur in normal persons during sleep. Esophageal reflux can cause cough in normal individuals and asthma symptoms in patients with more hyperreactive airways (Chapters 87 and 140). Mucociliary clearance declines with age, explaining in part the more frequent occurrence of respiratory infections in elderly patients.

The *conducting airways* begin with the trachea, a flexible tube held open by cartilaginous, horseshoe-shaped rings with a posterior muscular face that abuts the esophagus. The trachea is about 10 cm in length and contains about 15 rings. At the carina, it divides into two major bronchi, and thereafter multiple smaller bronchial branches diverge through many generations of smaller divisions. In aggregate, however, the branching creates a much greater overall cross-sectional area that not only reduces resistance to airflow but also decelerates the velocity of air molecules as they prepare to enter the acinar ducts and alveolar sacs. Airflow beyond the conducting airways is largely laminar; the slower movement further cleanses the air by allowing the settling out of any 0.5- to 3-μm particulates that still are present and would be impacted at branching points. This action seems especially important in the respiratory bronchioles, which serve as the transition segment between the conducting airways and alveoli, where several adaptations facilitate further removal of particulates or antigens. Throughout the conducting airways (E-Fig. 85-1), the mucosal surface provides a barrier function because of the tight apical junctions between epithelial cells. About half of the epithelial cells are ciliated; a fluid film and mucus cover the beating cilia, creating the mucociliary apparatus. The thickness of the mucosal surface attenuates as the pseudostratified cell layer flattens to become a single cell layer in the terminal bronchioles. Here the less protected surface may become more vulnerable to injury from inhaled toxins and microbes and more susceptible to ravages of chronic inflammation (bronchiolitis).

The airway layer of pseudostratified epithelial cells creates a physical barrier by forming tight apical junctions that control permeability and promote pericellular ion and fluid flux. About half of the epithelial cells have cilia to propel a covering layer of fluid and admixed mucus that can collect airway debris and eliminate it by a process known as *mucociliary clearance*. These epithelial cells have dynamic turnover of several days, with continuous self-renewal from progenitor stem cells, but the normal replication rate may vary at different locations along the airways. If airway injury has destroyed epithelial cells and denuded the surface, regeneration begins quickly from reservoirs of self-renewing stem cells found in niches in the ducts of submucosal glands in the trachea or bronchi and within the surface epithelium of more distal airways.

The *respiratory bronchioles,* which are positioned between the distal conducting airways and the alveolized air exchange surface, functionally separate the upper and lower respiratory tracts. This segment is a bottleneck for airflow and a last surface to capture small particulates and microbial or antigenic debris before the alveolar space; immune responses can be initiated here. The respiratory bronchioles can be the site of airway obstruction, caused by inflammation; a common form is termed *bronchiolitis obliterans* (Chapter 92) and is associated with several lung diseases, such as chronic graft rejection after lung transplantation (Chapter 101) and lung involvement by collagen vascular diseases (Chapter 92). In this transition region of the airway, several changes occur: the single-layer cuboidal epithelial surface further differentiates into alveolar type I cells that cover the alveolar lining surface; mucus-secreting cells disappear, although goblet cells can develop in cigarette smokers; and another secretory cell type emerges, the Clara cells. Pulmonary brush cells with a tuft of squat microvilli are dense in this area and may be involved with chemosensing or trapping of inhaled particles and pollutants as well as with regulation of fluid and solute absorption. Also, many dendritic macrophage-like cells, which may constitute 1% of the cells, are present to capture antigens. Surface host defenses change from mucociliary clearance to macrophage phagocytes, inflammatory cells (neutrophils or eosinophils), and opsonins. Lymphatic channels form to collect the lymphatic fluid squeezed up from the interalveolar interstitial spaces into lymphatic capillaries that course along pulmonary capillaries and venules in the alveolar walls. The bronchial arterial circulation supplies the conducting airways, whereas the pulmonary arterial to pulmonary capillary circulation encompasses the alveoli and is the locus for diffusion of oxygen into the blood and carbon dioxide from the blood.

The *air exchange* compartment, or the alveolar space, is composed of about 480 million alveoli supported by a fibrous scaffolding and intertwined with a meshwork of pulmonary artery capillaries that permit air-blood contact. Oxygen uptake and carbon dioxide elimination occur across a thin tissue layer of type I epithelial cells and capillary endothelium that in aggregate creates a large surface area of approximately 130 square feet. To increase the likelihood that respiratory function will support a healthy human lifespan despite pollutants, infections, or systemic diseases that affect the lungs, an intricate system of host defenses has evolved. The system specialized for the alveoli is different from the system described in the proximal airways. Although an alveolus is reasonably protected from airborne debris by aerodynamic filtration that occurs in the upper respiratory tract, small particles (<0.5 μm) can remain suspended in air or toxic gases can gain access to the alveoli directly.



E-FIGURE 85-1. A portion of the bronchial airway surface depicts the mucosa and its submucosal structures. The pseudostratified ciliated epithelium has a covering layer of mucus (produced by goblet cells and bronchial glands) and a film of fluid that contains various proteins, including immunoglobulins and free secretory component (SC). A few surface cells may be present, such as lymphocytes (from bronchial-associated lymphoid aggregates) and macrophages. Among the epithelial cells are absorptive microvillous cells and dendritic cells, whose cellular processes interdigitate with the mucosal surface. The epithelial cells can produce inflammatory cytokines that affect mucosal swelling and permeability. In the submucosa below the basement membrane, mast cells and plasma cells reside that secrete mediators (e.g., histamine) and local immunoglobulins (e.g., IgA). Interacting with all of these glandular and cellular networks are nerves, exerting their control through neuropeptides and by adrenergic and cholinergic nerve fibers. A rich bronchial arterial vascular supply also exists. (Modified from Reynolds HY. Pulmonary host defenses. *Chest*. 1989;95:223S-230S.)

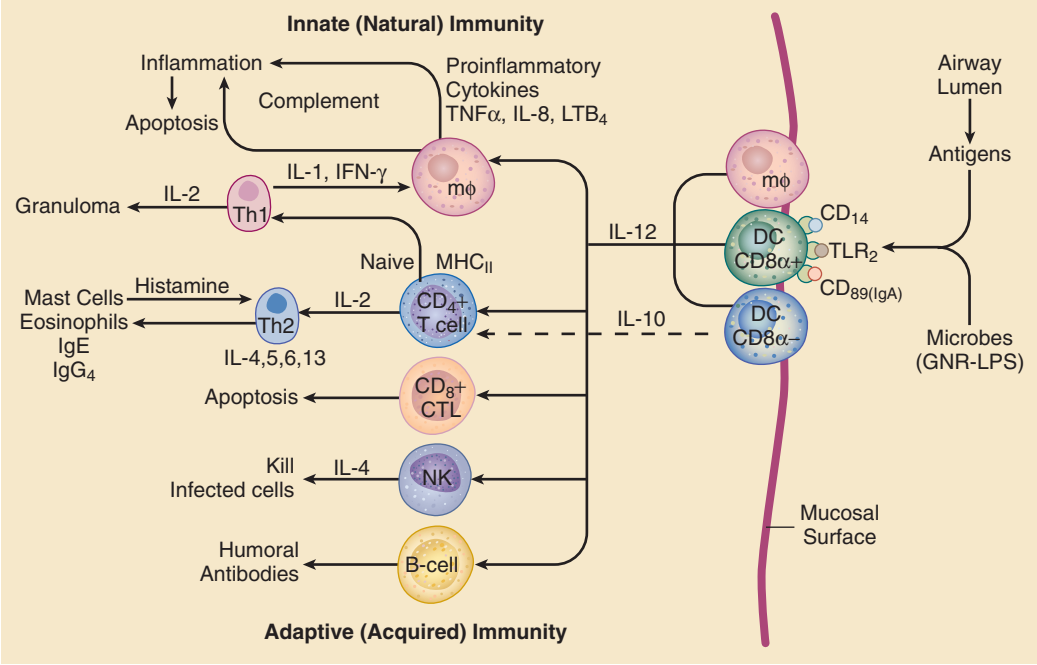
Cellular Host Defenses

Respiratory host defenses balance two mechanisms that eliminate or detoxify microbes and other antigenic materials that enter the airways (E-Fig. 85-2). First is an innate or quick response reaction that produces inflammation as an end point (bronchitis or pneumonitis) with subsequent apoptosis of neutrophils and suppression of inflammation to limit the reaction. Second is a more deliberate approach that stimulates lymphocytic pathways, creating a versatile and adaptive response involving specific T-cell activity or production of immunoglobulins (antibodies).

Microbes can be contained in aspirated fluid or carried intravascularly to the parenchyma (septicemia). A microbe entering an alveolus may encounter an antigen-presenting cell or several opsonins in the epithelial lining fluid, including immunoglobulin (Ig) G antibodies (IgG1 and IgG3 subtypes) and nonimmune substances (type II cell-secreted surfactant proteins A and D, fibrinogen, and complement fragments [C3b]) that can promote receptor-mediated uptake or phagocytosis by macrophages. Alveolar T lymphocytes can stimulate the macrophage with cytokines, such as interleukin (IL)-1 and interferon-γ, that enhance its bactericidal activity or, if microbes are too numerous or too virulent, can create an inflammatory response quickly. Chemokines, derived from macrophages or epithelial cells, including IL-8, leukotriene B_4, and tumor necrosis factor, can attract neutrophils and other inflammatory products from adjacent capillaries into the alveolus. If inflammation, or pneumonitis, is successful in eradicating infection, neutrophils undergo apoptosis, the inflammation resolves, and normal lung tissue function is restored. If the inflammatory process is prolonged, a smoldering, chronic inflammatory response can persist and lead to tissue injury that causes fibrosis and scarring, or depending on the antigen-particle or microbe involved, a granulomatous reaction may develop from IL-2 stimulating T_H1 lymphocytes. If this wound-type healing occurs after substantial injury, respiratory function can be lost permanently.

Epithelial cells have about the same repertoire of proinflammatory chemokines as alveolar macrophages, including IL-8, leukotriene B_4, transforming growth factor-β, monocyte chemotactic protein 1, and RANTES. They also can inhibit or downregulate inflammation. This dual capability to help initiate inflammation and then suppress it makes the epithelium crucial for the pathogenesis of diseases such as asthma (Chapter 87), bronchitis, emphysema (Chapter 88), and pulmonary fibrosis (Chapter 92). Chronic inflammatory changes can cause bronchiectasis (Chapter 90) or cell atypia that leads to endobronchial cancer (Chapter 197).

Dendritic cells or surface macrophages process antigens, using Toll-like receptors such as TLR2 and TLR4, and present them to major histocompatibility complex–compatible but naive $CD4^+$ lymphocytes, a process facilitated with the stimulatory cytokine IL-12. IL-2 produced by $CD4^+$ T cells subsequently can direct Th1 lymphocytes to develop and proliferate. Th1 cells can produce IL-1 and interferon-γ, which can stimulate macrophages for heightened activity (phagocytic uptake) in the inflammatory pathway. Also, IL-2 can induce clonal expansion of $CD4^+$ lymphocytes that contributes to creating granulomas for containment of certain microbes, such as mycobacteria, or particles (silica or beryllium).



E-FIGURE 85-2. **In bronchial airways, dendritic macrophage cells, embedded in the mucosa or residing on its surface, can direct the major protective immune pathways, innate and adaptive immunity, to confront microbes and foreign antigens that have evaded upper airway defense mechanisms and threaten the airway lumen, potentially disrupting normal respiration.** A choice of the inflammatory reaction for quick removal or a more deliberate cellular immune elimination is made and proceeds by the major lymphocytic pathways, T_H1 or T_H2, and other cell-mediated processes that are described in the text. CD = cluster of differentiation; DC = dendritic cell; GNR-LPS = gram-negative rods–lipopolysaccharide; IFN-γ = interferon-γ; Ig = immunoglobulin; IL = interleukin; mø = macrophage; MHC II = major histocompatibility complex class II; NK = natural killer; TLR = Toll-like receptor; TNF = tumor necrosis factor. (From Reynolds HY. Modulating airway defenses against microbes. *Curr Opin Pulm Med.* 2002;8:154-165.)

ASSESSMENT OF PULMONARY VENTILATORY FUNCTION

Pulmonary physiologic function can be measured by examining the relationships between expired airflow and volume or time or by using tests that measure exercise capacity or the distance that can be walked in a prespecified amount of time (typically 6 minutes). These functional tests provide measures of physiologic function and may be used to reproduce clinical symptoms, such as breathlessness or dyspnea, and to correlate these symptoms with the degree of physical limitation. These tests are used to measure baseline status, to monitor treatment, and to estimate prognosis.

Pulmonary Function Tests

Lung function tests (Table 85-1) measure a person's ventilatory capacity in comparison with that of normal subjects. By adjusting for sex, height, ethnicity, and age, the values for a given individual can be compared with those from otherwise normal individuals. Basic tests for preliminary assessment and for monitoring disease progression include spirometry, which is a record of exhaled volume versus time during a forced exhalation (with or without determination of the response to an inhaled bronchodilator for possible reversible airflow); diffusion capacity, which measures the transfer of carbon monoxide to indicate how well inspired gases cross the alveolar-interstitial-capillary endothelial interface into blood; and noninvasive pulse oximetry, for oxygen saturation measured at rest or during ambulation. Pulmonary function tests (PFTs) performed after graduated exercise on a treadmill or a timed walking test on a level surface provides a more dynamic assessment of pulmonary function and correlates well with prognosis in patients with chronic pulmonary conditions such as lung fibrosis and chronic obstructive disease. More specialized tests include body plethysmography to determine total lung volumes and airway resistance as well as maximal cardiopulmonary exercise testing to assess cardiac function and oxygen uptake and consumption. The clinical utility of these tests can be appreciated by understanding how they can be applied to representative types of patients (Table 85-2).

TABLE 85-1 PULMONARY FUNCTION TESTS

LUNG VOLUME	
TLC	Total lung capacity (volume of gas in lungs at the end of maximal inspiration)
FRC	Functional residual capacity (volume of gas in the lungs when elastic inward pull is balanced by outward pull of the chest wall and diaphragm)
ERV	Expiratory reserve volume (volume of gas expired from FRC to maximal expiration)
RV	Residual volume (FRC – ERV, volume of gas left in lungs after maximal exhalation)
EXPIRATORY FLOW	
FEV_1	Forced expiratory volume (in 1 second)
FVC	Forced vital capacity
$FEV_1\%$	FEV_1/FVC ratio (expressed as percentage)
DIFFUSING CAPACITY	
D_{LCO}	Diffusing capacity for carbon monoxide
ARTERIAL BLOOD GASES	
Pa_{O_2}	Arterial oxygen pressure
Pa_{CO_2}	Arterial carbon dioxide pressure
pH	

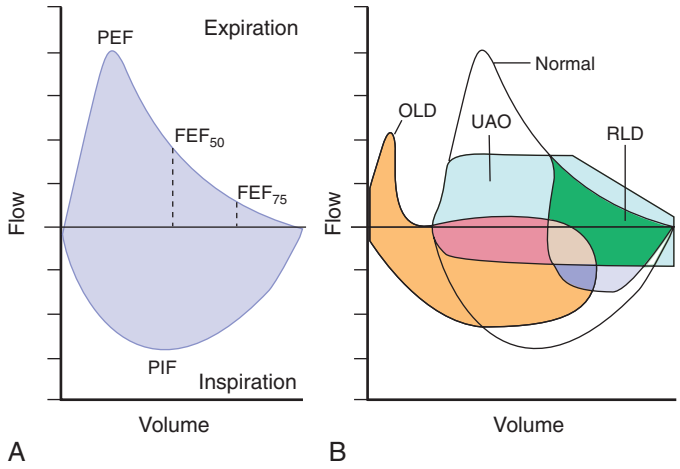
Spirometry

A tracing of the relationship between maximal expiratory airflow and time, termed a *spirogram,* is the most common measure of ventilatory lung function. It is used to make a preliminary diagnostic assessment or to monitor patients as lung or cardiac disease evolves and responds to treatment. Spirometry is recorded by having a seated subject breathe calmly several times at tidal volume, draw a maximal inhalation, perform a forced exhalation that is continued for at least 6 seconds with sustained vigorous effort (forced vital capacity [FVC]), and finally make a vigorous full inspiration (inspiratory vital capacity). These maneuvers are represented as a volume-time loop or as a flow-volume loop (plotting flow against FVC and inspiratory vital capacity). Flow-volume loops are scrutinized for special patterns that can indicate various clinical or anatomic conditions (E-Fig. 85-3). Considerable physical effort and attentiveness are required for adequate spirometry. Patients, especially during hospitalization, after medical procedures, or if they are deconditioned, often cannot give maximal effort or cooperate or coordinate well, and their test results will not be optimum. PFTs in a patient who is still under treatment for an exacerbation of chronic obstructive pulmonary disease (COPD) or asthma but who is not yet back to pre-illness status will show results that reflect their current status but not their baseline status. Recent treatment with a bronchodilator often improves PFT results and does not reflect intrinsic pulmonary function; about 8 to 12 hours should elapse from the last treatment to provide the most useful data. Reproducibility of several test attempts (at least three) is important and is a criterion for valid interpretation of test results. Other medical problems that can confuse spirometric testing include pulmonary congestion, coughing, thyroid dysfunction, neurologic illness, poor nutrition, and corticosteroid-associated muscle weakness. Serial testing is required to assess improvement, a return to baseline, or the need for intensified treatment in an outpatient.

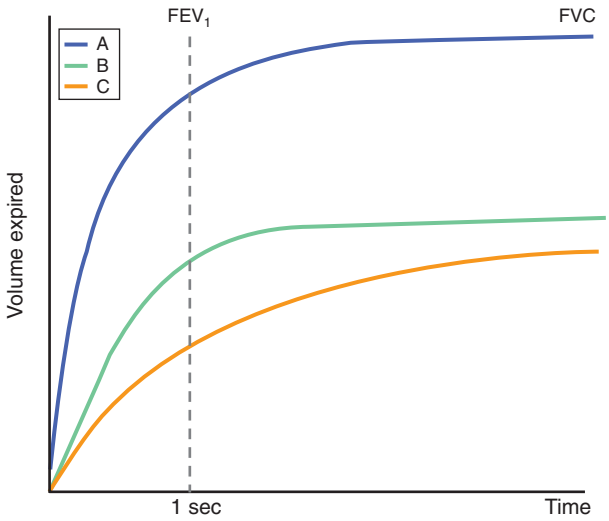
TABLE 85-2 CLINICAL EXAMPLES OF TESTING IN REPRESENTATIVE TYPES OF PATIENTS WITH COMMON PULMONARY COMPLAINTS

CLINICAL PRESENTATION	PHYSICAL FINDINGS AND CHEST RADIOGRAPH	PULMONARY FUNCTION TESTS	RESULTS OF VENTILATORY FUNCTION (% PREDICTED)	CHARACTERISTIC ABNORMALITIES	DIAGNOSIS	MONITORING OR PREDICTIVE USE OF TESTS
Young adult with episodic attacks of cough, wheezing, and anxiety	Rapid respiratory rate Wheezing and prolonged expiration Thorax hyperresonant Radiograph normal or hyperinflated	Spirometry (but cough and dyspnea may preclude complete results) Oximetry Arterial blood gas analysis (only if the episode is prolonged or severe)	PEFR > 60% FEV_1, 45-75% MMEFR, 30-50% ABG (while breathing ambient air): Pa_{O_2}, 70 mm Hg Pa_{CO_2}, 30 mm Hg	Decreased PEFR, FEV_1, MMEFR to grade as mild, moderate, or severe attack Hypoxemia, hypocapnia, and pH changes on blood gas analysis during an attack	Asthma exacerbation of moderate intensity	Spirometry after bronchodilator treatment or challenge testing Daily peak flow measurements (keep diary of results) FEV_1 may return to normal range after episode or therapy
Middle aged, male, former smoker	Abdominal obesity (large waist circumference) BP, 140/85 mm Hg BMI, 32 kg/m^2 Hyperglycemia Dyslipidemia	Spirometry	FEV_1, 80% FVC, 84% FEV_1/FVC, 82%	FEV_1 and FVC decreased; restrictive function	Metabolic syndrome with lung restriction from abdominal obesity	Regular spirometry not indicated
Middle aged, moderate smoker (20 cigarettes per day), mild dyspnea, occasional cough and sputum	Examination findings and radiograph are likely to be normal	Baseline spirometry and oximetry Optional baseline cardiorespiratory exercise test	FEV_1 > 80% FEV_1/FVC, 70% D_{LCO}, 80%	Slight decrease in FEV_1 and perhaps FVC	Normal smoker with occasional episodes of acute bronchitis Mild COPD	Spirometry with health maintenance visit/yearly Daily peak flow monitoring Reduce or stop smoking
Older middle aged, moderate smoker for 30-40 yr, dyspnea (with moderate exertion), morning cough and phlegm, mild weight loss	Respiratory rate is likely to be increased at rest Thorax hyperinflated Breath sounds decreased Scattered wheezes and crackles Nail-bed cyanosis Radiograph normal or hyperinflated; no mass lesions evident	Spirometry and oximetry or arterial blood gas analysis Timed walk test Cardiopulmonary exercise testing (especially if heart failure is evident)	FEV_1 > 30% but <50% FEV_1/FVC < 70% D_{LCO}, 30% TLC and RV ~ 100% Timed walk test shows less than predicted for age and sex	Decreased FEV_1 (usually about 40% predicted), FVC, and FEV_1/FVC (<0.70); increased residual volume and total lung capacity D_{LCO} decreased Hypoxemia CO_2 retention perhaps	COPD of moderate severity	Spirometry yearly and after exacerbations on return to baseline Daily peak flow monitoring Blood gas analysis yearly (if FEV_1 < 40% predicted) Echocardiogram with signs of CHF Chest radiograph yearly Reduce or stop smoking Observe nutritional status and weight
Elderly patient, prior smoker, with insidious onset of dyspnea (occurs only with exertion for past 2 years) and mild nonproductive cough, without prior, relevant occupational exposures	Gaunt Respiratory and heart rates increased Coarse crackles heard at lung bases Mild clubbing Radiograph with diffuse infiltrates, decreased lung volume, and cystic areas at bases	Spirometry D_{LCO} Timed walking, with oximetry and arterial blood gas analysis Cardiopulmonary exercise test advised Baseline ABGs	TLC, 65% FVC, 65% D_{LCO}, 45% Pa_{O_2}, 70% (RA) Timed walk test shows values about 50% of predicted	Reduced lung volumes (vital capacity, total lung capacity) FEV_1/FVC ratio increased D_{LCO} reduced Hypoxemia, but normal CO_2 Exercise tolerance limited	Pulmonary fibrosis	Spirometry at each visit every 6-12 mo Oximetry Timed velocity walk (with oxygen if O_2 < 88% at rest) Echocardiogram with signs of CHF
Patient above, seemingly stable for past 1 yr, and on no therapy, developed worsening dyspnea over 3 wk	As above Afebrile Radiograph with more diffuse ground-glass opacities No clear etiology	Spirometry D_{LCO} ABG	FVC, 52% D_{LCO}, 30% Tests difficult to obtain because of respiratory distress	As above, but tests may be difficult to obtain Will find more restriction and worsened gas exchange	Acute exacerbation Pulmonary fibrosis	Occurs in 10% of patients per year with 70% mortality Resume tests above, pending recovery
Middle-aged female with scleroderma and diffuse skin thickening disease for 3 yr; now exertional dyspnea Nonsmoker Taking prednisone 10 mg/day dose	Thickened skin, has Raynaud's, dry cough No overt cardiac failure HRCT with ground-glass opacities No pulmonary artery enlargement	Spirometry D_{LCO} ABG	TLC, 70% predicted FVC, 68% FEV_1/FVC, 83% FRC, 74% RV, 70% D_{LCO}, 47% (RA)	Ventilatory restriction with FVC between 45 and 80% D_{LCO}, 40-50%	Scleroderma-related interstitial lung fibrosis, possible mild pulmonary hypertension	Spirometry and D_{LCO} with health maintenance exams FVC decline of about 10%/year expected

ABG = arterial blood gases; CHF = congestive heart failure; COPD = chronic obstructive pulmonary disease; D_{LCO} = diffusing capacity of lung for carbon monoxide; FEV_1 = forced expiratory volume in 1 second; FVC = forced vital capacity; FRC= functional reserve capacity; MMEFR = maximum mid-expiratory flow rate; PEFR = peak expiratory flow rate, RV = residual volume; TLC = total lung capacity.



E-FIGURE 85-3. Flow-volume curve. A, The maximal expired flow-volume curve in a normal subject. The peak expiratory flow (PEF) and forced expiratory flows at 50% and 75% of the exhaled vital capacity (FEF_{50} and FEF_{75}) are indicated. **B,** In obstructive lung disease (OLD), hyperinflation pushes the position of the curve to the left, and there is characteristic scalloping on expiration. In restrictive lung disease (RLD), lung volumes are reduced, but flow for any point in volume is normal. The flow-volume curve displays different patterns with various forms of upper airway obstruction (UAO), with reduction in respiratory flow if the obstruction is outside the thoracic cavity and reduction in expiratory flow if the obstruction is caused by a fixed deformity. PIF = peak inspiratory flow. (From Diagnostic techniques and their indications. In: Andreoli TE, Carpenter CC, Griggs RC, et al, eds. *Cecil Essentials of Medicine,* 5th ed. Philadelphia: WB Saunders; 2001:183.)



E-FIGURE 85-4. Typical results of spirometry in a normal patient (A), a patient with a restrictive defect (B), and a patient with an obstructive defect (C). In a patient with a restrictive defect, the FEV_1/FVC ratio is preserved at the normal level, but both absolute values are reduced. In a patient with an obstructive defect, both absolute values are again reduced, but the FEV_1/FVC ratio is considerably reduced as the forced expiratory time required to reach the FVC is greatly prolonged. (Redrawn from Forbes CD, Jackson WF. *Color Atlas and Text of Clinical Medicine,* 3rd ed. London: Mosby; 2003.)

Among the most common measures made from a spirometric tracing are FVC (liters), forced expiratory volume in the first second of exhalation (FEV_1, liters), ratio of FEV_1 to FVC (percentage), and forced expiratory flow in the middle of expiration ($FEF_{25-75\%}$, liters/second). Residual volume (liters) cannot be determined by spirometry and often is measured by helium dilution or plethysmographic methods. Residual volume is necessary to compute total lung capacity (liters), which is a measure of the air capacity of the maximally inflated lung. FEV_1, although recorded as a volume, is equated with a measure of airflow and is effort dependent.

FEV_1 values, when expressed as a percentage of predicted values, correlate with the amount of physical activity a patient can sustain. Peak flow can be measured from a spirographic tracing or using a portable device made for the outpatient monitoring of lung function; these devices are commonly prescribed for patients with asthma, COPD, or interstitial lung diseases. Encouraging a patient to keep a daily log of peak flow rates to share with the physician or medical staff can improve compliance with therapy and monitor improvement or the lack of it.

Although a healthy young person can produce a peak flow of 500 to 600 L/minute, many people with COPD are unable to achieve a peak flow greater than 200 to 350 L/minute and experience significant exertional dyspnea when peak flow decreases to less than 200 L/minute. Patients whose peak flow is about 150 L/minute are usually sedentary.

Analysis of measured values for FEV_1 and FVC (and their ratio) and total lung capacity allows the physician to make a ventilatory diagnosis of the presence of obstructive or restrictive physiology (E-Fig. 85-4). A reduced FEV_1 and low FEV_1/FVC ratio combined with a large total lung capacity indicate obstructive disease of large airways and bronchi, a pattern typically observed in patients with COPD and asthma. FVC is preserved, but the time of exhalation is prolonged. After the administration of bronchodilators, the FEV_1 and FVC may increase by 10 to 15%, especially in asthma, indicating reversibility of airway obstruction. A lesser degree of improvement often is found, however, in patients who are already using inhaled bronchodilators regularly. A decrease in the $FEF_{25-75\%}$ with relatively preserved values of FEV_1 and FVC is typically found in patients with obstruction of small airways. If a person's postbronchodilator FEV_1 is less than 80% of the predicted value and FEV_1/FVC is less than 70%, airflow limitation is not fully reversible—the defining characteristic of COPD (Chapter 88). In patients with restrictive lung disease, the FEV_1 and FVC are reduced, as is total lung capacity, but the FEV_1/FVC ratio is usually normal or increased. Causes of restrictive interstitial lung disease include fibrosis of the lung parenchyma due to many toxic and inhalation exposures and toxic drug reactions (Chapter 94) and idiopathic interstitial lung diseases (Chapter 92). Restrictive physiology with a normal or low FEV_1 may reflect the chest wall habitus, chest wall muscle weakness or deformity, and pleural thickening (Chapter 99).

Diffusion Capacity

Diffusion capacity assesses how well a tracer gas in inspired air can cross from the air into the blood. The test measures the absorption of a low concentration of carbon monoxide in inhaled air by hemoglobin in red blood cells that circulate through pulmonary capillaries. Results must be corrected for reduced lung volumes, anemia, increased carbon monoxide levels in cigarette smokers, and high altitude. The diffusion capacity provides a general assessment of the air-blood interface; reduced values are obtained when interstitial fibrosis is extensive or when the capillary surface is compromised by vascular obstruction or nonperfusion (e.g., pulmonary embolism; Chapter 98) or is destroyed as in emphysema (Chapter 88).

Site-Specific Sampling, Including Bronchoalveolar Lavage

An assessment of airway inflammation can be made by measuring the fraction of nitric oxide in exhaled air or the pH of exhaled air condensates. It is also possible to measure endogenously produced biomarkers of oxidative stress in condensates (i.e., reactive oxygen and nitrogen species or aldehydes of lipid peroxides damaged in cell membranes). Mediators of inflammation can be measured in induced sputum (e.g., IL-8, leukotriene B_4, myeloperoxidase, IL-6, and elastase products). For example, as COPD worsens, induced sputum specimens or exhaled breath condensates provide evidence of neutrophilic inflammation with higher concentrations of exhaled nitric oxide, tumor necrosis factor-α, IL-6, transforming growth factor-β, IL-8, and growth-related oncogene-α as well as more leukotriene B_4.

Site-specific sampling to detach cells by washing or abrading the mucosal surface, coupled with endobronchial or transbronchial biopsy, can provide contiguous samples containing viable cells, noncellular secretions, and adjacent tissue. Multiple sites can be sampled; mucosal cell function can be compared between the nose and lower airways to assess allergic diseases. Bronchoalveolar lavage retrieves cells and secretions from the distal airways and the alveolar space surface. In combination with a thorough clinical evaluation and lung imaging studies, distinctive cellular patterns sometimes can obviate the need for lung biopsy (Table 85-3). Lung biopsy tissue can be microdissected with laser capture of specific cell types, and cells recovered in bronchoalveolar lavage fluid can be prepared for microarray analysis; gene chips created specifically for gene expression patterns may prove helpful for determining genetic susceptibility, aiding diagnosis, predicting response to certain therapeutic agents, and monitoring clinical activity.

TABLE 85-3 BRONCHOALVEOLAR LAVAGE CELL AND FLUID FINDINGS

STATUS OR ILLNESS	CELL PROFILE	NONCELLULAR COMPONENTS	OTHER ILLNESSES IN THE DIFFERENTIAL DIAGNOSIS WITH OVERLAPPING FINDINGS
Normal nonsmokers Mean, 1.3×10^5 cells/mL of recovered BAL fluid (range, 0.6-2.1)	Differential cell count (mean %): AM, 85%; lymphocytes, 7-12%; PMN, 1-2%; eosinophils-basophils, <1%; ciliated cells, 1-5%, 1% dendritic cells Lymphocyte subsets: CD4 helper, 50%; CD8 suppressor or cytotoxic, 30%; CD4/CD8 ratio, 1.5; B lymphocytes (plasma cells), 5%	95% as IgA (40% as IgA2), 90% IgA in dimeric form with secretory component, almost no IgM, IgG (IgG1-3/albumin ratios similar to serum), increased IgG4 Low concentrations of cytokines (IL-6, IL-8) Adhesion molecules detectable Histamine detectable Surfactant present	
Healthy moderate smokers Mean, 3.6×10^5 cells/mL of recovered BAL fluid (range, 2.2-4.8)	Three-fold increase of total cells, 95% AM, 3- to 5-fold increased AM, PMNs approximately 3% Lymphocytes 3% in differential cell count	Increased IgG as IgG/albumin ratio with serum, increased IgG3 and IgG4, decreased FSC, less surfactant recovered (lipid component profile same as that of nonsmoker) Decreased A_1AT elastase inhibitory activity Increased ACE (in AM) may be found	
INTERSTITIAL LUNG DISEASES			
Sarcoidosis	Lymphocytes, >30% total cells, increased CD4 cells, increased CD4/CD8 ratio AM-lymphocytes (T cells) form spontaneous rosettes PMNs > 3% may indicate deterioration and need for therapy Considerable increase in T lymphocytes as CD4 or T_H1 cells and a raised CD4/CD8 ratio is a common finding A raised neutrophil count may correlate with more severe disease on chest radiograph	Increased IL-2, IL-6, IL-8, IL-10, IL-12, MCP-1, TNF-α, interferon-γ ACE level can be increased Increased adhesion molecule ICAM-1 Increased fibronectin PPARγ deficient in AM MMP-12 and ADAMDECI gene and protein expression increased	Extrathoracic granulomatous diseases (e.g., Crohn's disease), primary biliary cirrhosis, extrinsic allergic alveolitis, idiopathic pulmonary fibrosis, collagen vascular disease
Extrinsic allergic alveolitis (hypersensitivity pneumonitis) Acute and chronic forms	Increased lymphocytes to >40-60% of total cells, often increased CD8 with slight reversal of CD4/CD8 ratio Foamy cytoplasm of AM Increased plasma cells, sometimes increased mast cells or basophils Striking increase of T lymphocytes with most as CD8 cells is usual	Increased IgM and IgG; IgG fraction may have specific precipitating antibody activity against etiologic antigens (thermophilic microbes) Increased IL-4, IL-10, interferon-γ, MIF, MCP	Drug-induced hypersensitivity Fibrotic form of NSIP
Idiopathic pulmonary fibrosis	Increased PMN; approximately 5-15% of cells Increased eosinophils, approximately 3-6% Increased lymphocytes, 15% in some cases A raised percentage of neutrophils and eosinophils is characteristic An increase of lymphocytes and neutrophils could indicate an NSIP pattern in lung biopsy	Increased IgG, increased monomeric IgA Increased IL-4, IL-6, IL-8, IL-13, TGF-β, MIF, galactin-1, CC chemokines (CCL 2, CCL 17, CCL 22) Increased collagenase and histamine levels Increased fibronectin, decreased interferon-γ, metalloproteases MMP7, MMP1, and their genes overexpressed	Usually diagnosis of exclusion (occupational, environmental) Increased lymphocytes may indicate EAA (HP) or NSIP
Bronchiolitis obliterans after lung transplantation	Increased PMNs that persist, CD4 T_H17 cells Persistence of neutrophils >3% in serial BAL cell count samples is a clue	Increased IL-1β, IL-6, IL-8, TNF-α, IL-17, fibronectin, collagenase	Autoimmune response to type V collagen in donor lung
Scleroderma (systemic sclerosis)	Increased PMNs to approximately 3-10% of cells Increased eosinophils to approximately 3% of cells Lymphocytes about 10%, but CD8 cells may be increased Myofibroblasts can be recovered BAL cell eosinophilia >4% may indicate more severe lung fibrosis	Increased IL-4, IL-8, IL-10, IL-12, MCP-1, PDGF, TGF-β, CTGT, and thrombin activity Interferon-γ increased in 15%	
Langerhans cell histiocytosis	Cell profile similar to that of smokers: increased CD1+ cells (>5% AM) Cytoplasmic X body or Birbeck granule on EM		Most patients are smokers
Alveolar lipoproteinosis (pulmonary alveolar proteinosis)	Foamy cytoplasm of AM	Milky, turbid fluid with altered phospholipid proportions; increased surfactant protein A	Extrinsic allergic alveolitis, lipoid pneumonia, drug-induced hypersensitivity (e.g., amiodarone), silicosis
Eosinophilic pneumonia	Increased percentage of eosinophils to 40% of cells	Increased IL-5, IL-18, and VEGF	Churg-Strauss, allergic bronchopulmonary aspergillosis, drug-induced hypersensitivity
Alveolar hemorrhage (Goodpasture's, Wegener's)	Hemosiderin-laden AM		
Inhalation exposure (asbestosis, fiber, silica)	Asbestos bodies or fiber in AM Modest increase in PMNs		Subclinical exposure must be considered in asymptomatic subjects

A_1AT = α_1-antitrypsin protease; ACE = angiotensin-converting enzyme; AM = alveolar macrophages; BAL = bronchoalveolar lavage; CD4 = helper T-lymphocyte subset; CD8 = suppressor T lymphocyte; CTGT = connective tissue growth factor; EM = electron microscopy; FSC = free secretory component; ICAM-1 = intercellular adhesion molecule 1; Ig = immunoglobulin; IL = interleukin; MCP = monocyte chemotactic protein; MIF = macrophage migration inhibition factor; MMP-12 and ADAMDECI = matrix metalloproteinases; NSIP = nonspecific interstitial pneumonia; PDGF = platelet-derived growth factor; PMN = polymorphonuclear neutrophil; PPARγ = peroxisome proliferator-activated receptor γ; TGF-β = transforming growth factor-β; TNF-α = tumor necrosis factor-α; VEGF = vascular endothelial growth factor.

DISORDERS OF VENTILATORY CONTROL

ATUL MALHOTRA

DEFINITIONS AND PATHOGENESIS

Ventilatory Control

Ventilation is controlled by complex interactions between central chemoreceptors, which predominantly are responsive to carbon dioxide (CO_2) tensions in arterial blood, and peripheral chemoreceptors, which predominantly are responsive to CO_2 and oxygen (O_2) tensions (Table 86-1). Disorders of ventilatory control are caused by derangements in these control mechanisms.

TABLE 86-1 CLASSIFICATION OF CENTRAL SLEEP APNEA

CENTRAL SLEEP APNEA SYNDROME	MECHANISM	THERAPY
Sleep transition apneas	CO_2 fluctuations during transitions from sleep to wake to sleep	Reassurance, occasionally hypnotics or oxygen
Chronic narcotic therapy	Lack of central drive	Reduce narcotic dose Consider positive-pressure device
Cheyne-Stokes breathing	High loop gain from robust chemosensitivity and ventilatory drive	Optimize medical therapy for heart failure, consider PAP devices
Idiopathic central apnea	Unknown	Supportive, bilevel PAP; consider ventilatory stimulants
Treatment of emergent central apnea or "complex apnea"	Lowering upper airway resistance at CPAP initiation improves efficiency of CO_2 excretion	Reassurance, generally resolves spontaneously
Sleep hypoventilation syndromes	Fall in drive with loss of wakefulness stimulus, loss of accessory muscle activity during REM sleep	Noninvasive ventilation

CPAP = continuous positive airway pressure; PAP = positive airway pressure; REM = rapid eye movement.

TABLE 86-2 CLASSIFICATION OF HYPERCAPNIC DISEASES

HYPERCAPNIC DISEASE	MECHANISM	DIAGNOSIS	TREATMENT
Narcotic overdose	Reduced central drive	History, narcotized pupils, toxicology	Supportive care, naloxone
Acute severe asthma	Severe airflow obstruction, high dead space	Typical history, wheezing on exam, low FEV_1/FVC	Bronchodilators, anti-inflammatories, mechanical ventilation (usually invasive)
Acute exacerbation of COPD	Airflow obstruction, high dead space	History, cigarette smoking, low FEV_1/FVC, infectious etiology	Bronchodilators, anti-inflammatories, noninvasive ventilation
Obesity-hypoventilation syndrome	Low respiratory system compliance, high upper airway resistance, low central drive	High BMI, lack of other diagnoses; blunted CO_2 response	Weight loss, nocturnal bilevel positive airway pressure
Central congenital hypoventilation syndrome	*PHOX2B* mutation, lack of central drive	Genetic testing	Supportive care, mechanical ventilation (usually noninvasive)
Neuromuscular disease (e.g., myasthenia gravis, ALS, polymyositis, GBS/AIDP)	Lack of respiratory muscle force	Immediate orthopnea, low VC, low MIPs/MEPs	Underlying cause; nocturnal noninvasive ventilation; supportive care
Severe parenchymal lung disease, e.g., COPD	Lack of alveolar surface area; high pulmonary dead space and work of breathing	Typical history, smoking, low FEV_1 and FEV_1/FVC	Bronchodilator, anti-inflammatory therapy, possible nocturnal noninvasive ventilation, smoking cessation
Kyphoscoliosis	Low respiratory system compliance	Physical examination	Supportive care, noninvasive ventilation

AIDP = acute inflammatory demyelinating polyneuropathy; ALS = amyotrophic lateral sclerosis; BMI = body mass index; COPD = chronic obstructive pulmonary disease; FEV_1 = forced expiratory volume in 1 second; FVC = forced vital capacity.

HYPOVENTILATION SYNDROMES

Hypoventilation syndromes are defined by a lack of adequate alveolar ventilation to maintain an arterial CO_2 tension of 40 mm Hg. The two most common clinical settings that result in hypoventilation are severe chronic obstructive pulmonary disease (COPD; Chapter 88) and morbid obesity (Chapters 100 and 227); less common etiologies include chronic opiate therapy, neuromuscular weakness (Chapters 429 and 430), and severe kyphoscoliosis (Chapter 99). The epidemiology of these hypoventilation syndromes is poorly studied, but about 15% of patients with severe COPD or morbid obesity have an elevated $Paco_2$. Regardless of the cause, patients with hypoventilation frequently have further worsening of their ventilation at the onset of sleep, owing to loss of the wakefulness stimulus, which is the normal drive to breathe while awake, and some degree of upper airway collapse after the onset of sleep (Chapter 100).

Patients with central sleep apnea (Chapter 100), which is a group of conditions in which cessation of airflow occurs because of a lack of respiratory effort, are classified into those with inadequate ventilatory drive and those with excessive drive. The paradox of how excessive drive leads to central apnea is explained by the concept of loop gain. A system with a high loop gain is prone to instability that leads to periods of excessive breathing followed by periods of apnea (Table 86-2). The prototype of a condition with high loop gain is periodic breathing or Cheyne-Stokes breathing (Fig. 86-1).

Cheyne-Stokes Breathing

Cheyne-Stokes breathing is a waxing and waning pattern of breathing that often includes periods of central apnea. It is seen most commonly during sleep in patients with heart failure.

EPIDEMIOLOGY

Cheyne-Stokes breathing is a form of ventilatory instability that occurs in 30 to 40% of patients with left ventricular systolic dysfunction and heart failure. Male sex, advanced age, low baseline $Paco_2$, and atrial fibrillation are risk factors for Cheyne-Stokes breathing among patients with heart failure. Controversy remains regarding whether this breathing pattern itself is deleterious or whether it is simply a marker of the underlying severity of cardiac disease. Cheyne-Stokes breathing represents about 5 to 10% of all cases of sleep apnea (Chapter 100) and is uncommon among patients who do not have heart failure.

PATHOBIOLOGY

Individuals with Cheyne-Stokes breathing have robust chemosensitivity as evidenced by marked increases in ventilation with small changes in $Paco_2$. The drive to breathe may be further increased by neural reflexes that are triggered by extravascular lung fluid and an elevated left atrial pressure. Intermittent hypoxemia and catecholamine surges, which are frequent in these patients, contribute to oxidative stress and neuroendocrine activation, both of which are thought to contribute to worsening of the underlying heart failure.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Patients with Cheyne-Stokes breathing can sometimes be diagnosed at the bedside by careful observation of their breathing pattern. During sleep or exercise, breathing becomes more dependent on metabolic stimuli. Patients may complain of fatigue or sleepiness because arousals from sleep tend to occur during the hyperpneic phase. Paroxysmal nocturnal dyspnea, a classic symptom of heart failure (Chapter 58), most commonly reflects underlying Cheyne-Stokes breathing. Patients often are diagnosed in the sleep laboratory while undergoing investigation for possible obstructive sleep apnea.

The diagnosis of Cheyne-Stokes breathing, if not readily apparent, can be made during overnight polysomnography, when the typical oscillatory pattern of tidal volume is seen in the absence of ventilatory efforts during the apneic periods. When evaluating such recordings, it is important to note that

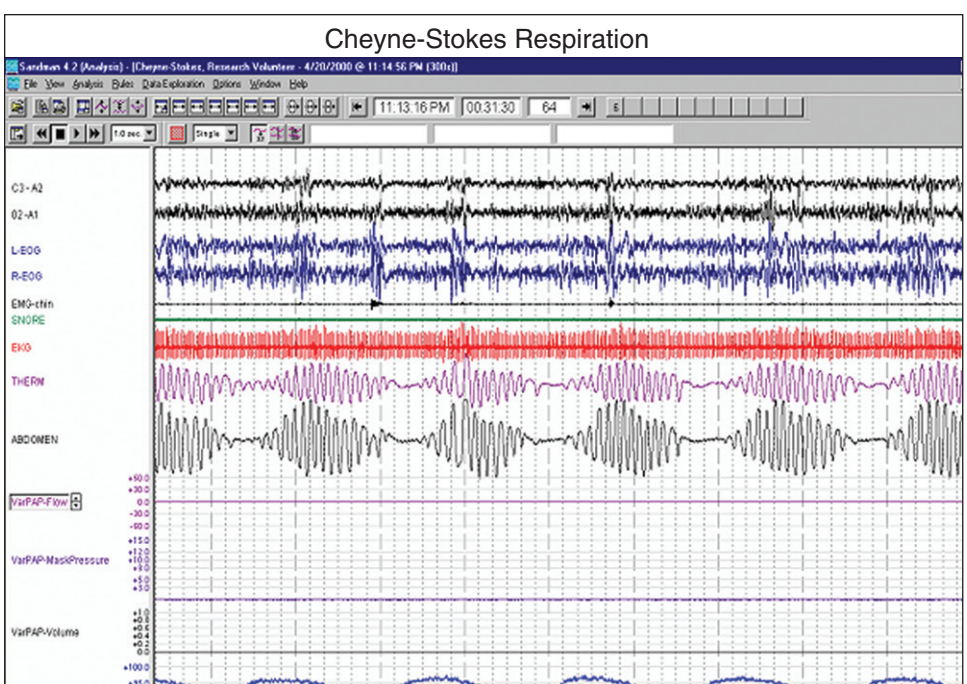

FIGURE 86-1. Cheyne-Stokes breathing with crescendo-decrescendo pattern of breathing. The thermistor detects air temperature changes at the mouth and nose. Note absences in airflow without respiratory effort seen in the abdominal belts. This breathing pattern leads to intermittent desaturations, arousals from sleep, and bursts of tachycardia. The loop gain concept can be understood by considering the thermostat analogy in which a control system is working to regulate a stable room temperature (e.g., 20° C). By analogy, the respiratory control system is working primarily to maintain a stable $PaCO_2$ of 40 mm Hg and stable pH. Situations in which marked fluctuations in room temperature might occur would include one in which the thermostat is excessively sensitive (i.e., furnace turns on if room temperature falls to 19.999° C); if the furnace is too powerful, a marked overshoot in room temperature will be followed by a prolonged period when the furnace does not run. In the analogy to Cheyne-Stokes breathing, CO_2 is equated to room temperature and would be predicted to be unstable if chemoresponsiveness (i.e., the thermostat) were excessively robust (i.e., a marked increase in ventilation for small change in CO_2), if the efficiency of CO_2 excretion were high (i.e., marked fall in $PaCO_2$ with increased ventilation), or if the end-expiratory lung volume were small. Situations that increase the propensity for CO_2 fluctuations lead to elevated loop gain and thus increase the risk for Cheyne-Stokes breathing.

Cheyne-Stokes breathing usually resolves during rapid eye movement (REM) sleep, that arousals on the electroencephalogram typically occur during the hyperpneic phase, and that Cheyne-Stokes breathing generally does not resolve immediately when nasal continuous positive airway pressure (CPAP) is applied.

TREATMENT Rx

Medical management of Cheyne-Stokes breathing most often is treatment of the underlying heart failure (Chapter 59). Many patients with clinically significant Cheyne-Stokes breathing are taking inadequate doses of angiotensin-converting enzyme inhibitors, β-adrenergic blockers, or diuretics. After optimization of medical management, the Cheyne-Stokes breathing pattern frequently resolves. By comparison, CPAP is no better than standard medical therapy.■

Central Congenital Hypoventilation Syndrome

DEFINITION AND EPIDEMIOLOGY

Central congenital hypoventilation syndrome is a rare congenital condition, previously referred to as Ondine's curse, characterized by a diminished ventilatory response to CO_2. The central congenital hypoventilation syndrome was traditionally diagnosed in neonates, but it is increasingly noted in adults.

PATHOBIOLOGY

The syndrome is now defined by a mutation in the *PHOX2B* gene, located on chromosome 4p12. Because most parents of affected children with the central congenital hypoventilation syndrome do not carry a *PHOX2B* mutation, the mutations are de novo. About 90% of patients are heterozygous for a polyalanine repeat expansion mutation, in which the affected allele has 24 to 33 alanines rather than the normal 20 alanines. The remaining 10% of central congenital hypoventilation syndrome patients have missense, nonsense, or frameshift mutations in the *PHOX2B* gene.

The *PHOX2B* gene is a paired-like homeobox that encodes a highly conserved transcription factor key to autonomic development in mice. Mice that are genetically modified for *PHOX2B* have irregular breathing, do not respond to hypercapnia, and die soon after birth from central apnea. These mice have neuronal loss in the retrotrapezoid nucleus and parafacial region of the brain stem, thereby suggesting the importance of this medullary region in normal breathing. Abnormalities in *PHOX2B* genes have also been associated with Hirschsprung's disease (Chapter 138), neural crest tumors, cardiac asystole (Chapter 63), and other abnormalities of the autonomic nervous system (Chapter 427).

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Neonates can present with cyanosis at birth, recurrent central apneas, or both. Adults can present with idiopathic central sleep apnea, unexplained hypercapnia, or autonomic abnormalities (Chapter 427). Confirmation of the diagnosis requires the demonstration of an abnormality in the *PHOX2B* gene.

TREATMENT Rx

There are currently no specific therapies for central congenital hypoventilation syndrome beyond supportive care. Genetic counseling is required for afflicted individuals and their families given the autosomal dominant pattern of inheritance. Patients must be cautioned against the use of sedatives, which could precipitate respiratory failure. Mechanical ventilation during sleep either invasively (through tracheostomy) or noninvasively (through bilevel positive airway pressure support [Chapter 100]) is required in most patients. Some patients remain fully ventilator dependent. Alternative treatments, such as ventilatory stimulants and diaphragmatic pacing, are generally ineffective.

Acquired Hypoventilation Syndromes

DEFINITION AND EPIDEMIOLOGY

Patients with hypoventilation syndromes cannot maintain adequate minute ventilation to keep their $PaCO_2$ at 40 mm Hg. Patients can be classified into those who lack central ventilatory drive and those who have a pulmonary mechanical or neuromuscular abnormality that prevents adequate gas exchange. The case frequency is unknown, but hypercapnic respiratory failure is one of the more common admission diagnoses in intensive care units.

PATHOBIOLOGY

Patients with conditions characterized by the lack of central drive have reasonably normal lungs and respiratory muscle function but lack adequate response to CO_2 and hypoxia. In contrast, most patients with mechanical or neuromuscular abnormalities have a larger work of breathing compared with normal individuals; the most common underlying conditions are severe

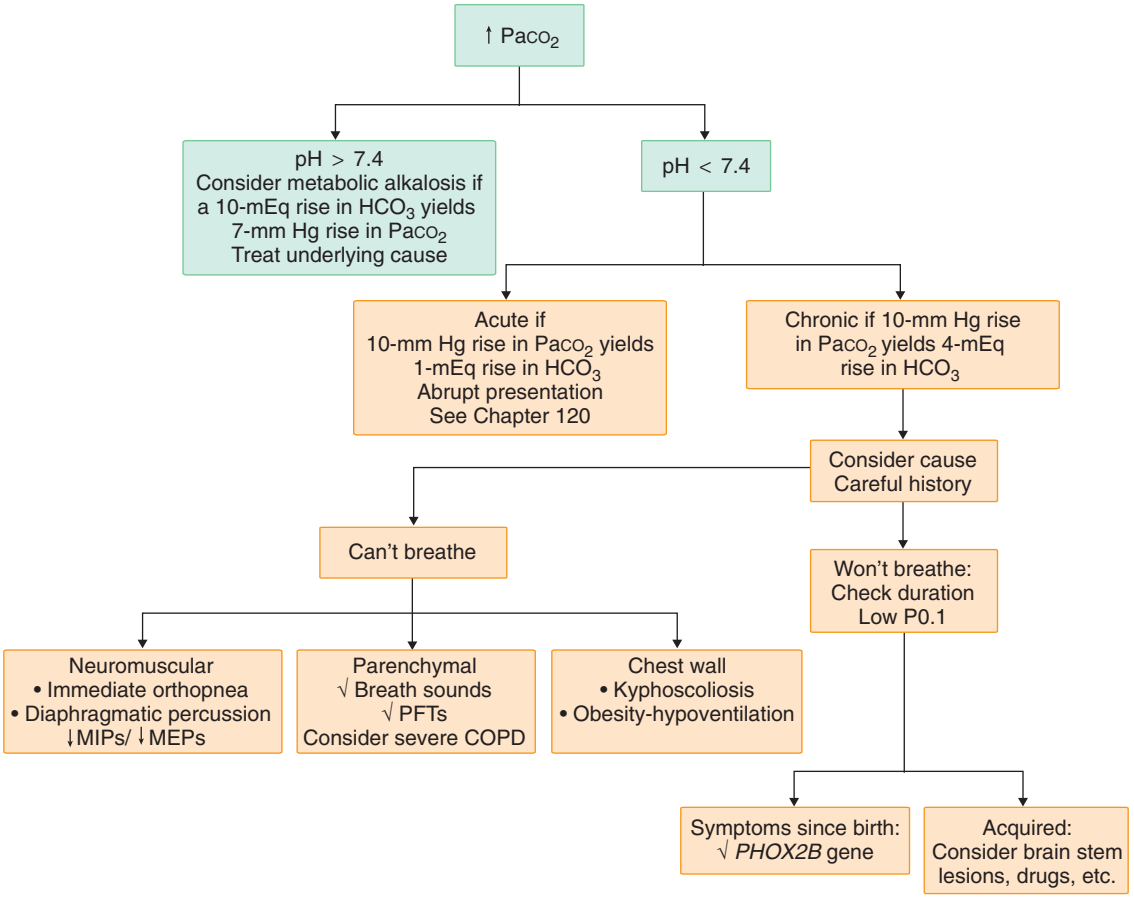

FIGURE 86-2. A flow chart of a systematic approach to hypercapnia and various causes of hypoventilation. The change in pH can help determine the cause and chronicity. A careful history and physical examination, coupled with pulmonary function testing, can help classify patients into those who "can't breathe" owing to neuromuscular or mechanical abnormalities of the respiratory system as compared with those who "won't breathe" owing to central nervous system pathology. COPD = chronic obstructive pulmonary disease; MEP = maximal expiratory pressure; MIP = maximal inspiratory pressure; P0.1 = the negative mouth pressure generated during the first 100 msec of an occluded inspiration; PFT = pulmonary function test.

COPD (Chapter 88) or morbid obesity (Chapter 227) with the obesity-hypoventilation syndrome. Such individuals have diminished but not absent chemoresponsiveness. Another cause of inadequate gas exchange is neuromuscular disease; common causes include disorders of neuromuscular transmission (Chapter 430), severe muscle weakness (Chapter 429), the residua from poliovirus infection (Chapter 423), Guillain-Barré syndrome (Chapter 428), or acute poisoning (Chapter 110).

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Patients with hypoventilation have a myriad of presentations ranging from asymptomatic abnormalities in laboratory testing (e.g., elevated $Paco_2$, unexplained low Sao_2, or an elevated serum bicarbonate level) to respiratory failure in the intensive care unit (e.g., respiratory infection with laboratory evidence of chronic abnormalities, such as acute-on-chronic respiratory acidosis). Patients who acutely overdose on sedative-hypnotic or narcotic agents may present with acute respiratory acidosis and loss of consciousness. Other patients may present with central sleep apnea-hypopnea or otherwise unexplained oxygen desaturation at night.

Once suspected, the diagnosis of hypoventilation is confirmed by the finding of $Paco_2$ higher than 42 mm Hg on analysis of an arterial blood sample. If the increase in $Paco_2$ is of short duration so that renal compensation has not yet occurred (Chapter 120), the serum bicarbonate level is increased by 1 mEq/liter for every 10-mm Hg rise in $Paco_2$. By comparison, if the respiratory acidosis is of sufficient duration for renal compensation to occur, the serum bicarbonate level will be increased by 4 mEq for every 10-mm Hg rise in $Paco_2$ (Fig. 86-2).

Once an elevated $Paco_2$ is established, it is appropriate to distinguish patients who "can't breathe" from those who "won't breathe." "Can't breathe" implies that a respiratory mechanical problem or neuromuscular weakness is causing the elevation in $Paco_2$. Abnormalities in pulmonary function testing (e.g., a markedly diminished vital capacity) are consistent with a pulmonary parenchymal or chest wall disorder.

Patients who "won't breathe" have central nervous system abnormalities that affect central drive or chemosensitivity, or both.

TREATMENT AND PROGNOSIS

Rx

The treatment of hypoventilation should focus on the underlying cause. Acute poisonings can be managed supportively or, in some cases, with specific antidotes (Chapter 110). Chronic conditions can be treated by addressing the underlying cause, such as weight loss in obesity hypoventilation syndrome or cholinesterase inhibitors in myasthenia gravis (Chapter 430). For parenchymal lung disease, treatment is directed at the underlying cause (Chapters 88 and 92).

Sedative medications should be used cautiously because they can occasionally precipitate acute respiratory failure. Although profound hypoxemia can clearly be deleterious, oxygen occasionally can precipitate severe acute respiratory acidosis, particularly in patients with acute exacerbations of COPD (Chapter 88). As a result, hypoventilating patients with COPD require the careful administration of supplemental oxygen, which should be titrated to an arterial oxygen saturation of 90% or an arterial oxygen tension of 60 mm Hg.

Severe hypoventilation requires mechanical ventilation (Chapter 105), such as noninvasive ventilation for an acute exacerbation of COPD. For other presentations in which the $Paco_2$ is believed to be acutely elevated, endotracheal intubation and mechanical ventilation are frequently used, especially in patients with impaired consciousness. For chronic hypoventilation in hypercapnic COPD, noninvasive bilevel positive airway pressure through a face mask during sleep can maintain alveolar ventilation and improve outcome. However, the considerable difficulty of adhering to nocturnal bilevel therapy in COPD emphasizes the need for discussions with patients and families regarding its risks and benefits. Other chronic hypoventilation syndromes are also commonly treated with bilevel positive airway pressure, although data are less compelling. In some chronic conditions, such as motor neuron disease (Chapter 418), tracheostomy should be discussed, although the impact of such interventions on quality of life should be carefully considered. Regardless of the underlying cause, an elevation in the $Paco_2$ level is considered a poor prognostic sign. End-of-life discussions are also important in such cases because the prognosis of chronic respiratory failure patients is generally poor.

ASTHMA

JEFFREY M. DRAZEN

DEFINITION

Asthma is a clinical syndrome of unknown etiology characterized by three distinct components: (1) recurrent episodes of airway obstruction that resolve spontaneously or as a result of treatment; (2) exaggerated bronchoconstrictor responses to stimuli that have little or no effect in nonasthmatic subjects, a phenomenon known as *airway hyperresponsiveness*; and (3) inflammation of the airways as defined by a variety of criteria. Although airway obstruction is largely reversible, it is currently thought that changes in the asthmatic airway may be irreversible in some settings.

EPIDEMIOLOGY

Asthma is an extremely common disorder affecting boys more commonly than girls and, after puberty, women slightly more commonly than men; approximately 8% of the adult population of the United States has signs and symptoms consistent with a diagnosis of asthma. Although most cases begin before the age of 25 years, new-onset asthma may develop at any time throughout life.

The worldwide prevalence of asthma has increased more than 45% since the late 1970s. The greatest increases in asthma prevalence have occurred in countries that have recently adopted an "industrialized" lifestyle. Data from many sources now show that children raised in a farming environment have a much lower risk of asthma than their peers raised in an urban environment; the specific exposures responsible for this decreased disease burden are not known.

Asthma is among the most common reasons to seek medical treatment. In the United States, it is responsible for about 15 million annual outpatient visits to physicians and for nearly 2 million annual inpatient hospital days of treatment. The yearly direct and indirect costs of asthma care are more than $25 billion; more than half of these costs are attributable to direct expenditures on medical care encounters or asthma medications.

PATHOBIOLOGY

Genetics

In twin studies, asthma has about 60% heritability, indicating that both genetic and environmental factors are important in its etiology. A locus on chromosome 17q21, at or near the locus for *ORMDL3*, a member of a gene family that encodes endoplasmic reticulum transmembrane proteins, has been associated with childhood-onset asthma. Although the exact functional variant in this region has not been identified, the isolation of a locus for childhood-onset asthma supports the clinical observation that adult- and childhood-onset asthma appear to be distinct disorders. Genetic variants that influence the response to treatment also have been identified and widely replicated.

Pathology

The pathology of mild asthma, as delineated by bronchoscopic and biopsy studies, is characterized by edema and hyperemia of the mucosa and by infiltration of the mucosa with mast cells, eosinophils, and lymphocytes bearing the T_H2 phenotype. Small placebo-controlled trials with daclizumab, an antibody against CD25, in patients with asthma of moderate severity provides solid evidence for the pathobiologic role of lymphocyte activation in asthma. Chemokines such as eotaxin, RANTES, macrophage inflammatory protein 1α, and interleukin-8 (IL-8), produced by epithelial and inflammatory cells, and the loss of the T-cell signaling molecule T-bet serve to amplify and to perpetuate the inflammatory events within the airway. The role of IL-4 and IL-13 as critical signaling molecules has been confirmed through small randomized controlled trials with pitakinra, an agent that inhibits binding of these cytokines to their receptors. As a result of these inflammatory stimuli coupled with the mechanical deformation of the epithelium from airway smooth muscle constriction, the airway wall is thickened by the deposition of type III and type V collagen below the true basement membrane. In addition, in severe chronic asthma, there is hypertrophy and hyperplasia of airway glands and of both surface and glandular secretory cells as well as hyperplasia of airway smooth muscle. Morphometric studies of airways from asthmatic subjects have demonstrated airway wall thickening of sufficient magnitude to increase airflow resistance and enhance airway responsiveness. During a severe asthmatic event, the airway wall is thickened markedly; in addition, patchy airway occlusion occurs by a mixture of hyperviscous mucus and clusters of shed airway epithelial cells.

The episodic airway narrowing that constitutes an asthma attack results from obstruction of the airway lumen to airflow. Although it is now well established that asthma is associated with infiltration of the airway by inflammatory cells, the links between these cells and the pathobiologic processes that account for asthmatic airway obstruction have not been clearly delineated. Three possible but not mutually exclusive links have been postulated: (1) the constriction of airway smooth muscle, (2) the thickening of airway epithelium, and (3) the presence of liquids within the confines of the airway lumen. Among these mechanisms, the constriction of airway smooth muscle due to the local release of bioactive mediators or neurotransmitters is the most widely accepted explanation for the acute reversible airway obstruction in asthma attacks. Several bronchoactive mediators are thought to be the agents that initiate the airway obstruction characteristic of asthma.

Mediators of the Acute Asthmatic Response

Acetylcholine

Acetylcholine released from intrapulmonary motor nerves causes constriction of airway smooth muscle through direct stimulation of muscarinic receptors of the M_3 subtype. The potential role for acetylcholine in the bronchoconstriction of asthma primarily derives from the observation that tiotropium bromide can be used as an effective asthma treatment.

Histamine

Histamine, or β-imidazolylethylamine, was identified as a potent endogenous bronchoactive agent 100 years ago. Mast cells, which are prominent in airway tissues obtained from patients with asthma, constitute the major pulmonary source of histamine. Clinical trials with novel potent antihistamines indicate a minor role for histamine as a mediator of airway obstruction in asthma.

Leukotrienes and Lipoxins

The cysteinyl leukotrienes, namely, LTC_4, LTD_4, and LTE_4, as well as the dihydroxy leukotriene LTB_4, are derived by the lipoxygenation of arachidonic acid released from target cell membrane phospholipids during cellular activation. 5-Lipoxygenase, the 5-lipoxygenase-activating protein, and LTC_4 synthase make up the cellular protein and enzyme content needed to produce the cysteinyl leukotrienes. The production of LTB_4 requires 5-lipoxygenase, the 5-lipoxygenase-activating protein, and LTA_4 epoxide hydrolase. Mast cells, eosinophils, and alveolar macrophages have the enzymatic capability to produce cysteinyl leukotrienes from their membrane phospholipids, whereas polymorphonuclear leukocytes produce exclusively LTB_4, which is predominantly a chemoattractant molecule; LTC_4 and LTD_4 are among the most potent contractile agonists ever identified for human airway smooth muscle. Clinical trials with leukotriene receptor antagonists or synthesis inhibitors have shown significant clinical efficacy in the treatment of chronic persistent

asthma, leading to the conclusion that the leukotrienes are important but not exclusive mediators of the asthmatic response. Lipoxins, which are double lipoxygenase products of arachidonic acid metabolism, have been shown to be endogenous downregulators of the inflammatory response. The amounts of lipoxins are decreased in the airways of patients with severe asthma.

Nitric Oxide

Nitric oxide (NO•) is produced enzymatically by airway epithelial cells and by inflammatory cells found in the asthmatic lung. Free NO• has a half-life on the order of seconds in the airway and is stabilized by conjugation to thiols to form RS-NO. Both NO• and RS-NO have bronchodilator actions and may play a homeostatic role in the airway. Paradoxically, high levels of NO•, when it is coavailable with superoxide anion, may form toxic oxidation products, such as peroxynitrite ($OONO^-$), which could damage the airway. Patients with asthma have higher than normal levels of NO• in their expired air, and these levels decrease consistently after treatment with corticosteroids.

Physiological Changes in Asthma

An increased resistance to airflow is the consequence of the airway obstruction induced by smooth muscle constriction, thickening of the airway epithelium, or free liquid within the airway lumen. Resistance to airflow is manifested by increased airway resistance and decreased flow rates throughout the vital capacity. At the onset of an asthma attack, obstruction occurs at all airway levels; as the attack resolves, these changes are reversed—first in the large airways (i.e., mainstem, lobar, segmental, and subsegmental bronchi) and then in the more peripheral airways. This anatomic sequence of onset and reversal is reflected in the physiological changes observed during resolution of an asthmatic episode (Fig. 87-1). Specifically, as an asthma attack resolves, flow rates first normalize at a high point in the vital capacity and only later at a low point in the vital capacity. Because asthma is an airway disease, not an air space disease, no primary changes occur in the static pressure-volume curve of the lungs. However, during an acute attack of asthma, airway narrowing may be so severe as to result in airway closure, with individual lung units closing at a volume that is near their maximal volume. This closure results in a change of the pressure-volume curve such that for a given contained gas volume within the thorax, elastic recoil is decreased, which in turn further depresses expiratory flow rates.

Additional factors influence the mechanical behavior of the lungs during an acute attack of asthma. During inspiration in an asthma attack, the pleural pressure becomes more negative than the 4- to 6-cm H_2O subatmospheric pressure usually required for tidal airflow. The expiratory phase of respiration also becomes active as the patient tries to force air from the lungs. As a consequence, peak pleural pressures during expiration, which normally are, at most, only a few centimeters of water above atmospheric pressure, may be as high as 20 to 30 cm H_2O above atmospheric pressure. The low pleural pressures during inspiration tend to dilate airways, whereas the high pleural pressures during expiration tend to narrow airways. During an asthma attack, the wide pressure swings, coupled with alterations in the mechanical properties of the airway wall, lead to a much higher resistance to expiratory airflow than to inspiratory airflow.

The respiratory rate is usually rapid during an acute asthmatic attack. This tachypnea is driven not by abnormalities in arterial blood gas composition but rather by stimulation of intrapulmonary receptors with subsequent effects on central respiratory centers. One consequence of the combination of airway narrowing and rapid airflow rates is a heightened mechanical load on the ventilatory pump. During a severe attack, the load can increase the work of breathing by a factor of 10 or more and can predispose to fatigue of the ventilatory muscles. The patchy nature of asthmatic airway narrowing results in a maldistribution of ventilation (V) relative to pulmonary perfusion (Q). A shift occurs from the normal preponderance of V/Q units, with a ratio of near unity, to a distribution with a large number of alveolar-capillary units, with a V/Q ratio of less than unity. The net effect is to induce arterial hypoxemia. In addition, the hyperpnea of asthma is reflected as hyperventilation with a low arterial P_{CO_2}.

CLINICAL MANIFESTATIONS

History

During an acute asthma attack, patients seek medical attention for shortness of breath accompanied by cough, wheezing, and anxiety. The degree of breathlessness experienced by the patient is not closely related to the degree of airflow obstruction but is often influenced by the acuteness of the attack. Dyspnea may occur only with exercise (exercise-induced asthma), after aspirin ingestion (aspirin-exacerbated respiratory disease), after exposure to a specific known allergen (extrinsic asthma), or for no identifiable reason (intrinsic asthma). Variants of asthma exist in which cough, hoarseness, or inability to sleep through the night is the only symptom. Identification of a provoking stimulus through careful questioning helps establish the diagnosis of asthma and may be therapeutically useful if the stimulus can be avoided. Most patients with asthma complain of shortness of breath when they are exposed to rapid changes in the temperature and humidity of inspired air. For example, during the winter months in less temperate climates, patients commonly become short of breath on leaving a heated house; in warm humid climates, patients may complain of shortness of breath on entering a cold dry room, such as an air-conditioned theater.

An important factor to consider in taking a history from a patient with asthma is the potential for occupational exposures in asthma (Chapter 93). Asthma that is brought on by occupational exposures is termed *occupational asthma*; preexisting asthma that is exacerbated by workplace exposures is termed *workplace-exacerbated asthma*. In reactive airway dysfunction syndrome (RADS), a single large exposure leads to a persistent asthma-like phenotype in a previously normal individual.

Physical Examination

Vital Signs

Common features noted during an acute attack of asthma include a rapid respiratory rate (often 25 to 40 breaths per minute), tachycardia, and pulsus paradoxus (an exaggerated inspiratory decrease in the systolic pressure). The magnitude of the pulsus is related to the severity of the attack; a value greater than 15 mm Hg indicates an attack of moderate severity. Pulse oximetry, with the patient respiring ambient air, commonly reveals an oxygen saturation near 90%.

Thoracic Examination

Inspection may reveal that patients experiencing acute attacks of asthma are using their accessory muscles of ventilation; if so, the skin over the thorax may be retracted into the intercostal spaces during inspiration. The chest is usually hyperinflated, and the expiratory phase is prolonged relative to the inspiratory phase. Percussion of the thorax demonstrates hyperresonance, with loss of the normal variation in dullness due to diaphragmatic movement; tactile fremitus is diminished. Auscultation reveals wheezing, which is the cardinal physical finding in asthma but does not establish the diagnosis (Chapter 83). Wheezing, commonly louder during expiration but heard

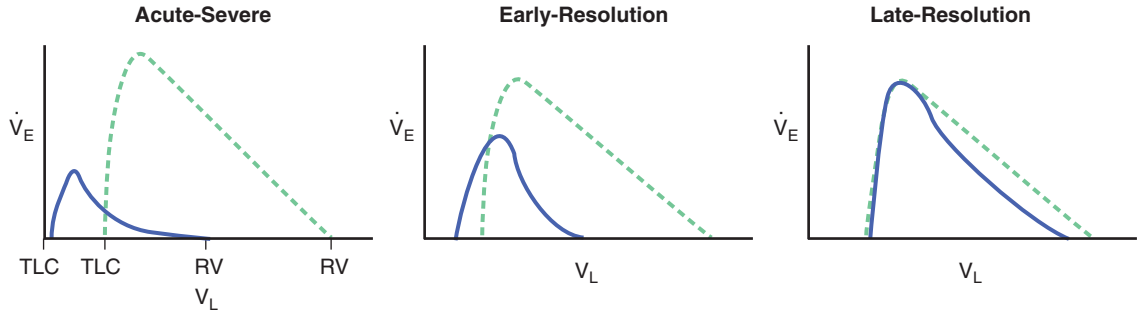

FIGURE 87-1. Schematic flow-volume curves in various stages of asthma. In each figure, the *dashed line* depicts the normal flow-volume curve. Predicted and observed total lung capacity (TLC) and residual volume (RV) are shown at the extremes of each curve. $\dot{V}_E$ = expiratory flow rate; V_L = lung volume.

TABLE 87-1 RELATIVE SEVERITY OF AN ASTHMATIC ATTACK AS INDICATED BY PEFR, FEV_1, AND MMEFR

TEST	PREDICTED VALUE (%)	SEVERITY OF ASTHMA
PEFR	>80	No spirometric abnormalities
FEV_1	>80	
MMEFR	>80	
PEFR	>80	Mild asthma
FEV_1	>70	
MMEFR	55-75	
PEFR	>60	Moderate asthma
FEV_1	45-70	
MMEFR	30-50	
PEFR	<50	Severe asthma
FEV_1	<50	
MMEFR	10-30	

FEV_1 = forced expiratory volume in the first second; MMEFR = maximal mid-expiratory flow rate; PEFR = peak expiratory flow rate.

during inspiration as well, is characterized as polyphonic in that more than one pitch may be heard simultaneously. A recording of wheezing from a patient with asthma can be heard at *www.expertconsult.com.* Accompanying adventitious sounds may include rhonchi, which are suggestive of free secretions in the airway lumen, or rales, which should raise the suspicion of an alternative diagnosis and are indicative of localized infection or heart failure. The loss of intensity or the absence of breath sounds in a patient with asthma is an indication of severe airflow obstruction.

DIAGNOSIS

Laboratory Findings

Pulmonary Function Findings

A decrease in airflow rates throughout the vital capacity is the cardinal pulmonary function abnormality during an asthmatic episode. The peak expiratory flow rate (PEFR), the forced expiratory volume in the first second (FEV_1), and the maximal mid-expiratory flow rate (MMEFR) are all decreased in asthma (Chapter 85). In severe asthma, dyspnea may be so severe as to prevent the patient from performing a complete spirogram. In this case, if 2 seconds of forced expiration can be recorded, useful values for PEFR and FEV_1 can be obtained. Gradation of attack severity (Table 87-1) *must* be assessed by objective measures of airflow; no other methods yield accurate and reproducible results. As the attack resolves, the PEFR and the FEV_1 increase toward normal together while the MMEFR remains substantially depressed; as the attack resolves further, the FEV_1 and the PEFR may normalize while the MMEFR remains depressed (see Fig. 87-1). Even when the attack has resolved clinically, residual depression of the MMEFR is not uncommon; this depression may resolve during a prolonged course of treatment. If the patient is able to cooperate such that more complete measurements of lung function can be made, lung volume measurements made during an attack demonstrate an increase in both total lung capacity and residual volume; the changes in total lung capacity and residual volume resolve with treatment. Because of the extra cooperation needed for this testing, it is not advised during an acute asthmatic event; such testing is, however, indicated between episodes of asthma.

Exhaled NO•

The fraction of NO• in the exhaled air (F_{ENO}) is elevated in patients with asthma. Although the exact concentration considered "elevated" will vary with the details of the technique, a concentration of 15 parts per billion is a convenient and reliable level that can be used to distinguish normal subjects from patients with untreated asthma. However, the measurement of exhaled nitric oxide has not been shown to be of value in the day-to-day management of asthma.

Arterial Blood Gases

Blood gas analysis need not be undertaken in individuals with mild asthma. If the asthma is of sufficient severity to merit prolonged observation, however, blood gas analysis is indicated; in such cases, hypoxemia and hypocapnia are the rule. With the subject breathing ambient air, the Pa_{O_2} is usually between 55 and 70 mm Hg and the Pa_{CO_2} between 25 and 35 mm Hg. At the onset of the attack, an appropriate pure respiratory alkalemia is usually evident; with attacks of prolonged duration, the pH returns toward normal as a result of a compensatory metabolic acidemia. A normal Pa_{CO_2} in a patient with moderate to severe airflow obstruction is reason for concern because it may indicate that the mechanical load on the respiratory system is greater than can be sustained by the ventilatory muscles and that respiratory failure is imminent. When the Pa_{CO_2} increases in such settings, the pH decreases quickly because the bicarbonate stores have become depleted as a result of renal compensation for the prolonged preceding respiratory alkalemia. Because this chain of events can take place rapidly, close observation is indicated for asthmatic patients with "normal" Pa_{CO_2} levels and moderate to severe airflow obstruction.

Other Blood Findings

Asthmatic subjects are frequently atopic; thus, blood eosinophilia is common but not universal. In addition, elevated serum levels of immunoglobulin E (IgE) are often documented; epidemiologic studies indicate that asthma is unusual in subjects with low IgE levels. If indicated by the patient's history, specific radioallergosorbent tests, which measure IgE directed against specific offending antigens, can be conducted. In rare instances during severe asthma attacks, serum concentrations of aminotransferases, lactate dehydrogenase, muscle creatine kinase, ornithine transcarbamylase, and antidiuretic hormone may be elevated.

Radiographic Findings
